INTRODUCTION

By the term "discharge," usually the physical phenomena associated with the interaction of an electric or electromagnetic field with a volume of gas are described. Since the conditions under which such an interaction takes place vary over a wide range of gas pressures and compositions, temperatures, frequencies of the electromagnetic field, and other factors, such as the presence or absence of electrodes, a generally accepted classification is missing. Electrical discharges may be of natural origin, such as lightning or Saint Elmo's fire, or manmade discharges may be tailored for specific applications. In each case the discharge contains charged particles, such as electrons and ions; frequently, also neutral particles are present. The composition of the particle mixture is often such that it contains equal numbers of different charges. In this case one speaks of "quasineutrality." In general, gas mixtures containing charged particles are called "plasma." In recent years the field of applications has increased dramatically. While the use of electrical arc discharges for the generation of light was one of the earliest applications, today's discharges may still be used for the generation of radiation, but now the range of applications is best described by the term "plasma chemistry and technology." Some of the most important potential applications of discharges such as controlled fusion power generation are described elsewhere in the *Encyclopedia of Applied Physics* (see Fusion, Inertial Confinement; Fusion, Magnetic Confinement; Plasma Devices; Plasma Etching). In the present article applications of discharges are covered after a discussion of the physical phenomena describing the type of discharge in question. Considering the technical applications of the discharges leads to a classification either by the temperature range realized in the discharge plasma or by the gas pressure in which the discharge is operated. Using the temperature as

the classifying parameter, one may speak of "high-temperature" and "low-temperature" plasma, the borderline separating the two areas not being well defined. We shall use a classification by pressure: It is usual to call discharges in gases at atmospheric pressure or above "high-pressure discharges."

1. INTRODUCTION TO ELEMENTARY COLLISION THEORY

Let us consider an elastic two-body collision. Particle A with mass m_A and the initial velocity $\mathbf{v}_A$ collides with a particle $B(m_B$ and $\mathbf{v}_B)$; after the collision the velocities are $\mathbf{v}'_A$ and $\mathbf{v}'_B$.

The conservation of momentum requires

$$m_A\mathbf{v}_A + m_B\mathbf{v}_B = m_A\mathbf{v}'_A + m_B\mathbf{v}'_B = m_0\mathbf{v}_S = \text{const} \tag{1}$$

with $m_0 = m_A + m_B$, $\mathbf{v}_S$ being the velocity of the center of gravity of the two particles. The conservation of energy reads:

$$\tfrac{1}{2}m_A\mathbf{v}_A^2 + \tfrac{1}{2}m_B\mathbf{v}_B^2 = \tfrac{1}{2}m_A\mathbf{v}_A'^2 + \tfrac{1}{2}m_B\mathbf{v}_B'^2 + Q = \text{const}; \tag{2}$$

$Q = 0$ characterizes the elastic collision. By introducing the relative velocities before and after the collision, $\mathbf{g} = \mathbf{v}_A - \mathbf{v}_B$ and $\mathbf{g}' = \mathbf{v}'_A - \mathbf{v}'_B$ (χ is the angle between $\mathbf{g}$ and $\mathbf{g}'$), it can be shown easily that $|\mathbf{g}| = |\mathbf{g}'|$.

By estimating the relative kinetic energy (W) loss of a particle (A) with mass m_A colliding elastically with a second particle (B), a first conclusion regarding the establishment of thermal equilibrium between electrons and heavy particles may be drawn from these elementary considerations:

$$\frac{W_A - W'_A}{W_A} = \frac{\Delta W_A}{W_A} = 2\,\frac{m_A m_B}{(m_A + m_B)^2}(1 - \cos\chi). \tag{3}$$

Considering the difference in mass between electrons and heavy particles in the plasma, $m_e \approx 10^{-30}$ kg and $m_{\text{heavy}} > 10^{-27}$ kg, it is evident that it takes a very large number of collisions before thermal equilibrium between these two species can be established.

The probability of a collision is best described by the collision cross section. The differential collision cross section is defined by

$$S_{12}(g) = \frac{dN_1(\theta,\phi)/dt\,d\Omega}{\Phi_1}, \tag{4}$$

where $dN_1(\sigma,\varphi)/dt\,d\Omega$ is the number of test particles ("1") traveling into the solid angle $d\Omega$ in the direction (σ,φ) after interacting with one field particle ("2") at rest, given that the incident flux density of test particles with velocity $\mathbf{g}$ is Φ. Then the total cross section is $\sigma_{12} = \int dS_{12} = \int (dS_{12}/d\Omega)d\Omega$, and the momentum transfer cross section needed for kinetic theory is given by

$$\sigma_{12}^{(1)}(g) = \int_{4\pi} (1 - \cos\chi)dS_{12}. \tag{5}$$

Leaving the microscopic particle model, it is advantageous to work with averages. Let $f_j(\mathbf{r},\mathbf{v},t)$ be the distribution function of particles of type j in the six-dimensional phase space, the μ space. The number of j particles present in the volume element of μ space at a given time is then given by

$$d^6N_j = f_j(\mathbf{r},\mathbf{v},t)d^3\mathbf{v}d^3r. \tag{6}$$

For binary collisions the kinetic equation describing the variation of the distribution function with time is called the Boltzmann equation:

$$\frac{\partial f_j}{\partial t} + \mathbf{v}\cdot\nabla_r f_j + \frac{\mathbf{F}_j}{m_j}\cdot\nabla_v f_j = \left(\frac{\partial f_j}{\partial t}\right)_{\text{coll}}. \tag{7}$$

The $\mathbf{F}_j$ in Eq. (7) represents external forces acting on the particles, while the term on the right-hand side is the so-called collision term. By multiplying the Boltzmann equation (7) with particle properties depending on $\mathbf{r}$, $\mathbf{v}_j$, t such as mass, momentum, and energy and integrating over the velocity space, the so-called Enskog equation follows. It is a general balance equation from which the specific conservation equations for mass, momentum (Navier–Stokes equation), and energy may be deduced. Evaluating the collision terms in Eq. (7) then allows the determination of the transport properties of a plasma: electrical and thermal conductivities, diffusion coefficients, and viscosity.

2. THERMODYNAMIC EQUILIBRIUM

Total thermodynamic equilibrium (TTE) is defined as a state in which $T_e = T_h = T_{\text{radiation}}$ holds, where T_e and T_h are the temperatures of electrons and heavy particles (molecules, atoms, and ions), respectively, and $T_{\text{radiation}}$ is the temperature to be used for the computation of the intensity of the blackbody radiation field according to the Planck function. Because of the poor energy exchange in elastic collisions of electrons with heavy particles [Eq. (3)], TTE is not realized in electrical discharges. If certain conditions are met in the plasma, a state more or less close to TTE may be present. In particular, the concept of local thermal equilibrium (LTE) is a useful means to describe the high-pressure arc column. The underlying idea is that in such an arc column the particle number densities and therefore the number of collisions are sufficient to ensure one common temperature of any species constituting the plasma. The properties of the plasma volume under consideration may then be described by a single temperature and the ambient pressure.

Exempted from this thermal equilibrium is the radiation field only. Since most plasmas radiate a considerable portion of the spectrum without appreciable self-absorption, the radiation field will, in general, not be governed by the Planck radiation law, as required by TTE. A closer look at the implications of LTE leads to the criteria for estimating the parameter range where this concept can be applied successfully.

2.1 Criteria for the Establishment of LTE

The basis for any thermal descriptions is the nearly equal temperatures of the Maxwell–Boltzmann velocity distributions of the heavy species and the electrons.

The amount of energy that is picked up by the electrons from the electric field in between collisions (i.e., $\lambda_e eE$) will not be completely redistributed to the heavy particles by collisions. λ_e denotes the mean free path length of the electrons, given by $\lambda_e^{-1} = \Sigma n_k \sigma_{ek}$, where σ_{ek} is the collision cross section of electrons with the species k of particle number density n_k. The resulting excess temperature of the electrons may be estimated by the Maecker–Finkelnburg (Maecker and Finkelnburg, 1957) criterion, which compares $\lambda_e eE$ to the energy transferred by elastic collisions to the heavy particles:

$$\frac{T_e - T_h}{T_e} = \frac{m_{\text{heavy}}}{4m_e}\left(\frac{\lambda_e eE}{\frac{3}{2}kT_e}\right)^2. \tag{8}$$

This criterion gives a fair insight into the requirements for the application of LTE and yields a good approximation for a homogenous and weakly ionized plasma. The higher the temperature and the larger the particle number densities for a prevailing electrical field, the better is the basis for the establishment of an LTE plasma.

Generally speaking, high pressures will diminish the temperature gap $T_e - T_h$ in an arc discharge, where an increase in pressure reduces λ_e to a larger extent than it strengthens the electric field E. Equally favorable are high current densities, which usually result in high temperatures and high electrical conductivities. The Joule heat input $\mathbf{j} \cdot \mathbf{E}$ necessary to retain a certain temperature requires less field strength when the electrical conductivity is high. This criterion is usually fulfilled to a good degree in a high-pressure and high-current arc column.

A more stringent requirement is the validity of the Boltzmann relation for the population density of any energy level of the heavy species. As mentioned above, radiation may play an important role as a loss term, and the population density of an energy level, especially the lower-lying ones, may deviate from the Boltzmann relation as a result of radiative depopulation. To ensure thermal population densities to within 10%, collisional excitation should exceed the radiative population rate by a factor of approximately 10. Griem (1964) among others gives a criterion for the minimum electron number density required:

$$n_{e\,\min} \geq 10^{18}\sqrt{T_e}(E_{21})^3\ \text{m}^{-3}. \tag{9}$$

The energy gap E_{21} between the ground state and the first excited state, which is usually the largest, has to be inserted in eV and T_e in K. This minimum electron number density might be relaxed by a factor of up to 10 if the resonance lines are reabsorbed. At least a partial reabsorption of resonance line radiation is quite often found in arc columns, and

$n_{e\,\min}$ may be lowered by an appropriate factor.

Another condition might be easily violated in the column of some arc devices. The electron temperature must not vary considerably within a distance that a heavy particle traverses until it is in ionization or excitation equilibrium according to the local electron temperature. An estimate of this diffusion length is given by Griem (1964) and reads

$$d \approx 5 \times 10^{17}\left(\frac{1}{A}\right)^{1/4}\sqrt{\frac{kTE_{21}}{f_{21}}} \times \frac{1}{\sqrt{(n_a + 2n_i)(n_a + 11n_i)}} \exp\left(\frac{E_{21}}{2kT}\right) \text{ m.} \quad (10)$$

Here A is the atomic mass, f_{21} denotes the absorption oscillator strength of the resonance line, i.e., the number of classical absorbers of unit amplitude that would be equivalent to one quantum absorber (see Richter, 1968; Fowler, 1956); and n_a and n_i are the particle number densities of atoms and ions, respectively.

The more restrictive criteria of Eqs. (9) and (10) depend only on the particle number densities for a given temperature, which may be approximated by the ambient pressure for a single ionized gas. Because of quasineutrality, the square root of the particle number densities given in Eq. (10) is larger than the total number density. This may be expressed in terms of pressure according to Dalton's law, as long as the electron temperature does not severely exceed the temperature of the heavy particles; i.e., if the Maecker–Finkelnburg criterion of Eq. (8) yields a sufficiently small number, then

$$\sqrt{(n_a + 2n_i)(n_a + 11n_i)} \geq (n_a + 2n_i) \propto p.$$

Therefore, the pressure dependence can be safely estimated by $d \propto p^{-1}$.

The pressure dependence of the electron number density in a plasma where the temperature gap is not too large may be approximated by $\sqrt{p}$, as may be shown from an Eggert–Saha equation (Eggert, 1919; Saha, 1920):

$$\frac{n_e n_z}{n_{z-1}} = 2\frac{U_z(T,\Delta E)}{U_{z-1}(T,\Delta E_{z-1})}\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2} \times \exp\left[-\frac{E_{z-1} - \Delta E_{z-1}}{kT}\right]. \quad (11)$$

Here U_z denotes the partition function of the z-fold ion (a resulting subscript 0 denotes the atom) and ΔE_{z-1} is the lowering of the ionization potential, which is taken from

$$\Delta E_{z-1} = ze^2/4\pi\epsilon_0 r_{\mathrm{D}},$$

with the Debye radius r_{D}, according to the Debye–Hückel theory.

All of the requirements are more likely to be met at higher pressures. The diffusion length decreases most rapidly with increasing pressure, $d \propto p^{-1}$, while the electron density changes only moderately with pressure, $n_e \propto \sqrt{p}$, and the temperature gap $T_e - T_h$ is usually not a very restrictive criterion for high-pressure arcs.

Therefore, one might use the minimum electron number density and the diffusion length to estimate the validity of LTE. At atmospheric pressure, small electron number densities and large diffusion lengths d may cause deviations from LTE at moderate temperatures. Table 1 gives numerical values for an argon plasma. The minimum electron number density of 10^{23} m^{-3} is attained at 13 000 K. This corresponds to an $n_{e\,\min}$ of Eq. (9) relaxed by a factor of ≅0.6, i.e., only partial reabsorption of resonance line radiation.

2.2 Selected Properties of LTE and PLTE Plasmas

If LTE holds, the particle number densities are calculated from quasineutrality, Dalton's law, and the Saha-Eggert equation (11). The population densities of the excited levels are then taken from the Boltzmann relation:

$$n_k = n_z \frac{g_{z,k}}{U_z} \exp\left(-\frac{E_k}{kT}\right). \quad (12)$$

Table 1. Temperature dependence of LTE criteria for argon at atmospheric pressure.

	LTE Criterion	
T (K)	Temperature gap	Diffusion length d (mm)
11 000	<0.04	~1.5
12 000	<0.02	~0.8
13 000	<0.01	~0.5

The subscript k denotes the energy level k, and $g_{z,k}$ is the statistical weight and E_k the energy of this excited state, where n_z is again the number density of the z-fold ion or the atom, respectively.

The transport coefficients of the LTE plasma depend on the temperature, the pressure, and possibly the mass fraction, if mixing of different gases is to be considered.

If the electron number density is not sufficiently high to ensure that the Boltzmann relation holds for every energy level, a partial local thermal equilibrium (PLTE) model may be used. In this case it is assumed that only the higher-lying states are in equilibrium with the electron temperature while the ground state may be severely overpopulated. A generalized Saha equation may be used, where the number densities n_e, n_z are given with respect to an excited level k of the species n_{z-1}:

$$\frac{n_e n_z}{n_{z-1,k}} = 2\frac{U_z}{g_{z-1,k}}\left(\frac{m_e k T_e}{2\pi\hbar^2}\right)^{3/2} \times \exp\left[-\frac{E_{z-1} - \Delta E_{z-1}}{kT_e}\right]. \tag{13}$$

3. THE ELECTRICAL ARC DISCHARGE

The electrical arc owes its name to the curved shape of the discharge, which was operated between horizontal carbon electrodes since the beginning of the 19th century. The buoyancy of the gas heated by the discharge is the origin of the upward curvature of the field of isotherms. Early applications made use of the plasma radiation for illumination purposes. The high temperatures achievable with this discharge make it suitable for materials processing. Arc discharges are self-sustained discharges with currents typically above 1 A and with a cathode fall of less than 20 V. As in all electrical discharges containing electrodes, a cathode fall is present in the discharge. This is a potential drop between the cathode and the arc plasma; its value depends on gas composition, the gas pressure, and the cathode conditions, such as material shape and temperature. In the cathode-fall region, the electrons released at the cathode gain the energy necessary for ionization processes. The low cathode fall together with the high current distinguishes the arc discharge from the glow discharge with its currents in the milliampere region and with cathode falls well above 100 V. The electron emission mechanism at the cathode of an arc discharge is mostly based on a combination of thermionic and field emission. Different types of arc discharges may be characterized by the pressure range (several times 10^2 to 10^9 Pa) in which they are operated; other distinguishing properties are the type of stabilization and the interaction of the discharge with external flow fields. The discharge is often started by high-voltage breakdown. Other starting procedures consist of initially establishing contact between the electrodes before separation occurs, or making use of an exploding wire. Once the arc discharge is operating, three regions can be distinguished: the cathode and the anode regions and the arc column proper.

The governing equations for the basic variables describing the state of the arc column consist of the set of conservation equations for mass, species, momentum, and energy, Ohm's law, and the appropriate Maxwell equations.

The temperature distribution is determined by the energy conservation equation, which reads in its time-dependent form

$$\rho\frac{Dh_k}{Dt} = \mathbf{j}\cdot\mathbf{E} + \frac{\partial p}{\partial t} + \mathrm{div}(\mathbf{v}\cdot\boldsymbol{\tau}) + \mathrm{div}(\lambda\,\mathrm{grad}T) - u, \tag{14}$$

with ρ = mass density, h_k = specific enthalpy, $\mathbf{j}$ = current density, $\mathbf{E}$ = electrical field strength, p = pressure, $\mathbf{v}$ = velocity, $\boldsymbol{\tau}$ = stress tensor, $\boldsymbol{\lambda}$ = thermal conductivity, $u = e - a$ = balance between emitted and absorbed radiation, and $D/Dt = \partial/\partial t + \boldsymbol{\omega}\cdot\mathrm{grad}$. The convective enthalpy flux balances the difference of Ohmic heating and radiation losses together with the heat conduction, and the change in pressure with time. This equation may be extended to include the diffusive and convective enthalpy fluxes due to concentration gradients, if the mixing of two gases is to be considered.

The velocity is given by the solution of the Navier–Stokes equation

$$\rho\frac{D\mathbf{v}}{Dt} = -\mathrm{grad}\,p + \mathrm{div}(\boldsymbol{\tau}) + \rho\mathbf{g} + \mathbf{j}\times\mathbf{B}. \tag{15}$$

The pressure gradient and the viscous forces together with the Lorentz forces $\mathbf{j} \times \mathbf{B}$ ($\mathbf{B}$ denotes the magnetic field) and natural convection $\rho\mathbf{g}$ balance the acceleration of the plasma. The mass continuity completes the fluid dynamic equations:

$$\frac{\partial\rho}{\partial t} + \operatorname{div}(\rho\mathbf{v}) = 0. \tag{16}$$

If turbulence is to be accounted for, one might use the so-called κ-ϵ model, where two additional transport equations, for the turbulent kinetic energy κ and its rate of change ϵ, are to be solved. From these two quantities the eddy (turbulent) part of viscosity, thermal conductivity, and possibly the diffusion coefficients needed for mixing flows are calculated.

The current density is governed by a generalized Ohm's law,

$$\mathbf{j} = \sigma\left(\mathbf{E} + \mathbf{v} \times \mathbf{B} + \frac{1}{en_e}\mathbf{j} \times \mathbf{B} + \frac{1}{en_e}\operatorname{grad} p_e\right), \tag{17}$$

which often simplifies for the arc column to $\mathbf{j} = \sigma\mathbf{E}$. The electrical conductivity is denoted by σ, and $p_e = n_e kT$ is the partial pressure of the electrons. The magnetic field is found via Maxwell's equations, which reduce to

$$\operatorname{curl} H = \mathbf{j} \tag{18}$$

as long as the displacement current densities can be neglected relative to $\mathbf{j}$. This set of closely coupled nonlinear equations can only be solved numerically.

In many applications the stability of the arc plays an important role. As one example: The proper function of arc discharge lamps depends on the arc stability since instabilities not only may lead to a thermal overload of lamp parts but will also affect the focusing properties of the lamp. On the other hand, instabilities may also have a positive effect in applications such as high-voltage circuit breakers where they can enhance the quenching of the arc during current zero. Different types of instabilities have to be considered: Besides electrode instabilities, hydrodynamic and magnetic instabilities exist. The electrode instability is a complex problem involving properties of the electrode material as well as hydrodynamics of the jet at the arc root formed by evaporating material and self magnetic fields (Mentel, 1978). Hydrodynamic instabilities are similar to the ones encountered in aerodynamics. Only magnetic instabilities are specific for the arc discharge and can be treated in a more general manner (Mentel, 1985). Self magnetic fields play a role as well as superimposed fields. A perturbation theory has been applied to the column; it yields predictions of stability regions that are in good agreement with experiments.

3.1 High-Pressure Arcs

3.1.1 Wall-Stabilized Arcs Arcs operating at atmospheric pressure or above are called high-pressure arcs. In this pressure range collision frequencies are high, and LTE can frequently be assumed. The LTE arc column may then be described as a conducting fluid, with this set of basic variables: temperature T, velocity $\boldsymbol{v}$, current density $\mathbf{j}$, and pressure p. In most applications a flow-stabilized discharge is used. Because of the complexity of this discharge type, most basic investigations have been made up to now with the so-called cascade arc (Maecker and Steinberger, 1967). This situation has changed recently, since the "free burning arc," as described below, is now well understood and investigated from both the theoretical and the experimental standpoints. Beginning with a short review of the wall-stabilized cascade arc, some basic properties of the arc discharge can be described. The arc column is stabilized by enclosing it in a cylindrical tube with an inner diameter in the range of typically 2–30 mm. Its simplest uncooled form is shown in Fig. 1 (taken from Poisel *et al.*, 1986). In this case the arc was operated between a tungsten cathode located on the axis of the system and a tungsten ring anode. The tube that confines the column has to be isolating in the axial direction. It should have high thermal conductivity in the radial direction in order to be able to handle the high power flux coming from the plasma without melting. This combination of properties is obtained by using copper plates with a central bore of 2 mm that are isolated from each other by a ceramic

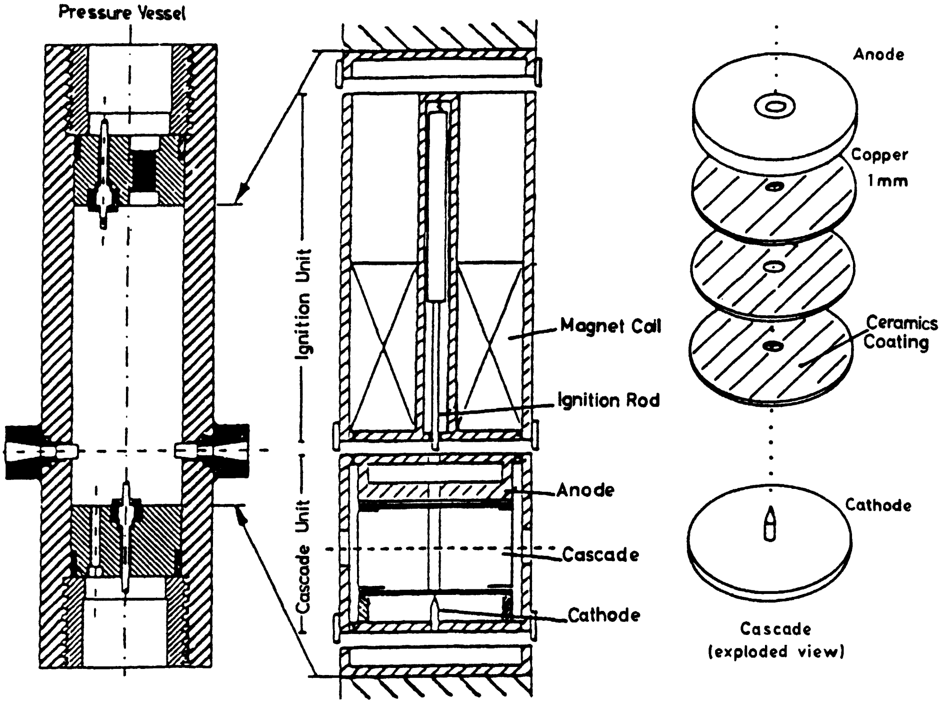

FIG. 1. Cascade arc assembly. A sufficient number of cascade plates fill the space between cathode and anode. (From Poisel *et al.*, 1986.)

coating of 0.2 mm thickness. The arc is operating in argon through the central holes. The cascade assembly consists of 40 plates, each plate is 1 mm thick. Arc currents of 10–100 A are used at atmospheric pressure with a pulse duration of several seconds. A maximum temperature of 15 000 K is obtained, and the power load of the inner channel surface reaches 8 kW/cm^2. With water-cooled cascades of the Maecker type, the corresponding values are 26 000 K in nitrogen, the power load being 20 kW/cm^2. Cascade arcs have been operated at pressures up to 25 MPa. Depending on the pressure, the temperature profiles are more or less flat in the center part. A flat T distribution is found at higher pressures; it is due to the increased importance of radiation transport in the energy balance of the column. Figure 2 (taken from Schade, 1970) gives $T(r)$ profiles measured spectroscopically in an atmospheric-pressure nitrogen arc of 5 mm diameter. At currents below 100 A, a shoulder becomes visible in the profiles. This is typical for molecular gases and is due to the high thermal conductivity in the dissociation region where diffusion processes lead to an enhanced radial transport of dissociation energy. The field-strength/current (E/I) characteristic of high-pressure arc discharges consists of a falling part at low currents and a rising part in the high current range, Fig. 3 (taken from Bauder *et al.*, 1973); see also Fig. 12, part EF, in Sec. 5 (Glow Discharges). If operated in the falling part of the arc characteristic, the discharge requires for stable operation an Ohmic resistance in series with the arc; by this measure a rising characteristic results for the arc/resistance system at a given current.

The energy-balance equation takes a very simple form in the case of a wall-stabilized arc without flow. The general energy equation for an arc column, Eq. (14), simplifies to the modified Elenbaas–Heller equation (Elenbaas, 1936):

$$\sigma E^2 + \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial S}{\partial r}\right) - u = 0, \qquad (19)$$

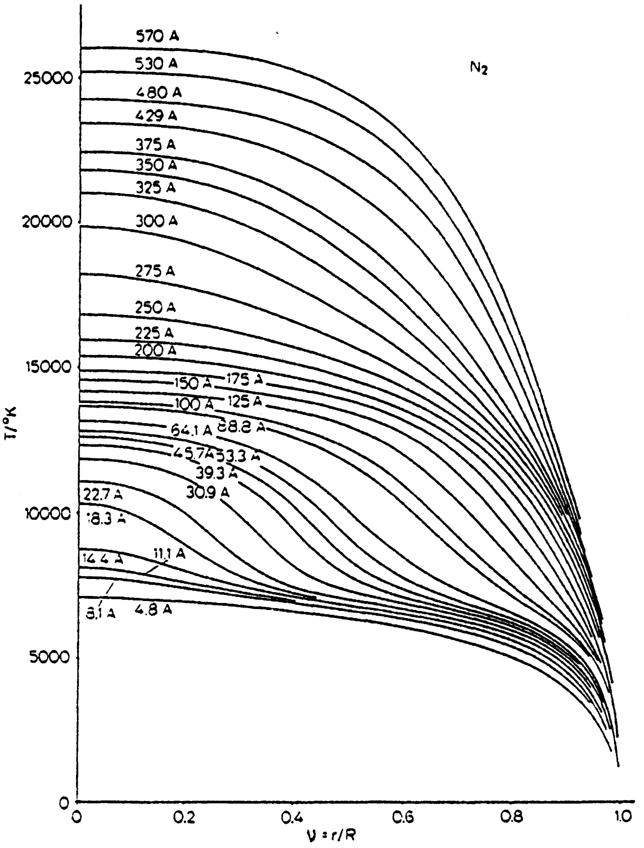

FIG. 2. Temperature distributions of an N_2 arc at different arc currents (from Schade, 1970).

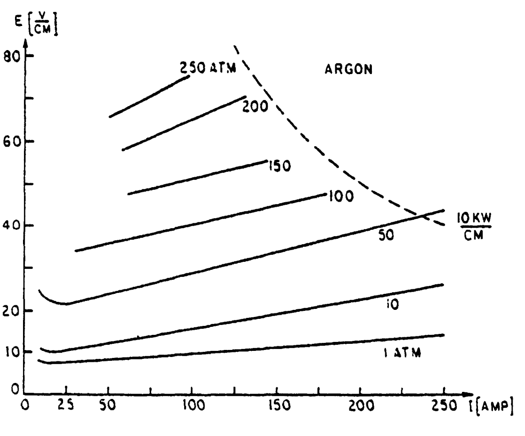

FIG. 3. Voltage–current characteristics of an argon cascade arc at different pressures (from Bauder *et al.*, 1973).

where σ is the electrical conductivity and $S = \int \lambda \, dT$ is the heat-flux potential. If radiation can be neglected, Eq. (19) may be rewritten:

$$\frac{\sigma L}{\pi \int_0^1 \sigma d(\xi^2)} + \frac{1}{\xi}\frac{\partial}{\partial \xi}\left(\xi \frac{\partial S}{\partial \xi}\right) = 0 \qquad (20)$$

with $\xi = r/R$ (R being the radius of the arc column) and $L = IE$ the Ohmic heating per unit arc length. Equation (20) is independent of the total radius R, and therefore equal values of L lead to identical $T(r)$ distributions. This property of the simplified energy balance is used for the prediction of E and I values of columns with different radii (similarity laws).

The cascade arc has been used mostly in scientific applications. As a result of its cylindrical symmetry, it is well suited for the experimental determination of transport properties of plasmas. Values have been published for the electrical conductivity σ, the thermal conductivity λ, the viscosity, and the total emissivity integrated over the whole wavelength range. The pressures used were between 0.1 and 20 MPa; gases like hydrogen, helium, nitrogen, oxygen, argon, and sulfur hexafluoride have been investigated. By performing spectroscopy in the range between the infrared (IR) and vacuum ultraviolet (VUV) and by interferometric measurements on the cascade-arc plasma, atomic data have been determined: transition probabilities and excitation and ionization cross sections as well as data on spectral line broadening and line shift due to the Stark effect and to neutral–neutral and neutral–charged-particle interaction. On the other hand, the technological difficulties with steady-state cascade arcs are considerable. For this reason the free-burning arc is now used frequently for such investigations.

3.1.2 Flow-Stabilized Arcs An arc may generate the stabilizing flow itself, when the arc diameter and therefore the related current density change along its axis. A self-stabilizing arc exhibiting cylindrical symmetry is realized, for example, in the tungsten inert-gas (TIG) welding arc or in high-pressure arc lamps. These arcs are operated between a conical cathode and a more or less flat anode. The electrode spacing is of the order of a few millimeters. dc currents of some ten to a few hundred amperes may be used; the ambient pressure reaches up to 10 MPa.

The current density peaks at the cathode tip and falls off with increasing distance from the cathode. The Lorentz force, which originates from the interaction of the self magnetic field with the current density, is therefore reduced along the axis. This decrease of the Lorentz force results in a pinch-pressure gradient along the axis of the arc, which drives the stabilizing flow. At the anode the plasma impinges on a solid wall and is deflected accordingly.

The voltage–current characteristics of these arcs resemble the E-I curves of wall-stabilized arcs, where the pressure dependence of the arc voltage may be approximated by

$$V = \bar{E}p^{m}l + V_0. \tag{21}$$

The mean value of the electric field $\bar{E}$ in the arc column depends for a given current on the gas used and decreases slightly with increasing arc length l; likewise, the exponent m varies for different gases. The voltage V_0 accounts for the cathode and anode fall and is essentially independent of the ambient pressure.

The temperature distributions of such free-burning argon arcs have been measured at pressures up to 10 MPa by spectroscopic means. The arc is operated in a water-cooled electrode chamber, which removes any excess heat from the high-pressure vessel into which it is fitted. At ambient pressures of several megapascals, more than half of the input power of a few kilowatts leaves the plasma as radiation losses. The water-cooled cathode is a rod of thoriated tungsten with a tip machined to a vertex angle of 60°. The anode consists of a water-cooled copper block lined with tungsten. This design allows for relatively high temperatures in the colder, nonionized gas, which surrounds the arc column. High temperatures are necessary in order to keep the effect of schlieren in the colder gas to a tolerable level. Schlieren are disturbances in the light transmission due to variations in the index of refraction. A Pyrex glass bell fitted with quartz windows ensures that all the gas in the optical path is at elevated temperatures, where the change of the refractive index is less pronounced. Figure 4 illustrates this temperature dependence of the refractive index for argon. The electrode chamber, which is used for temperature measurements, is shown in Fig. 5.

The spectroscopic temperature measurement of the arc column utilizes the known temperature dependence of the particle number and population densities in an LTE plasma for a given ambient pressure. These quantities may be obtained via the intensity of line and continuum radiation. The intensities that are measured consist of the integral of emission and absorption along the line of sight and have to be converted into the local emission quantities. This may be achieved by various methods for solving the Radon integral equation (Radon, 1917), which are routinely employed in computer tomography. In case of cylindrical symmetry and moderate absorption, this simplifies to an Abel integral equation.

The line emission coefficient denotes the radiated power per solid angle, which stems

FIG. 5. Schematic drawing of the electrode assembly of a high-pressure free-burning arc.

from spontaneous radiative transition between two discrete energy levels. In LTE it depends only on the population density of the upper level E_k, when the transition probability A_{ki} is known, and reads

$$\epsilon_L = \frac{h\nu}{4\pi} A_{ki} n_z(T) \frac{g_k}{U_z(T)} \exp\left[-\frac{E_k}{kT}\right] \quad \frac{\mathrm{W}}{\mathrm{m}^3\mathrm{sr}}, \tag{22}$$

n being the frequency and g_k the statistical weight of level k in the ionization state z. The spectral distribution of the radiated power within this spectral line may further be used to determine particle number densities in the high-pressure arc plasma. In general, the wavelength dependence of the radiated power can be denoted by

$$\begin{aligned} \epsilon_\nu &= P(\nu)\epsilon_L, \\ 1 &= \int_{\mathrm{Line}} P(\nu) d\nu, \end{aligned} \tag{23}$$

with $P(\nu)$ a normalized profile. Stark and possibly van der Waals broadening often dominate the line profile in high-pressure arcs, while Doppler broadening plays a minor role because of the relatively low temperatures. While the electron number density may be taken from the Stark effect, the atom density is taken from van der Waals broadening. Both of these mechanisms lead to a dispersion relation, and the sum of the half widths due to these Lorentzian profiles yields the actual half width of the line.

The continuum radiation arises from recombination (free–bound) and bremsstrahlung (free–free) transitions and is usually given in terms of hydrogen, with appropriate correction factors, the so-called Bibermann factors. For a high-pressure plasma the contribution of electron–atom encounters has also to be taken into account, and the continuum emission coefficient becomes

$$\epsilon_C = \epsilon_{ff}^{ei} + \epsilon_{ff}^{ea} + \epsilon_{fb}. \tag{24}$$

The terms may be calculated from

$$\begin{aligned} \epsilon_{ff}^{ei} &= \frac{1}{(4\pi\epsilon_0)^3} \frac{16\pi e^6}{3c^3(6\pi m_e^3 k)^{1/2}} \sum_z \frac{n_e n_z}{T_e^{1/2}} z^2 \\ &\quad \times \exp\left[-\frac{h\nu}{kT_e}\right] \xi_{ff}(\nu, T_e, z), \end{aligned} \tag{25}$$

$$\begin{aligned} \epsilon_{ff}^{ea} &= \frac{1}{4\pi\epsilon_0} \frac{32e^2}{3c^3} \left(\frac{k}{2\pi m_e}\right)^{3/2} n_a n_e T_e^{3/2} Q_{ea}(T_e) \\ &\quad \times \left\{\left(1 + \frac{h\nu}{kT_e}\right)^2 + 1\right\} \exp\left[-\frac{h\nu}{kT_e}\right], \end{aligned} \tag{26}$$

$$\begin{aligned} \epsilon_{fb} &= \frac{1}{(4\pi\epsilon_0)^3} \frac{16\pi e^6}{3c^3(6\pi m_e^3 k)^{1/2}} \sum_z \frac{n_e n_z}{T_e^{1/2}} \\ &\quad \times z^2 \left\{1 - \exp\left[-\frac{h\nu}{kT_e}\right]\right\} \frac{g_{z,1}}{U_z} \xi_{fb}(\nu, T_e, z). \end{aligned} \tag{27}$$

As an example, for a temperature measurement the two-dimensional intensity distribution of the continuum radiation is recorded, utilizing a CCD camera and an interference filter. The intensities are converted to local continuum emission coefficients by solving the Abel integral equation and are translated into temperatures. Alternatively, line radiation may be recorded using a spectrometer with imaging capabilities and a CCD camera instead of an exit slit. The spectral distribution of the line radiation is obtained for one cross section of the plasma, and the spatially resolved line profiles can be determined from this measurement.

The comparison of two different published temperature measurements is shown in Fig. 6 for an argon arc with 5-mm electrode gap and 200-A dc current at atmospheric pressure. Also shown in this figure is the calculated temperature distribution, which was derived according to the next section.

For a theoretical description of this arc column, the governing equations (14)–(18) simplify for this quite moderate type of complexity: steady state, cylindrical coordinates in two dimensions, no turbulence, and no mixing of different gases. The resulting equations are given below, where the convective parts are expressed in terms of div($\rho\mathbf{v}$ . . .) rather than in $\rho\mathbf{v}\cdot$grad(..), which is due to the numerical scheme used for solving this set of equations.

The energy conservation may be rewritten in terms of enthalpy only, the kinetic energy being small compared to the enthalpy of the gas. Furthermore, viscous effects do not contribute to any significant extent to the energy balance and may be neglected as well. This gives

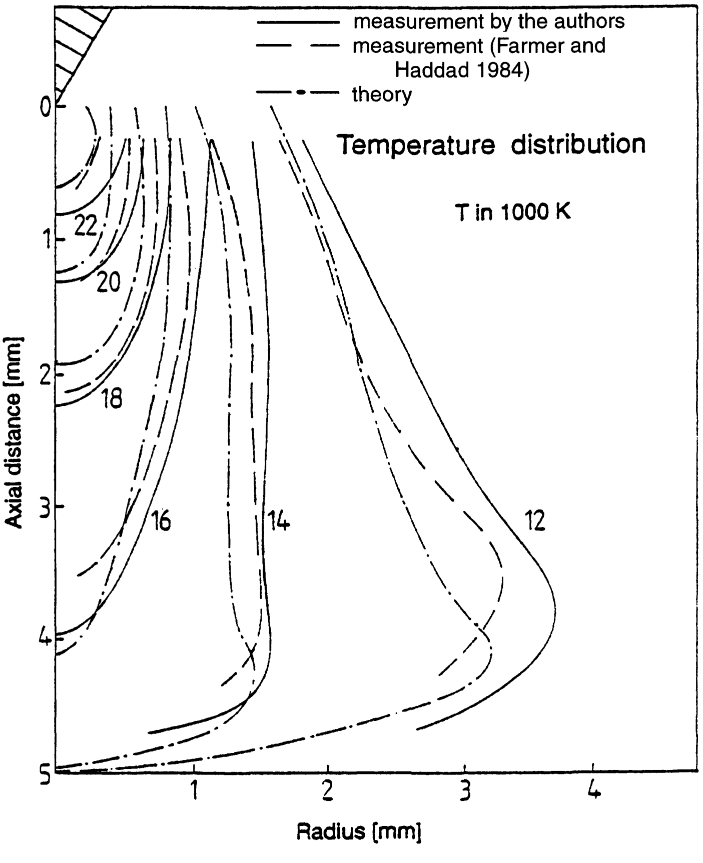

FIG. 6. Temperature distribution $T(r)$ of the free-burning arc at $p = 0.1$ MPa, $I = 200$ A.

$$\frac{1}{r}\frac{\partial}{\partial r}(r\rho v_r h) + \frac{\partial}{\partial z}(\rho v_z h) = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\lambda}{c_p}\frac{\partial h}{\partial r}\right) + \frac{\partial}{\partial z}\left(\frac{\lambda}{c_p}\frac{\partial h}{\partial z}\right) + \frac{j_r^2 + j_z^2}{\sigma} - u. \tag{28}$$

The heat flux is represented in terms of enthalpy with c_p being the specific heat. The radial and axial momentum equations cannot be simplified considerably; the radial momentum balance reads

$$\begin{aligned}\frac{1}{r}\frac{\partial}{\partial r}(r\rho v_r^2) + \frac{\partial}{\partial z}(\rho v_r v_z) &= -\frac{\partial P_\Delta}{\partial r} - j_z B_\theta \\ &+ \frac{1}{r}\frac{\partial}{\partial r}\left(2r\eta\frac{\partial v_r}{\partial r}\right) + \frac{\partial}{\partial z}\left[\eta\left(\frac{\partial v_z}{\partial r} + \frac{\partial v_r}{\partial z}\right)\right] \\ &- 2\eta\frac{v_r}{r^2} - \frac{\partial}{\partial r}\left[\frac{2}{3}\eta\left(\frac{1}{r}\frac{\partial(rv_r)}{\partial r} + \frac{\partial v_z}{\partial z}\right)\right].\end{aligned} \tag{29}$$

The corresponding axial momentum equation is given by

$$\begin{aligned}\frac{1}{r}\frac{\partial}{\partial r}(r\rho v_r v_z) + \frac{\partial}{\partial z}(\rho v_z^2) &= -\frac{\partial P_\Delta}{\partial z} + j_r B_\theta \\ &+ \frac{\partial}{\partial z}\left(2\eta\frac{\partial v_z}{\partial z}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left[r\eta\left(\frac{\partial v_z}{\partial r} + \frac{\partial v_r}{\partial z}\right)\right] \\ &- \frac{\partial}{\partial z}\left[\frac{2}{3}\eta\left(\frac{1}{r}\frac{\partial(rv_r)}{\partial r} + \frac{\partial v_z}{\partial z}\right)\right] + \rho g.\end{aligned} \tag{30}$$

For computational convenience, the pressure is calculated in terms of $P_\Delta = p - p_{\text{ambient}}$. The mass continuity becomes

$$\frac{1}{r}\frac{\partial}{\partial r}(r\rho v_r) + \frac{\partial}{\partial z}(\rho v_z) = 0. \tag{31}$$

The current density is calculated from the charge continuity and Ohm's law, where the electrical field strength is given by the gradient of the potential distribution:

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\sigma\frac{\partial\phi}{\partial r}\right) + \frac{\partial}{\partial z}\left(\sigma\frac{\partial\phi}{\partial z}\right) = 0;$$
$$j_r = -\sigma\frac{\partial\phi}{\partial r}, \quad j_z = -\sigma\frac{\partial\phi}{\partial z}. \tag{32}$$

The magnetic field is given by

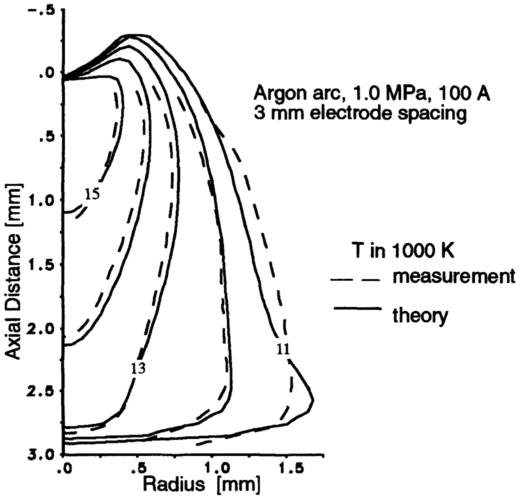

FIG. 7. Comparison of theoretical and experimental $T(r)$ distributions at p = 1 MPa.

$$\frac{1}{r}\frac{\partial}{\partial r}(rB_\varphi) = \mu_0 j_z, \tag{33}$$

where μ_0 is the permeability of free space.

For a numerical solution of the governing equations, the finite-volume approach, also called control volume, is widely used (Patankar, 1980). The computational domain is divided into a sufficiently large number of control volumes, and the conservation equations are integrated over each volume. The diffusive and convective terms yield fluxes across the boundaries of the quantity under consideration. These fluxes are conserved exactly, so that the conservation equations are modeled numerically.

The numerical solution of this set of equations yields the distribution of the basic variables. It has been shown that the arc column can be simulated self-consistently, with the total input current and the electrode geometry as boundary conditions (Lowke *et al.*, 1992), while neglecting the nonthermal sheath layers at the cathode and anode. Figure 7 shows the comparison of calculated and measured temperature distribution of an argon TIG (tungsten–inert-gas)-type welding arc at an elevated pressure of 1 MPa.

An analysis of the energy conservation equation for this arc is shown in Fig. 8,

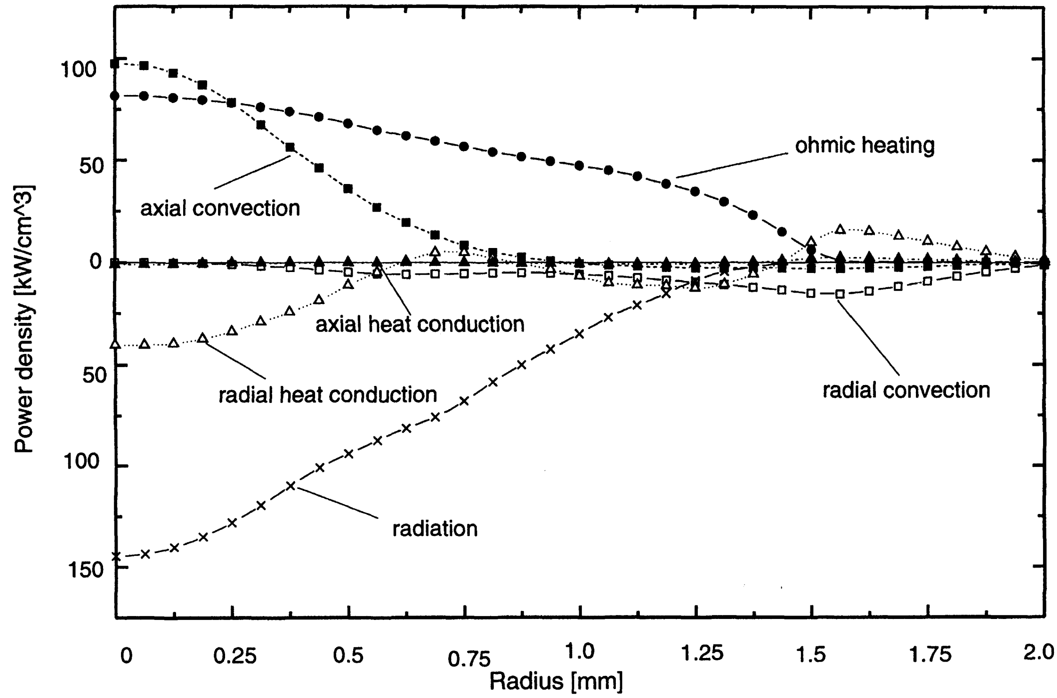

FIG. 8. Radial profile of the energy densities in the midplane between the electrodes of a TIG arc at p = 1 MPa, I = 100 A.

where the radial profile of the energy densities is given for the midplane between the electrodes.

At the center the axial enthalpy flow dominates the energy input and slightly exceeds Ohmic heating, while the radiative losses clearly excel the conduction losses. The arc behavior is strongly influenced by the plasma flow. The cold gas is drawn into the arc at the cathode and heated, and the plasma flows toward the anode. The resulting velocity distribution is shown in Fig. 9. The driving force arises from the gradient of the pinch pressure due to the self magnetic field of the arc. This pressure field is determined by the current density, which thus has a dominating influence on the convective flow of arc plasma and, hence, of temperatures and diameters. The arc properties depend on the arcing current and the arc root at the cathode, where the velocities, temperatures, and diameters are increasing with larger input current.

On account of the strong convective flow, the arc is not influenced largely by the downstream conditions; therefore, a change in arc length has only a minor influence on the properties of the discharge, as long as laminar flow prevails.

The pressure dependence of the discharge is determined by the transport coefficients and the radiation losses. The transport properties, such as electrical conductivity, thermal conductivity, and viscosity, do not depend strongly on the ambient pressure. For example, the conductivities σ and λ of an argon plasma at common arc temperatures vary less than a factor of 2–3 when pressure changes 100-fold from 0.1 to 10 MPa. The mass density scales approximately with p, and hence it dominates the pressure dependence of the transport coefficients. Neglecting the pressure dependence of the reabsorption in the pressure range under consideration, radiation losses are also roughly proportional to the ambient pressure, for singly ionized plasmas.

For the arc at 1 MPa, shown in Fig. 7, radiation is already more important than heat conduction, and therefore the curvature of

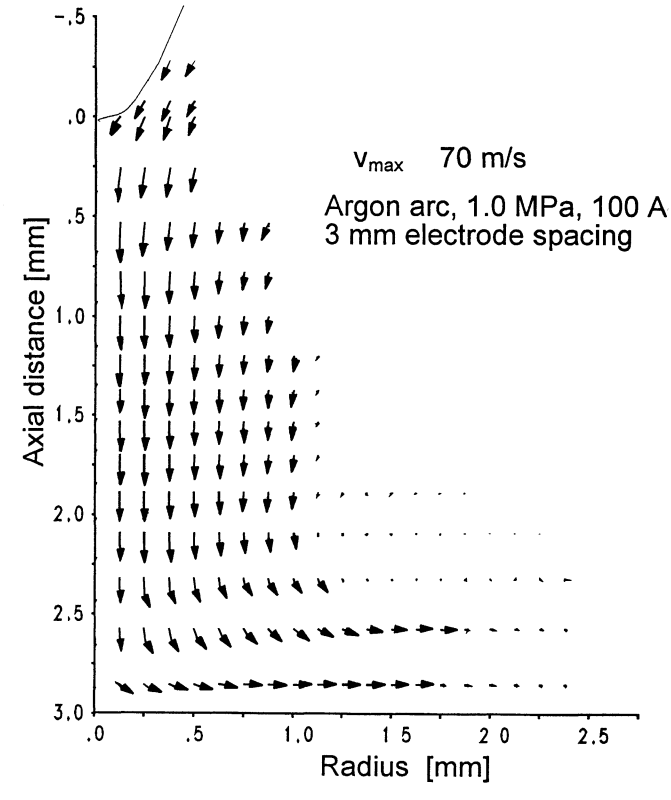

FIG. 9. Velocity distribution of a TIG arc at p = 1 MPa, I = 100 A.

the temperature profiles is only moderate up to a radius where most of the current is carried. With increasing pressure, heat conduction contributes even less to the energy balance, and the radial temperature profiles become more flat. For example, if the pressure is increased to 5 MPa, virtually all the heat is removed by radiation, and hardly any change in the heat flux is required for balancing the heat input near the axis. The temperatures are decreasing with increasing ambient pressure.

The change in mass density results in a stronger convective cooling of the plasma, especially at the cathode at the arc root. The arc constricts, so that the current densities and Lorentz forces are increased, resulting in larger pinch-pressure gradients. This increase is more than compensated for by larger inertia of the plasma; hence the velocities decrease with increasing pressure.

Besides applications in the fields of welding and cutting, the arc discharge influenced by flow effects has important applications in high-power radiation sources, high-power and -voltage circuit breakers (the arc gas being then typically SF_6), and electrothermal launchers.

3.1.3 Arc Jets While in flow-stabilized arcs, convection plays a role in the stabilization of the column, arc discharges making use of gas flow through and around the column have important technological applications. Depending on the design, application, and power range of the device, different names are in use. "Arc jets" can be used for spraying refractory materials for surface treatment or for producing special crystalline structures such as diamonds. The same applications are possible with "plasma torches," which are also used to heat and melt surface material, e.g., for welding and cutting purposes. "Arc heaters," called "Plasmatrons" in the Russian literature, are available with dc, ac, radio-frequency, or microwave power supplies. They can be used for the applications named above or for the production of high-enthalpy gas, e.g., for the test of heat shields of space vehicles returning to Earth (re-entry in an N_2–O_2 atmosphere) or entering the atmosphere of other planets with different gas compositions. Another application is the generation of high-power laser radiation. In space applications "plasma thrusters" are used for propulsion purposes; the high temperatures achievable lead to a more efficient use of the material emitted for propulsion. Additional magnetic effects are used in magneto-plasmadynamic (MPD) thrusters (Auwetter-Kurtz, 1992). In principle, all the named plasma generators use an arc discharge for producing high-enthalpy gas, which flows mainly in the direction of the arc or which is injected radially sometimes as swirl flow. Powdered material that can be heated to the melting point may be injected into the gas before or after it is influenced by the arc discharge (Fig. 10). The high-enthalpy gas or the mixture of gas and refractory material exits through a nozzle. In many applications an axial cathode is used together with a ring anode, which, in turn, may be part of the nozzle. In so-called transferred arcs used for coating purposes and for some arc welding applications, the material to be coated or worked on serves as anode. The arc is operated at high power levels, and it may be additionally confined by a cascaded wall (Buuron, 1993). In industrial torch applications it may be of interest to mix the plasma gas with dissimilar ambient

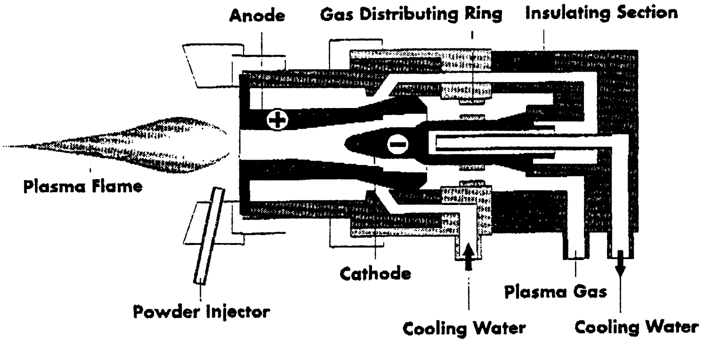

FIG. 10. Arc jet in use for spraying refractory materials (courtesy of Plasma Technik AG, Wohlen, Switzerland; reproduced by permission).

gas. The flow conditions in the arc and in the plume frequently are turbulent; a theoretical model of such torches has been developed (Murphy and Kovitya, 1993), and the comparison of the results with experimental values leads to excellent agreement.

3.2 Low-Pressure and Vacuum Arcs

The main difference between high-pressure and low-pressure arcs ($p < 0.1$ MPa) is concerned with the question of local thermodynamic equilibrium (LTE). While this condition may be nearly realized in the high-pressure arc column, discharges operated at pressures below atmospheric are characterized by a pronounced temperature nonequilibrium. Low-pressure wall-stabilized cascade arcs have been operated in the pressure range down to 1 kPa. They have been used for the determination of electronic excitation coefficients of the O II system (Awakowicz, 1991). This plasma was in a state called "corona equilibrium," where excitation occurs only from the ground level by electron collisions and deexitation is by spontaneous emission.

If a vacuum gap is used for arc initiation, different effects have to be considered. For its existence the electrical arc discharge needs gas that can be ionized and thereby forms the plasma of the arc column. If such gas initially is not present, as in the case of the vacuum-arc discharge, it has to be generated by the evaporation of electrode material. After breakdown of the electrode gap in vacuum has been achieved, in most cases it is the cathode of the discharge that is locally heated to the evaporation temperature of the cathode material. Some types of vacuum arcs exist that use evaporated anode material as arc gas (Ehrich *et al.*, 1990); in either case, vacuum arcs are usually metal vapor arcs. The current passage at the cathode typically occurs in localized zones, which are called cathode "spots." Since the spots are crucial for the vacuum arc, much work has been devoted to the understanding of their mechanism (Mesyats and Proskurovsky, 1989). On account of the small dimensions and of the nonstationary nature of spots, experimental investigations are difficult, and the physical phenomena occurring in the vacuum arc are not all and fully understood as of yet. Depending on the condition of the cathode surface, two different types of cathode spots may be present; they are called spots of type I and II, respectively (Rakhovsky, 1976; Jüttner, 1994). The craters of type I spots are small in dimension (0.1–several μm) and move at high velocities (1 m/s–several hundred m/s). Type II craters are found on clean surfaces. Their characteristic parameters are crater diameters up to several hundred μm, increasing with the temperature of the cathode; slower spot movement with several m/s velocities decreasing with increasing cathode temperature; and slightly higher erosion rates and total arc voltages compared to spots of type I. The type I spot is found on contaminated surfaces, a typical example of the contamination being an oxide layer of the cathode material. If the surface is clean or if it has been cleaned by previous arcing, type II spots are present. In the following the characteristic properties of both spot types are presented together with the known data on the related vacuum-arc discharge columns. Since the detailed spot data vary somewhat with the cathode material, only general properties and ranges of parameters can be given. The spot velocity depends also on the arc current and on the absence or presence of a superimposed magnetic field. On a stainless steel electrode in a cross magnetic field, the spot velocity showed a nearly linear dependence on the current (Fang *et al.*, 1982). Craters similar to the ones formed at the cathode of vacuum arcs are also found in high-pressure arcs. The corresponding arc-spot formation time has been determined experimentally (Nachtigall and Mentel, 1991). It is interesting to note that vacuum arcs exposed to a magnetic field move in a retrograde motion, i.e., a direction opposed to the direction of the Lorentz force $\mathbf{j} \times \mathbf{B}$, j being the current density in the arc. At the present time the question has not been resolved whether this retrograde motion is related only either to the direction of the spot movement or to that of the column, or whether it is a combination of several effects. The current-carrying capability of the cathode spots again depends on the material. Values of 10 A to several hundred amperes have been reported, the highest values being found for tungsten (Harris, 1980). Since vacuum arcs frequently are operated at very high current levels (kA), such as in the case of circuit breakers, a multitude of spots may be present simultaneously. If the current transport in the vacuum arc is mainly through type I cathode craters, the erosion rate is smaller than in the case when type II spots are present. The definition of erosion rate is mass lost per charge transported; values found extend from 10 mg/C to several hundred mg/C, the lower values corresponding to arcs with type I craters. For a discussion of the erosion rate, one has to differentiate between a net erosion of the cathode and the erosion rate of a single crater. Experiments have shown that erosion occurs not only by evaporation but also by the emission of droplets of molten material. These droplets partially fall back on the cathode surface, making the difference between net erosion in the crater and values determined by weighing after arc extinction. The total arc voltage is small as compared with high-pressure arcs. Values below 20 V are typical for arcs with type I craters. Voltage–current arc characteristics are rising, which signifies that vacuum arcs do not require a resistance in series with the arc. By solving the time-dependent conservation equations for mass, momentum, and energy for the crater volume, predictions of the formation time of an individual crater may be obtained (Prock, 1986). Ohmic heating and energy deposited by ion impact are the main energy input mechanisms; the loss terms contain electron emission, thermal conduction, and enthalpy of the material leaving the crater in the form of vapor or droplets. Spot formation times depending on the arc current result. They are in the nanosecond range, and these values compare well with measured formation times (Anders *et al.*, 1992). The plasma of the vacuum arc exhibits some peculiarities: Besides its retrograde motion in magnetic fields, the mechanisms responsible for the very high energies of ions leaving the cathode (velocities of up to 10^4 m/s have been observed) are not fully understood.

Vacuum arcs are of substantial technological interest. High-power circuit breakers for the medium-voltage range ($V < 80$ kV) make use of the fast "resolidification" of the electrode gap with respect to electrical breakdown after current zero when the ac-voltage builds up again. Resolidification signifies that the electrode gap recovers its capability to withstand high breakdown voltages; this effect is due to a fast decrease in the number of charged particles in the electrode gap of vacuum arcs. During the high-current phase, the arc in circuit breakers exists with a multitude of cathode spots, and self magnetic fields are being used to force the spots to move from the center of the electrode toward the edge in a radial direction. Fast-moving spots that disappear when they have reached the electrode edge lead to low electrode erosion, thus preserving the vacuum and diminishing the probability of an unwanted breakdown in the vacuum circuit-breaker gap. Another potentially important application of vacuum-arc technology is related to controlled nuclear fusion. In fusion reactors—e.g., in the JET tokamak operated in Culham, Great Britain—traces of so-called "unipolar arcs" are found on walls that are in contact with the fusion plasma (Behrisch, 1986). Vacuum arcs generating the arc gas by anode erosion are used for surface-treating techniques such as producing coatings.

4. SPARKS

The spark discharge is a nonstationary, high-current discharge at atmospheric pressure or above. In all spark cases there holds for the product of pressure (p) and electrode gap (d) $pd \geq 1$ kPa m; this requires interelectrode distances exceeding several centimeters. The breakdown mechanism for this discharge type may be described by the avalanche–streamer–leader model. If a dc voltage is applied to an electrode configuration, free ions and/or electrons that are either present (e.g., due to natural radioactivity or cosmic radiation) or generated (e.g., by field emission) are accelerated—in the case of negative ions and electrons—toward the anode. On their way they experience elastic and inelastic collisions, thereby creating new electrons through ionization processes. Assuming the electrical field strength to exceed a minimum critical value given by the condition that the rate of production is higher than the rate of electron attachment, a primary and successive avalanches are formed (Fig. 11).

Atoms excited by collisions emit photons, which enhance the formation of secondary avalanches by photoionization processes. The avalanches move toward the anode, and

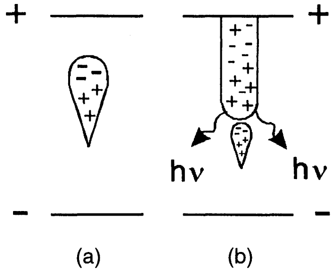

FIG. 11. Breakdown by the avalanche–streamer process between anode and cathode. (a) Avalanche, (b) streamer advancing toward the cathode by interaction with a secondary avalanche, created by photons.

the original field is distorted by the space charge generated in the avalanches. If the amplification of the electron generation process is high and if the total number of electrons contained in the avalanche exceeds $N_{\mathrm{crit}} = 10^8$, a streamer is formed. It consists of a weakly ionized, thin plasma channel and usually grows in the direction of the cathode. The streamer advances probably through the following mechanism: Secondary avalanches that reach the positive space charge at the streamer tip neutralize it and thereby create a new positive space charge located further in the propagation direction of the streamer. Thus, photons play a role in streamers directed toward the cathode. Once the streamer reaches the cathode, free electrons are created at a higher rate, and they are accelerated in the field created by the streamer. A return wave of high ionization propagates with high velocity (10^7 m/s) toward the anode, and the spark channel is formed. Anode-directed streamers are also possible; in this case the propagation is field enhanced and is similar to the propagation of an ionization wave. The ignition process via the described streamer mechanism is much faster than the growth velocity of avalanches or the drift of ions would allow; the streamer velocity exceeds 10^6 m/s. If the electrode gap is very extended, $d \geq$ several meters, the avalanche–streamer process is replaced by the avalanche–streamer–leader process. The leader is a narrow channel containing plasma with a high degree of ionization and is formed in the wake of streamers. Experimental work (Gallimberti, 1977) on streamers has shown that a large amount of the Joule heat deposited by the current is first stored as vibrational energy in molecular gases. Once this energy is relaxed into thermal energy, it increases the electrical conductivity of the plasma. The time constant for this process depends on the nature of the gas, the pressure, and the humidity, the order of magnitude being 10^{-5} s. The velocity of propagation of the leader is similar to the values obtained for streamer propagation. Once the spark channel is formed, current density, field strength, temperatures, and number densities are identical to the ones found in arc discharges. The difference from the arc lies in the fact that usually the spark discharge is too short to allow a heating of the cathode, which would lead to thermionic emission. Applications of the spark are found in radiation sources and for switching purposes (spark gaps).

5. GLOW DISCHARGES

5.1 Mechanism and Electrical Characteristics

Figure 12 shows schematically the voltage–current dependence of a number of different discharges between electrodes. The type of gas may vary as well as the pressure levels.

If the electrical field between the electrodes exceeds values typical for the given gas, Paschen breakdown occurs: $U > U_{\mathrm{P}} = f(pd)$, p being the gas pressure and d the distance between (plane) electrodes. With a field strength high enough, collision processes lead to an avalanche and to the ionization of the interelectrode space. The so-called Townsend breakdown takes place at

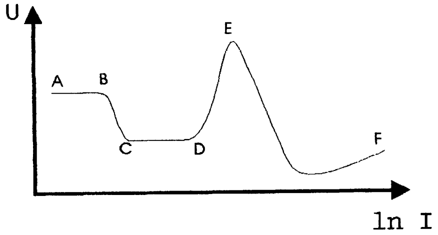

FIG. 12. Voltage–current characteristic of discharges. AB: Townsend dark discharge; CD: normal glow discharge; DE: abnormal glow discharge; EF: arc discharge.

pd values up to approximately $pd = 250$ Pa m. A self-sustained discharge is initiated if

$$\exp[(\alpha - \eta)d] \geq (\alpha - \eta)/\alpha\gamma + 1, \tag{34}$$

where α = first Townsend coefficient for ionization, η = electron attachment coefficient, and γ = coefficient for electron generation by ion impact at the cathode surface.

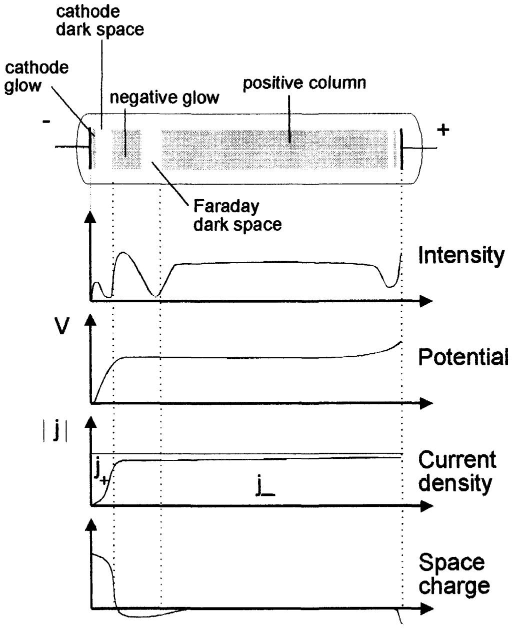

FIG. 13. Schematic drawing of the normal glow discharge.

While the Townsend dark discharge with currents in the range $I < 10^{-5}$ A owes its name to the (near) absence of visible radiation due to the small degree of ionization, the normal glow discharge shows different light-emitting zones. All portions of the *U-I* characteristics in Fig. 12 belong to self-sustaining discharges. While the arc discharge draws its electrons from the cathode via thermal emission or through the combination of thermal and field emission, glow discharges typically operate with cold cathodes. The release of electrons at the cathode is mostly due to secondary emission resulting from the bombardment with positive ions. The pressure range in which such discharges are operated extends from 1 Pa to approximately 1 kPa. In recent years a number of Russian publications (e.g., Raizer, 1991) also described glow discharges at much higher pressures reaching up to several times 10 kPa. Figure 13 shows the most important regions of a normal glow discharge in a simplified and schematic drawing. Let us start with a brief discussion of the properties and phenomena of the normal low-pressure glow discharge. Their voltage–current characteristics correspond to the portion CD of Fig. 12. Such discharges are typically operated with diameters of several centimeters and with a length up to 1 m. Current levels extend up to 0.1 A, and voltages of 10^2–10^3 V result. As shown in Fig. 13, different zones can be distinguished optically along the discharge column; this is because they are either dark or light-emitting spaces. Starting the description at the cathode-fall region, a first narrow dark space named Aston dark space separates the cathode from the cathode glow. Since the electrons leave the cathode with low energies (<1 eV), they have to be accelerated by the electrical field before they can excite atoms (Fig. 14). Emission from atoms that may be in different excited states leads to the cathode glow identified in Fig. 13. These details have been omitted in Fig. 14, which explains only the principal mechanisms in the formation of a glow discharge. Once the electron energy reaches a level where the excitation cross sections decrease significantly, the cathode dark space is formed. In the zone between the cathode and the negative glow, the current density is mainly due to the ionic component, and a positive space charge results. In the negative glow, ionization of atoms is due to inelastic collisions with electrons, and the electric field decreases. The Faraday dark space is due to the fact that most electrons have dissipated their energy. The positive column that follows is a quasineutral plasma with a low degree of ionization and a strong deviation from thermal equilibrium (LTE) be-

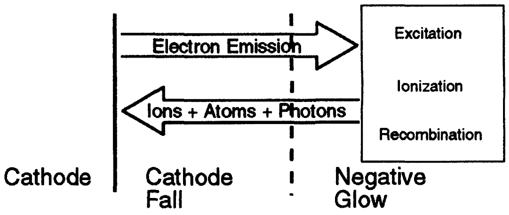

FIG. 14. Cathode region of the glow discharge.

tween electrons and heavy particles, its luminosity being due to new excitation processes of accelerated electrons. The velocity distributions of electrons and heavy particles are Maxwellian but correspond to differing temperatures (several electron volts for the electrons, very low energies for the atoms and ions). The particle number density of electrons extends to values of $n_e < 10^{12}$ cm^{-3}; this is very low compared to the number densities found in arc discharges and is at the origin of the non-LTE condition. At the anode the electrons disappear from the plasma, ions are repelled, and a positive space charge results (anode fall region). The theory of the cathode-fall region was developed very early (Von Engel and Steenbeck, 1934). It allows precise predictions for different gases. Instabilities of the positive column may occur, and they can prevent the use of glow discharges in applications such as gas lasers, e.g., CO_2 lasers. Besides striations of the column, filamentation corresponding to high current densities due to contractions have been observed. Causes of instabilities include thermal effects as well as field and electron temperature disturbances. The corresponding stability theory has made substantial progress over the last years. Moving striations with velocities in the range of 100 m/s have found their explanation by considering ionization waves moving through the plasma.

For laser as well as for pollution-control applications, it is desirable to increase the discharge current to values of at least 1 A. An increase in gas pressure to levels close to atmospheric pressure has also been achieved. At higher pressures the glow discharge becomes unstable; filamentation occurs, leading to a strong nonuniformity of the plasma. It is possible to use high-pressure glow discharges in a number of interesting applications. For this purpose either the current may be pulsed or a gas flow can be used to stabilize the column; in addition it may then be necessary to segment the cathode so as to maintain a constant column diameter. Pulsed discharges have shown great potential for laser applications. In particular, rare-gas halide lasers—e.g., XeCl lasers with preionization by x rays—are under intensive investigation (Bötticher, *et al.*, 1992). Increasing the gas pressure leads to a decrease in length of the different discharge zones described above. The cathode layer, negative glow, Faraday dark space, and anode layer shorten inversely proportionally to the gas pressure. The dependence of current density at the cathode on gas pressure, $j \propto p^2$, is still valid at pressure levels up to several atmospheres, but instabilities of the cathode layer may occur, leading to cathode-spot formation. Experimental investigations performed in nitrogen and air (Napartovich and Akishev, 1993) demonstrated the importance of energy-transfer processes between molecular vibrational levels and electronic levels in such discharges. The applications of high-pressure glow discharges range from the excitation of the active medium of lasers in CO_2, CO, and Ar^+ to the removal of pollutants such as SO_2 and NO_x from air (Akishev *et al.*, 1993). In the technologically interesting case of high-power CO_2 lasers in the multikilowatt range used for welding or cutting, high gas-flow rates of the gas mixture of $CO_2 + N_2 +$ He provide the removal of the excess power. If the current in the glow discharge is increased beyond the value at which the glow covers the whole cathode, the portion of the voltage–current characteristic that is to the right of point D in Fig. 12 applies. In this case an abnormal glow discharge is produced as a transition to the arc discharge. The current density at the cathode rises in this case; values of j in the range 10–10^2 A/cm^2 have been observed. Optically, the abnormal glow discharge exhibits a shorter cathode dark space, and the Aston dark space directly in contact with the cathode disappears. The cathode fall increases to very high values (several kilovolts are possible), and the voltage–current characteristic acquires a positive slope. The electrons leaving the cathode are accelerated in the cathode fall to high energies, but after collision with atoms and ions, low-energy electrons are produced in the negative glow. Ions from the negative glow are accelerated toward the cathode, and charge-exchange processes with neutrals take place in the cathode-fall region. Electron emission results from the impact of ions and neutrals on the cathode surface. Additional energy transfer to the cathode may result from radiation and the release of excitation energy.

5.2 Hollow-Cathode Discharges

Before discussing the so-called pseudospark and its modern applications, it is necessary to consider the hollow-cathode effect and the cold hollow-cathode discharge. A good description of the hollow-cathode effect is given in the recent literature (Gundersen and Schaefer, 1990). By replacing the plane cathode of a glow discharge by a hallow cathode of cylindrical or slit geometry and by operating the discharge in a specific range of parameters, a condition can be obtained where the negative glow is located on the inside of the hollow cathode. Such discharges operate at lower voltages and much higher currents than the normal glow discharge. The pressure range in which the hollow-cathode effect occurs may be expressed by the product *pd*, where *p* is the gas pressure and *d* is the inner diameter of the hollow cathode. In rare gases this range extends between 1 Pa m $< pd <$ 10 Pa m, while molecular gases have lower corresponding values. In a hollow-cathode configuration, the cathode fall increases only weakly with the current density. If the cathode fall is kept at a constant value, the current density increases strongly with decreasing values of *pd*. The cathode fall reaches a minimum for a particular value of *d* at given pressure and current density. The hollow-cathode effect is very sensitive to the geometrical dimensions (length and aperture of the hollow structure) as compared to the mean free path length of electrons. Several mechanisms contributing to the hollow-cathode effect are directly associated with the hollow geometry; they are as follows:

1. There is a higher probability of photons and excited atoms leaving the negative glow on the inside of the structure to reach the cathode surface.
2. Electrons leaving the cathode surface that, after acceleration in the cathode fall, reach the opposite cathode surface are reflected and become pendular electrons, changing the potential distribution in the cathode fall, and increase the ionization rate in the negative glow.
3. Charge-transfer collisions are less likely in the cathode fall under hollow-cathode conditions since the fall length is reduced, as compared to a plane geometry. The results are impacting ions with higher energies and an increase of secondary electrons.
4. The density of sputtered cathode material increases as well as the plasma density inside of the hollow structure. Since the sputtered metal atoms have a lower ionization potential, plasma density is further increased, and multistep processes become more likely.

Different electrode configurations are described in the literature; cylindrical or spherical cathodes have been used as well as several plane structures forming a cavity. By pulsing the current of a hollow-cathode discharge, very high values can be obtained before the cathode heats up, leading to thermal emission and to an arc discharge. Current values of more than 1000 A with current densities up to several kA/cm^2 and with voltages of only several hundred volts have been reported for so-called "superdense cold hollow-cathode glow discharges." Hartmann and Gundersen (1988) described a possible mechanism for this anomalous cathode emission. The applications of hollow-cathode discharges range from high-current closing switches and hollow-anode thyratrons to laser applications and to the production of intense electron beams for the excitation of cw lasers and for material processing. Of particular interest are the metal-ion laser discharges using hollow cathodes, since laser action can be obtained in the UV and VUV spectral region, and even radiation standards for this region have been developed (Warner and Persson, 1979; Gerstenberger *et al.*, 1980; and Danzmann *et al.*, 1988).

5.3 Pseudosparks

A special type of self-sustained hollow-cathode glow discharge has been given the name "pseudospark" because of the high currents and current densities that are used in the discharge for short periods of time but in a repetitive mode for most applications. Four phases in time can be distinguished in a pseudospark discharge:

1. ignition,
2. development of the hollow-cathode discharge,
3. high-current discharge, and
4. decay of the discharge.

Let us consider the basic pseudospark geometry as described in the original paper (Christiansen and Schultheiss, 1979). Two metal plates with a central borehole are separated by an insulator and serve as cathode and anode, respectively (Fig. 15). The diameter of the central hole and the plate separation are small as compared to the diameter of the plates. The insulator ring prevents the discharge from operation in the exterior space (accordingly, d_{eff} is the longest possible electrical field line). For parallel plane electrode geometries, the breakdown curve shows a minimum for pd values around 1 Pa m, p being the gas pressure and d the electrode spacing. If an electrode configuration is used that is similar to the one shown in Fig. 15, a high-current pseudospark discharge can be established within a very short time and at pressures below the minimum of the breakdown curve. The applied electrical field causes values of $E/n \approx 10^{-11}$ V cm^2 in the electrode gap, E being the electrical field strength in V/cm and n the particle number density in cm^{-3}. Electrons coming from the wall of the cathode are accelerated and cause a strong avalanche growth in a very short time (10^{-7}–10^{-8} s). At a discharge current around 10 A, the plasma is formed in the hole region between the electrodes, i.e., in the hollow cathode. A space-charge–neutralized narrow electron beam with very high current densities (10^4–10^5 A/cm^2) leaves the device through the hole on the anode side; this phase lasts 10–30 ns. The high-current discharge that follows is a superdense glow discharge whose duration is determined mainly by the parameters of the external circuit. The internal resistance of the pseudospark is low and decreases with an increase in current. High currents with a short rise time can be carried as a result of a high conductivity. These properties are useful for high-power switches. However, limitations exist regarding the breakdown voltage levels, but for a single-gap system operating with hydrogen, a range up to 40 kV seems possible. Data given for a high-current pseudospark switch with tungsten electrodes are breakdown voltage exceeding 7–18 kV, maximum current 150 kA, lifetime 10^6 discharges, and trigger with a jitter of less than 20 ns. By cascading many single-gap systems in series, it is possible to create an intense, medium-energy electron beam whose small diameter is due to the pinch effect. The applications of pseudosparks range from materials processing to the excitation of laser media.

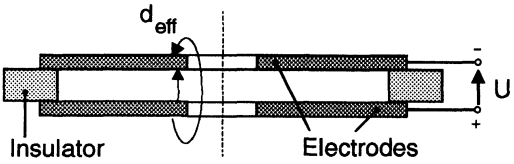

FIG. 15. Schematic drawing of a single-gap pseudospark electrode configuration.

6. HIGH-FREQUENCY DISCHARGES

If breakdown conditions of the gas are met for the frequency range of interest and if power supplies are available for the frequency under consideration, high-frequency discharges can be operated in the whole frequency range from ac to optical frequencies. In the latter case the discharge is called optical discharge, the power of such discharges being supplied, for instance, by a CO_2 laser.

The interaction of an electromagnetic wave with a plasma can be described by solving Maxwell's equations together with the equations of motions of electrons and ions in the E and B field components of the wave. Assuming a plane harmonic wave of frequency ω to travel through a low-pressure plasma, a simple description of the phenomena can be given. Considering the ratio of magnetic and electric forces of a charged particle (charge q) traveling with a velocity v in a direction perpendicular to the B vector of the wave (c being the vacuum velocity of light),

$$\frac{|\mathbf{F}_{\text{magn}}|}{|\mathbf{F}_{el}|} = \frac{qvB}{qE} = \frac{v\mu_0 H}{E} = v\mu_0\sqrt{\frac{\epsilon_0}{\mu_0}} = v\sqrt{\epsilon_0\mu_0} = \frac{v}{c}, \tag{35}$$

it is clear that the magnetic force can be neglected as long as $v \ll c$. Solving the wave equation for the case of negligible friction losses due to collisions leads to the following equation for the index of refraction of the plasma:

$$n^2 = 1 - \omega_{pe}^2/\omega^2, \tag{36}$$

where $\omega_{pe} = (n_e e^2/\epsilon_0 m_e)^{1/2}$ is the plasma frequency of the electrons (n_e and m_e are electron number density and electron mass). The ions may be neglected by reason of their high mass. Only if the plasma frequency exceeds the frequency of the wave in Eq. (36) does wave propagation result. In general, collisions have to be included in the considerations; this leads to a complex index of refraction. Since the plasma is generated by the absorption of electromagnetic energy, the high-frequency discharges have the great advantage of working without electrodes. This allows the use of aggressive gases in the corresponding reactors.

6.1 Microwave Discharges

6.1.1 Electron-Cyclotron Resonance Discharges By virtue of the simplicity of the apparatus and of the wide range of applications, this discharge type has great potential. Its main characteristic is a steady-state magnetic field being superimposed on the discharge that results from the absorption of electromagnetic energy deposited either directly or via capacitive or inductive coupling. Assuming the direction of the static magnetic field to coincide with the direction of wave propagation, two solutions of the wave equation are obtained: a right-hand (R) and a left-hand (L) polarized wave. The complex index of refraction may then be approximated by (Wilhelm, 1993)

$$N_{L/R} \approx \sqrt{1 - \frac{\omega_{pe}^2/\omega^2}{(1 \pm \omega_{ce}/\omega) - i v/\omega}}, \qquad (37)$$

where $\omega_{ce} = eB/m_e$ is the electron gyrofrequency and v is the collision frequency. Without magnetic field and neglecting collisions (i.e., $v/\omega \approx 0$), Eq. (37) becomes equal to Eq. (36). With magnetic field, two characteristic cases may be distinguished for the index of refraction of the right-hand polarized R wave:

1. $N_R \rightarrow \pm\infty$ for $\omega = \omega_{ce}$; i.e., for a certain value of B, this corresponds to the resonance case, phase velocity and wavelength $\Rightarrow 0$
2. $N_R = 0$ for $\omega_{pe}^2/\omega^2 = (1 - \omega_{ce}/\omega)$; i.e., for a certain value of n_e, this corresponds to the "cutoff" case, phase velocity and wavelength $\Rightarrow \infty$

Wave propagation is not possible in the evanescent region where the index of refraction becomes imaginary ($N^2 < 0$). The dispersion conditions for the R wave can be represented in a CMA diagram, Fig. 16 (taken from Wilhelm, 1993). The CMA diagram is a representation of the dispersion relations for an electromagnetic wave in a magnetized plasma; it is named after the initials of its authors: P. C. Clemmow, R. F. Mullaly, and W. P. Allis. The abscissa of this diagram depends on electron number density, whereas the ordinate depends on the magnetic induction. The dashed line in the diagram separates the cutoff region from the evanescent region. In the case of R resonance, i.e., if absorption is to be achieved, curve (a), access is possible from two sides. The "low-field access," curve (b), can be achieved using permanent magnets, but the wave has to tunnel through the evanescent region in front of the resonance. The "high-field access," curve (c), may be difficult in cases where the real part of the index of refraction takes on high values, because of steep magnetic field gradients and high plasma densities.

The power absorbed by the electrons is given by

$$P_{R+L} = \frac{n_e e E_0^2}{2 m_e v}\left[\frac{1}{2}\left(\frac{v^2}{(\omega - \omega_{ce})^2 + v^2}\right) + \frac{1}{2}\left(\frac{v^2}{(\omega + \omega_{ce})^2 + v^2}\right)\right], \qquad (38)$$

where E_0^2 is the amplitude of the wave. The first part in the bracket corresponds to the R

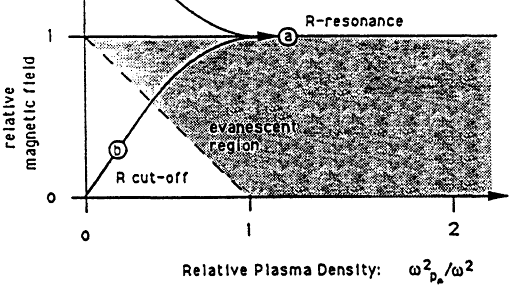

FIG. 16. CMA dispersion diagram (from Wilhelm, 1993).

wave, while the electron cyclotron resonance (ECR) condition is obtained for $\omega = \omega_{ce}$.

The ECR reactors are used for coating, surface treatment, and microstructuring by reactive ion etching. A "standard reactor" is shown together with the magnetic field topology in Fig. 17 (taken from Wilhelm, 1993). This type of reactor cannot be used for large-scale industrial operation, but it is relatively simple and flexible, and therefore it is found in many applications, such as providing carbon coating on the first wall parts (e.g., limiter plates or tiles) of nuclear fusion machines. The cylindrical vessel of the reactor contains the sample holder; it is enclosed by magnetic coils. For better penetration of the ions coming from the plasma, the sample may be subjected to a dc or rf biasing. The *R* wave enters the vessel from the top via a circular horn antenna located behind a quartz window. The pressure range for these discharges lies between fractions of a pascal and several hundred pascals. Frequently, readily available magnetron sources with a frequency of 2.45 GHz and with power levels up to 6 kW are used. If large surfaces have to be treated in mass-production applications, other reactor types, such as the "distributed ECR reactor" (Pomathiod *et al.*, 1984) or a "reactor with elongated mirror geometry (EMG)" (Geisler *et al.*, 1990), are used.

A modification of the ECR reactor is the "electron cyclotron wave resonance reactor" (ECWR). It uses frequencies that are only close to the ECR condition. The increase of the index of refraction in the vicinity of ECR causes a strong reduction of the wavelength in the plasma. This leads to a condition where the wavelength becomes smaller than the plasma dimension. Since the damping of the wave decreases for $\omega < \omega_{ce}$, the wave penetration into the plasma increases, and a standing wave may be obtained in the reactor. The energy introduction into the vessel can be obtained either by capacitive or by inductive coupling. For the case of inductive coupling, one or several ring electrodes are wound around the discharge vessel, and the reactor functions like a transformer whose secondary winding is the plasma itself. Such reactors can be used from the low-pressure range up to atmospheric pressure. In the Russian literature they are called plasmatrons, and the range of frequencies used extends from the microwave frequencies to radio frequencies. Important recent developments make use of microwave plasmas for lasing purposes (CO_2 and excimer lasers) and for excimer lamps.

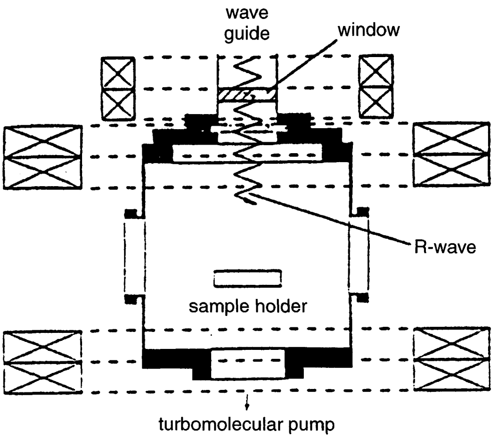

FIG. 17. "Standard ECR reactor" and magnetic field topology (from Wilhelm, 1993).

6.2 Radio-Frequency Discharges

Discharges produced by electromagnetic fields in the radio-frequency (rf) range, i.e., approximately between 100 kHz and 100 MHz, obtain the deposited power either by capacitive or by inductive coupling. While in the inductively coupled discharge as described above no electrodes are used, this may or may not be true for the case of the capacitively coupled discharge. Analytical solutions for the prediction of voltage–current characteristics have been worked out for the electrodeless case as well as for the rf discharge using electrodes (Raizer, 1991). Depending on the gas pressure at which the discharge with electrodes is operated, two different modes of the discharge have been observed, specifically in hydrogen. At pressures below 100 Pa, the light emitted from the discharge is higher in intensity and comes from distinct layers reaching close to the electrodes, whereas rf discharges in H_2 operating at pressure levels above several hundred pascals exhibit a diffuse glow in the center of the gap, the electrode regions being dark. The mechanisms leading to these different discharge modes are not fully understood as yet, but it has been shown that the current densities differ by an order of magnitude for the two cases (Yatsenko, 1981).

Because there is an increased absorption of wave energy in the plasma if a helicon wave is used, discharges of this type have become an interesting and important application of rf discharges. Helicon waves are right-handed circularly polarized waves that propagate in the direction of the superimposed magnetic field and have an electric field component parallel to this B field; see Fig. 18 (taken from Chen, 1991). This type of discharge is operated at a frequency ω that is given by the condition (Komori, *et al.*, 1991) $\omega_{ci} \ll \omega_l \ll \omega \ll \omega_{ce} \ll \omega_{pe}$. The quantity $\omega_{ci} = qB/m_i$ is the ion cyclotron frequency, q being the charge; $\omega_l \approx [\omega_{pi}^2/(1 + \omega_{pe}^2/\omega_{ce}^2)]^{1/2}$ is the lower hybrid frequency, ω_{pi} being the plasma frequency of ions; and $\omega_{pi} = (n_i q^2/\epsilon_0 m_i)^{1/2}$. Depending on the electron number density in the low-pressure (0.1-Pa range) discharge, the role of collisional damping versus Landau damping may be altered, smaller electron number densities ($n_e < 10^{13}$ approximately, in a 7-MHz discharge operated in argon at a pressure of $p < 0.4$ Pa) favoring Landau damping.

Important applications of rf discharges are, among others, the heating of fusion plasmas and the production of high-power

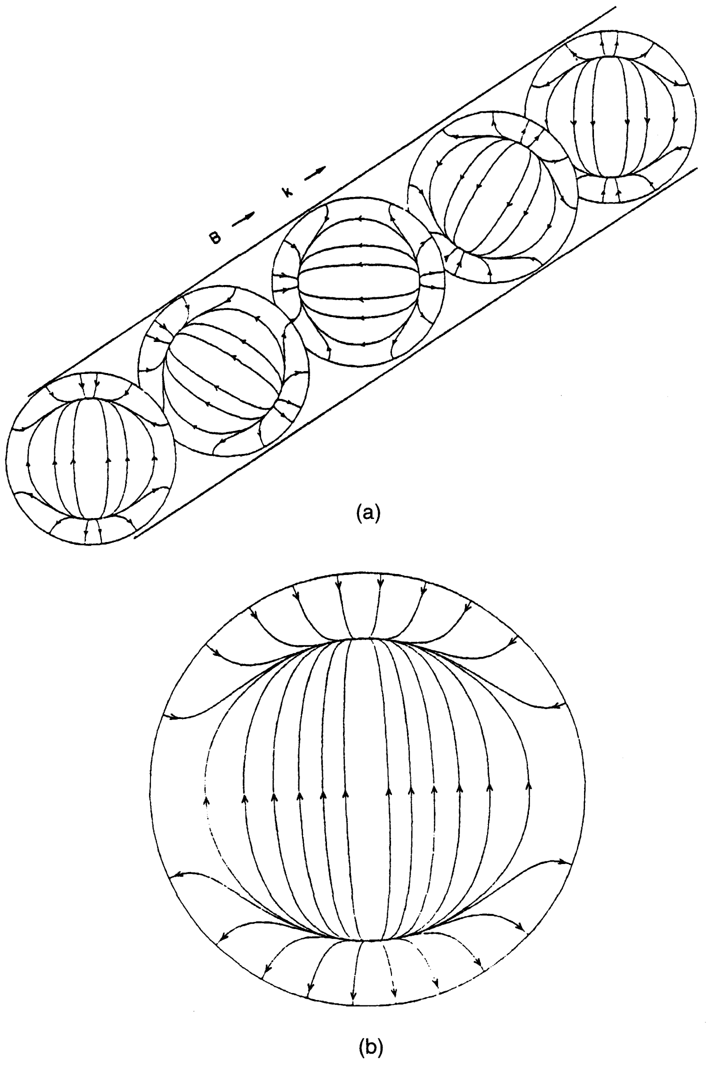

FIG. 18. Electric field line patterns for the $m = 1$ mode of a helicon wave. (a) 3D representation; (b) detailed pattern for $k/a = 1/3$ (from Chen, 1991).

CO_2 laser plasma, of plasmas used for sputtering purposes, and of plasmas used for technological plasma–wall interaction processes.

6.3 Dielectric-Barrier Discharges

The dielectric-barrier discharge (DBD), which is also called "silent discharge," was proposed by Siemens as early as 1857. In recent years it has acquired considerable attention because of its numerous applications. This type of discharge can be operated at different pressure levels (0.01–1 MPa) and frequencies (50 Hz–1 MHz), and a wide range of different gases is used. Typical electrode configurations of DBD's are shown in Fig. 19 (from Kogelschatz, 1992). In all three configurations, which might be used for different applications, a dielectric barrier separates at least one electrode from the discharge space. As a result mainly of the work performed by Eliasson and co-workers (Eliasson and Kogelschatz, 1991; Eliasson *et al.*, 1994), modeling of DBD has made great progress during the last decade. Considering a DBD in a high-pressure gas, the discharge consists of many current filaments existing simultaneously and reforming after extinction. The number of filaments may be high enough to lead to the appearance of a fairly homogeneous discharge in the gap. In a gap with a spacing of the order 1 mm, the radius of the filaments is typically around 0.1 mm, and the current density lies in the range 100–1000 A/cm^2. The electron density in the gap is of the order 10^{14}–10^{15} cm^{-3}, and the mean electron energy is between 1 and 10 eV. Three distinct phases can be distinguished for each filament:

1. the electrical breakdown of the gap, i.e., the formation of the discharge;
2. the passage of the current pulse; and
3. the reaction kinetics in the gas.

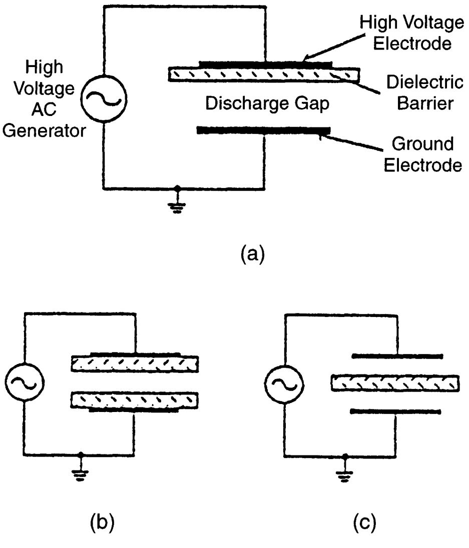

FIG. 19. Typical electrode configurations of dielectric barrier discharges (from Kogelschatz, 1992).

The breakdown occurs if the field inside the gap exceeds the reduced Paschen field, i.e., the so-called Paschen voltage, which corresponds to the minimum of the Paschen curve, divided by the product of number density in the gap and the extent of the gap. An avalanche forms, and at its head a considerable space charge leads to a local self-induced field ("eigenfield") superimposed on the applied field. Thus the field is enhanced in the direction of propagation toward the anode. After the space charge reaches the anode, a high-field wave may be reflected back toward the cathode. This process is completed within nanoseconds; it leaves a discharge channel through which the current pulse occurs. Current transport will take typically 1–100 ns. If there is a dielectric in front of the anode, the charges accumulate on it. This leads to an electric field that is directed against the applied field, and the current flow stops in this filament. If the field is high enough, a second current pulse may be generated; this has been observed in a high-pressure oxygen discharge. During and after the passage of the current, the molecules and atoms go into excited states. Reaction kinetics, i.e., plasma chemistry, takes place, the time scale of which may last up to seconds. Numerical modeling of this process has been successful. By solving the Boltzmann equation (7) together with the continuity equation (for all charged particle species) and Poisson's equation, the relevant features of such discharges can be predicted. Among the most important and oldest applications of such discharges stands the generation of ozone from oxygen or air according to $e + O_2 \rightarrow e + 2\ O$ followed by the reaction $O + O_2 + M \rightarrow O_3 + M$, where M is a collision partner such as O_2, O, O_3, or N_2.

Recently, much work has been devoted toward using DBD for the formation of excimers to be used in UV and VUV radiation sources. Further applications are the pumping of CO_2 lasers, surface treatment (deposition and dry etching), pollution control by the destruction of toxic materials, and, last but not least, CO_2 hydrogenation for the formation of methanol according to the reaction $CO_2 + 3\,H_2 \rightarrow CH_3OH + H_2O$.

7. CORONA DISCHARGES

If the electrical field between electrodes is inhomogeneous, e.g., between a pointed and a plane electrode, a corona discharge may be initiated at one electrode, for example, at the pointed electrode. Depending on the polarity of this electrode, different phenomena are observed. As described in Secs. 4 and 5, a voltage U applied to an electrode gap leads to different types of breakdown mechanisms and discharges, depending on the type of gas, the pressure, the electrode spacing d, and the value of the voltage U. Only if the field strength is high enough to insure multiplication of electron production processes will a self-sustaining discharge start. Let us consider the case of a dc voltage being applied to an electronegative gas like air. The electrode at which the corona discharge should be observed is the negative electrode (negative corona case). Ignition of the corona discharge is only possible if the following ignition criterion is fulfilled:

$$\int_0^P (\alpha - \eta)\,ds = \ln(1 + 1/\epsilon), \qquad (39)$$

where α and η have been defined in Eq. (34) and ϵ is the secondary Townsend coefficient relating the number of electrons coming from the cathode to the corresponding number generated by collision processes in the gas. The integration over the distance from the electrode has to be extended to the point P where the production of electrons ends because $\alpha = \eta$. Equation (39) is similar to the streamer-formation criterion:

$$\int_0^P (\alpha - \eta)\,ds = \ln N_{\mathrm{crit}}, \qquad (40)$$

where N_{crit} is the critical number of electrons in the avalanche, $N_{\mathrm{crit}} = 10^8$; see Sec. 4. Accordingly, the phenomenological description of a negative corona at increasing voltage reaches from a stage (a) in which the space close to the electrode surface shows constantly moving luminous fans, to a glow mode (b), and finally to a prebreakdown streamer (c). The discharge of stage (a) exhibits intermittent short (tens of microseconds) current pulses that have values below a milliampere; they are called Trichel pulses. The processes leading to the Trichel pulses are related to space charge and screening phenomena. Since their frequency is in the range of radio and television signals, they can lead to noise. In stage (b) the glow extends into the gap; the current is more stable and has amplitudes reaching up to 100 mA. If the discharge is of the prebreakdown streamer type (c), a bright streamer of several centimeters in length can be seen in the gap, and the current has pulses in the millisecond range and amplitudes up to amperes. If the dc polarities are reversed, the corona discharge appears at the anode (positive corona). The stages (a)–(c) described for the negative corona exist also; now (a) is called "burst corona," a plasma film that covers the electrode; the glow (b) extending into the gap has higher currents, and the streamer stage (c) exhibits a bright filament with more branching and longer than in the negative corona case. The current pulses have approximately the same duration and amplitude as before. If corona discharges with ac voltages are considered, the effects observed in each half-cycle correspond to the dc effects described above. The only difference between dc and ac corona discharges is that the space charge remaining from the previous cycle leads predominantly to negative-corona Trichel pulses (a) and to positive glow (b) and prebreakdown (c) coronas. Corona discharges have a negative effect on high-voltage power transmission, since the power losses associated with these discharges between power lines may reach the same order of magnitude as the Ohmic losses. On the other hand, corona discharges have applications in Geiger–Müller counters and in electric filters and separators (Goldman and Goldman, 1978).

8. LIGHTNING PHENOMENA

The natural phenomena "lightning" and "Saint Elmo's fire" must always have impressed man, as documented in numerous archeological representations; see, e.g., Poroda (1949). In later times disastrous lighting strokes led to the explosion of stored gun powder, destroying houses and killing people, such as in Brescia in 1769 where 3000 deaths resulted. As described in Golde (1977), early research in different countries was carried out. Once the electrical nature of lightning was understood, man searched for protection. In 1750 B. Franklin proposed the lightning rod. It first proved its usefulness when, in 1760, lightning struck the house of the merchant West in Philadelphia. In recent years lightning recording and research stations have made direct and time-resolved recordings of the current pulse, the electrical and magnetic fields, and the optical phenomena associated with lightning phenomena. From these experimental data and from modeling calculations, the following conclusions may be drawn. At thunderstorm times, the always present natural electrical field with a field strength of 100–400 V/m, which is due to the negative charge of the earth (5×10^5 C) and a corresponding positive charge in an atmospheric layer at a height of approximately 100 km, is disturbed. The disturbance in the lower atmosphere is caused by charge separation in clouds. Different mechanisms, not fully understood as yet, are at the basis of that charge separation: Because of strong convection in the atmosphere, turbulence occurs in clouds, precipitation droplets polarized by the electric field collide, and charge transfer and charge separation may be the consequence. In addition, convective electrification mechanisms may play a role: The cloud may acquire charge by taking in both positive ions from point discharges on the ground and negative ions from the upper atmosphere. Another electrification mechanism that has been proposed is connected with the presence of supercooled rain droplets together with ice crystals. As a result of the electrification, a cloud dipole is formed; maximum field strengths are in excess of 4×10^5 V/m, and charges of many Coulombs are reported. The typical cloud-to-ground stroke starts with a stepped leader, the first one having a step length of 10–200 m, a time interval between steps of typically 50 ms, and a velocity of propagation of approximately 10^6 m/s, the branches having a downward direction. Figure 20 (taken from Berger in Golde, 1977, p. 136) schematically represents the different stages in the formation of the stroke. Once the downward-directed leader of either polarity

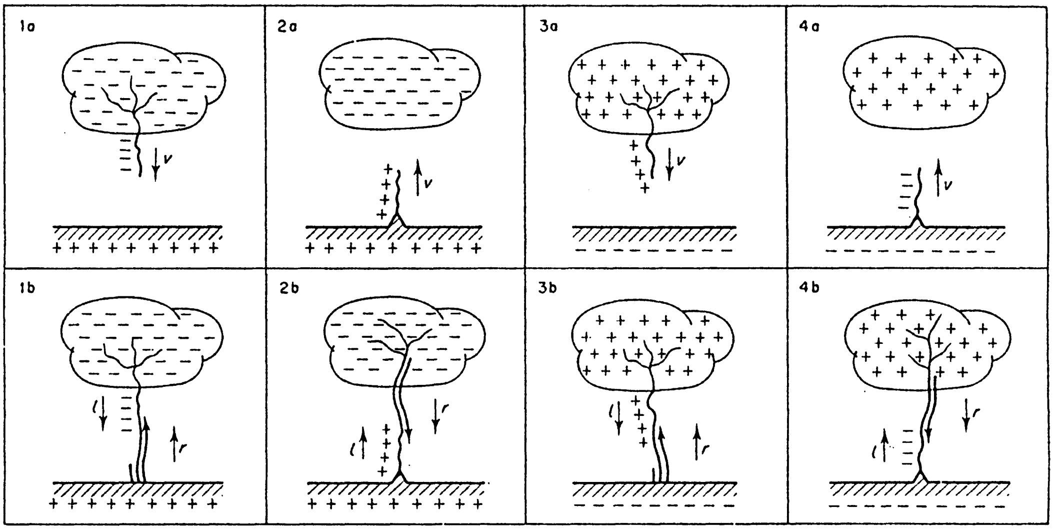

FIG. 20. Schematic representation of the eight types of lightning flash. Types depend on polarities and directions of leader and return strokes: *l*, leader; *r*, return stroke; *v*, direction of propagation (from Golde, 1977, p. 136).

is close to ground, an upward streamer is generated, and a complete discharge channel is formed. From the junction point, an upward-directed ground potential wave travels with a speed on the order of 10^8 m/s. The so-called return stroke carries tens of kiloamperes in an arc channel with the properties described in Sec. 3; its shock wave is at the origin of the thunder. The same formation phases can be identified in an upward lightning stroke. Negative first strokes typically carry a charge of several coulombs. Different return-stroke current models exist—no final theory has been formulated (Uman, 1990). Once the current has stopped, there remain free charges in the extinguished channel for times extending from milliseconds to seconds. If additional charges are available, a subsequent stroke may start, using, approximately, the previous path. Besides strokes of the described type, there exist ground-to-cloud, cloud-to-cloud, and intracloud strokes. Depending on the optical appearance of the stroke channel, different names, such as bead lightning, are given to the phenomenon. Ball-lightning events have also been reported without a final explanation.

GLOSSARY

Abel Equation: Analytical solution of the radiation transport equation for cylindrical nonabsorbing media.

CMA Diagram: Representation of the dispersion relations for an electromagnetic wave in a magnetized plasma. The diagram is named after the initials of its authors: P. C. Clemmow, R. F. Mullaly, and W. P. Allis.

Leader: Propagating channel containing free charges, preceding an electrical breakdown.

Oscillator Strength: Dimensionless quantity that gives the absorption strength of a transition defined as "number of classical oscillators per atom" in the lower state.

Partition Function: Normalization factor for the distribution function, i.e., sum over all energy levels.

Plasma: A mixture of electrons, ions, and neutral particles that is quasineutral, i.e., contains equal numbers of charges of either polarity. Because of the high temperatures necessary for ionization, plasmas emit radiation in a variety of spectral regions.

Radon Equation: Integral that yields the intensity along a line of sight of either an emitting or an absorbing medium. It is the governing equation for computed tomography.

Resonance Line: Line radiation with a transition to the ground state of an atom or ion.

Saint Elmo's Fire: A natural luminous discharge to be seen at the top of pointed objects, e.g., ship masts, at times of high local electrical field strength.

Sputtering: A process by which surface atoms typically from metal electrodes are removed by ion or neutral bombardment. The sputtering process may be used either for a controlled removal of material (e.g., sharpening of razor blades) or for creating deposited layers of sputtered material on a target.

Vacuum Ultraviolet Radiation (VUV): Due to the radiation absorption of molecular oxygen, air is not transparent below 200 nm. Observation of VUV radiation therefore requires evacuated systems.

INTRODUCTION

This article is devoted to the theory and applications of a set higher transcendental functions that arise naturally in mathematical physics. These higher transcendental functions are referred to as special functions, and they arise

1. when solving, in certain curvilinear coordinate systems, partial differential equations that are defined by physical problems and/or
2. when finding eigenfunctions and eigenvalues of differential operators.

The partial-differential-equations approach to special functions involves use of the separation-of-variables method and either the Frobenius–Fuchs power series solutions of one or more resulting ordinary differential equations or an Infeld–Hull type factorization procedure for finding eigenfunctions and eigenvalues of second-order ordinary linear differential equations.

The focus is on a class of physical prob-

lems whose differential-equation formulation involves the Laplacian operator, ∇^2. The resulting partial differential equations include the Laplace equation, the heat-conduction (diffusion) equation, the mechanical wave-motion equation, and the Schrödinger wave equation. After application of the separation-of-variables method, the resulting time-independent parts of all these partial differential equations may be written in the form of the Helmholtz differential equation, $\nabla^2 u + k^2 u = 0$. Problems involving the Helmholtz differential equation in spherical coordinates lead to spherical harmonics, Legendre polynomials and associated Legendre functions, Laguerre and associated Laguerre polynomials, and spherical Bessel functions. Problems modeled by use of Helmholtz's differential equation in cylindrical coordinates involve the various types of Bessel functions. Solutions of the Schrödinger wave equation for a linear harmonic oscillator are expressed in terms of Hermite polynomials.

Special functions such as Hermite polynomials, Legendre polynomials and associated Legendre functions, spherical harmonics, Laguerre and associated Laguerre polynomials, and Bessel functions are widely used in mathematical physics and are the main focus of this article; these special functions are special cases of the hypergeometric function ${}_2F_1(a,b,c;z)$ or confluent hypergeometric function ${}_1F_1(a,c;z)$. There exist other useful special functions in mathematical physics that are not expressible in terms of ${}_2F_1$ or ${}_1F_1$. The functions ${}_2F_1$ and ${}_1F_1$ may be developed from the following main viewpoints:

1. ordinary differential equations and the Frobenius–Fuchs power series method,
2. factorization of ordinary differential equations, and
3. representation theory of local Lie groups.

In a lecture course, *The Application of Group Theory to the Special Functions of Mathematical Physics* (unpublished lecture notes, Princeton University, Princeton, NJ, 1955; see Talman, 1968), Wigner pointed out that certain classes of special functions arise as matrix elements of the representations of local Lie groups. Since Wigner's work, many other group-theoretical approaches to special functions have been developed. The purposes of these various group-theoretical approaches are to show unity (or demonstrate a central foundation) among the extremely large number of special functions and to derive their various known basic properties. It is important, however, to note that there exist no single approach to special functions that unites all special functions and illuminates all of their various properties.

Section 1 is devoted to a treatment of the Sturm–Liouville theory and orthogonal polynomials, since these concepts provide insight into properties of solutions of the second-order ordinary linear differential equations in which we are interested. The factorization method of Infeld and Hull and its connection to a group-theoretical foundation of certain special functions are summarized in Secs. 1.5 and 1.6.

A discussion of the properties of the hypergeometric differential equation and the hypergeometric function ${}_2F_1$ is given in Sec. 2. The Legendre polynomials and associated Legendre functions are special examples of ${}_2F_1$, and their important properties are developed in Sec. 2. Also, some discussion of the Chebyshev polynomial, Gegenbauer polynomial, and Jacobi polynomial is given in Sec. 2.

Section 3 is devoted to special functions that are special cases of the confluent hypergeometric function, ${}_1F_1$. These special functions include the various Bessel functions, Laguerre and associated Laguerre polynomials, and the Hermite polynomials. Also, discussions of some properties of the confluent hypergeometric differential equation and properties of confluent hypergeometric function are given in Sec. 3.

In Sec. 4, a comprehensive treatment of the Helmholtz differential equation in cylindrical coordinates and the resulting Bessel functions is given. A summary of certain other special functions used in mathematical physics is given in Sec. 5.

1. THE STURM–LIOUVILLE THEORY

1.1 Introduction

Linear operators are basic to linear differential equations, and the solutions of each of the differential equations we will consider form a vector space. Hence, we begin with the essentials of the theory of linear operators.

A vector space (also known as a linear space or linear manifold) V is a nonempty set of elements $\{\psi_i\}$, called vectors (here vector is used in an abstract mathematical sense), for which the operations of addition and multiplication by a scalar are valid. Addition is a rule that assigns an element for $\psi_1 + \psi_2$ in V for every pair of elements ψ_1 and ψ_2 in V. The operation of multiplication by a scalar is a rule that assigns an element for $a\psi_1$ in V to each complex a and each ψ_1 in V. In addition, a zero element and negative elements exist, and the associative and commutative properties of addition are valid.

A function T that transforms (maps) vectors in V into a vector space W, $T : V \rightarrow W$, is called a linear transformation if $T(\psi_1 + \psi_2) = T(\psi_1) + T(\psi_2)$ and $T(a\psi_1) = aT(\psi_1)$ are valid for all vectors and all real scalars in V. The case $T : V \rightarrow V$ is called a linear operator on V. A real number λ is an eigenvalue (characteristic value) of the linear operator T if there is a nonzero vector ψ (called the eigenvector of T) in V for which $T(\psi) = \lambda\psi$.

In mathematical physics, the linear operator is normally a differential operator, the eigenvalue equation is a differential equation, and the eigenfunctions (solutions) form a vector space and satisfy certain imposed boundary conditions.

For physical problems, the three basic types of boundary conditions are

1. Dirichlet, specification of the solution at each point on the boundary;
2. Neumann, specification of the normal derivative of the solution at each point on the boundary; and
3. Cauchy, specification of both Dirichlet and Neumann conditions.

Typically, the actual physical problem is used as a guide for the formulation of boundary conditions. Sometimes, however, it is difficult to formulate the appropriate boundary conditions for a problem. Hence, it is important to understand what conditions are appropriate for a particular type of differential equation (see, e.g., ANALYTIC METHODS).

The Laplace equation, the time-independent heat-conduction (diffusion) equation, and the time-independent mechanical wave equation may be put into the form of the Helmholtz differential equation. The Helmholtz differential equation, $\nabla^2 u + k^2 u = 0$ for constant k^2, is an eigenvalue equation where $-k^2$ is the eigenvalue, u is the eigenfunction and is subject to boundary conditions, and ∇^2 is the operator. The time-independent Schrödinger wave equation contains the operator ∇^2 and is an eigenvalue equation of the form $\hat{H}\psi = E\psi$ where $\hat{H} = (-\hbar^2/2m)\nabla^2 + V(x,y,z)$.

The separation-of-variables method applied to Helmholtz's differential equation and to the time-independent Schrödinger's wave equation in various coordinate systems leads to ordinary differential equations that may be written in the following general form:

$$\frac{d}{dx}\left\{p(x)\frac{du}{dx}\right\} - q(x)u + \lambda\rho(x)u = 0. \tag{1}$$

The parameter λ is a separation constant (in some cases, more than one separation constant may appear; we will focus on the case of one separation constant). Equation (1) is the well-known Sturm–Liouville equation, and it may be written in the following operator form:

$$\mathcal{L}(u) + \lambda\rho(x)u = 0. \tag{2}$$

The Liouville operator, a linear operator, is defined by

$$\mathcal{L}(u) = \frac{d}{dx}\left\{p(x)\frac{du}{dx}\right\} - q(x)u. \tag{3}$$

For the general differential operator $M(u) = p(x)u'' + r(x)u' + q(x)u$, the operator $\bar{M}(u) = (pu)'' - (ru)' + qu$ is defined as the adjoint of $M(u)$. Note that $M(u) = \bar{M}(u)$ when $p' = r$, and $M(u)$ is said to be a self-adjoint operator in this case. On applying the general definition for the adjoint of an operator to Eq. (3), we find that $\mathcal{L}(u) = \bar{\mathcal{L}}(u)$, which means that the Liouville operator is a self-adjoint operator. In fact, it can be shown that every second-order differential operator can be transformed to the self-adjoint form (see Courant and Hilbert, 1953, p. 279).

In the Sturm–Liouville equation, the function $\rho(x)$ [$w(x)$ and $r(x)$ are also used] is called the density or weight. This name for

$\rho(x)$ is related to the historical origin of the Sturm–Liouville equation, which involved finding the solution for the one-dimensional mechanical wave equation, $[p(x)u_x]_x = \rho(x)u_{tt}$, representing the motion of a nonhomogeneous string. In the mechanical wave equation, $u(x,t)$ is the displacement of the string from its equilibrium position, $p(x)$ is proportional to the modulus of elasticity, and $\rho(x)$ is the mass per unit length of the string. Separation of variables leads to the ordinary differential equations $(pX')' + \lambda\rho X = 0$ and $\ddot{T} + \lambda T = 0$, where λ is the separation constant and $u(x,t)$ is assumed to equal the product $X(x)T(t)$, with typical boundary conditions given by $X(a) = X(b)$ and $p(a)X'(a) = p(b)X'(b)$.

In Eq. (1), the functions $p(x)$, $q(x)$, and $\rho(x)$ are assumed to be real, continuous with continuous derivatives, and nonzero in the region of interest, $[a,b]$. Moreover, it is assumed that $p(x)$ and $\rho(x)$ are always positive in $[a,b]$. The Sturm–Liouville equation is a generalized form of the usual eigenvalue equation since the eigenvalue is multiplied by the density function $\rho(x)$, which may be different from unity. The sign convention for $q(x)$ in Eqs. (1) and (3) conforms to the usage of Courant and Hilbert; some authors use a plus sign for $q(x)$ in these equations. The function $u(x)$ is subject to appropriate boundary conditions. With appropriate substitutions, the following differential equations are among the list of important differential equations in mathematical physics that may be put in the Sturm–Liouville form: Legendre and associated Legendre, Laguerre and associated Laguerre, Schrödinger equation for the linear harmonic oscillator, and Bessel. Hence, a study of the general properties of the Sturm–Liouville equation is extremely useful in mathematical physics. A summary of the relations between the differential equations for many important special functions and the Sturm–Liouville equation is given in Table 1.

The problem of determining the dependence of the eigenfunction $u(x)$ on the eigenvalue λ and of the eigenvalue λ on the boundary conditions imposed on $u(x)$ is often referred to as the Sturm–Liouville problem. The Sturm–Liouville problem is important for problems in both classical and quantum theory. Sturm–Liouville theory unites properties of the solutions of second-order ordinary linear differential equations related to

1. Hermitian and self-adjoint operators;
2. reality of eigenvalues of Hermitian and self-adjoint operators;
3. orthogonality and completeness of eigenfunctions;
4. degeneracy of eigenvalues (if N linearly independent eigenfunctions correspond to the same eigenvalue, then the eigenvalue is said to be N-fold degenerate); and
5. the fact that eigenvalues of the Sturm–Liouville equation form a discrete set of values such that $\ldots \lambda_1 \le \lambda_2 \le \lambda_3 \ldots$

These properties are important in the study

Table 1. Relation to the Sturm–Liouville equation.

of problems that lead to each of the differential equations we analyze in this article.

1.2 Hermitian Operators and Their Eigenvalues

Consider two twice-differentiable functions u_i and u_j. By use of Eqs. (1) and (2), we obtain

$$u_i^*\mathcal{L}(u_j) - [\mathcal{L}(u_i)]^*u_j = \frac{d}{dx}\left\{p\left(u_i^*\frac{du_j}{dx} - u_j\frac{du_i^*}{dx}\right)\right\}. \tag{4}$$

In Eq. (4), the asterisk is used to denote complex conjugate of the respective functions. Integrating both sides of Eq. (4) over the range of interest yields

$$\int_a^b \{u_i^*\mathcal{L}(u_j) - [\mathcal{L}(u_i)]^*u_j\}dx = \left\{p\left(u_i^*\frac{du_j}{dx} - u_j\frac{du_i^*}{dx}\right)\right\}_{x=b} - \left\{p\left(u_i^*\frac{du_j}{dx} - u_j\frac{du_i^*}{dx}\right)\right\}_{x=a}.$$

Note that the above equation results from the fact that $\mathcal{L}$ is self-adjoint. The operator $\mathcal{L}$ is said to be Hermitian if the following endpoint boundary conditions are imposed on the two functions and their derivatives.

$$\left\{p\left(u_i^*\frac{du_j}{dx} - u_j\frac{du_i^*}{dx}\right)\right\}_{x=b} = \left\{p\left(u_i^*\frac{du_j}{dx} - u_j\frac{du_i^*}{dx}\right)\right\}_{x=a}. \tag{5}$$

By use of the boundary conditions in Eq. (5), the Hermitian relation may be written as

$$\int_a^b u_i^*\mathcal{L}(u_j)dx = \int_a^b [\mathcal{L}(u_i)]^*u_j dx. \tag{6}$$

Thus far, the Liouville operator has been assumed to be real. In quantum mechanics, operators are generally complex (for example, the x component of the linear momentum operator is given by $p_x = -i\hbar\partial/\partial x$), and it is assumed that wave functions satisfy the boundary conditions in Eq. (5). The Hermitian condition in quantum mechanics for linear operator $\hat{A}$ takes the form

$$\int_{\text{all space}} \psi_i^*\hat{A}\psi_j d\tau = \int_{\text{all space}} (\hat{A}\psi_i)^\dagger\psi_j d\tau. \tag{7}$$

An arbitrary linear operator may be put in matrix form, and the notation $\hat{A}^\dagger$ means

1. interchange rows with columns and
2. take the complex conjugate of each element

(this process is called the Hermitian conjugate); in this connection, note that $(\hat{A}\psi_i)^\dagger = \psi_i^*\hat{A}^\dagger$. When an operator satisfies the condition $\hat{A} = \hat{A}^\dagger$, the operator is said to be Hermitian. In the bra and ket vector notation, Eq. (7) becomes $\langle\psi_i|\hat{A}\psi_j\rangle = \langle\hat{A}\psi_i|\psi_j\rangle$.

For solution $u_i = u_j = u$ in Eq. (6) and use of Eq. (2), we obtain

$$\int_a^b [u^*\mathcal{L}(u) - u\mathcal{L}(u^*)]dx = (\lambda - \lambda^*)\int_a^b \rho(x)u^*u dx = 0. \tag{8}$$

The result in Eq. (8) means that eigenvalues of Hermitian operators are real, $\lambda = \lambda^*$.

1.3 Orthogonality Condition and Completeness of Eigenfunctions

By use of Eq. (2) for distinct eigenfunctions u_i and u_j with distinct eigenvalues, the Hermitian relation in Eq. (6) may be written as

$$\int_a^b \{u_i^*\mathcal{L}(u_j) - [\mathcal{L}(u_i)]^*u_j\}dx = \int_a^b [u_i^*(-\lambda_j\rho u_j) + \lambda_i^*\rho u_i^*u_j]dx = (\lambda_i^* - \lambda_j)\int_a^b u_i^*u_j\rho(x)dx = 0.$$

Since $\lambda_i \neq \lambda_j$ and λ_i is real, the above equation implies that

$$\int_a^b u_i^*(x)u_j(x)\rho(x)dx = 0. \tag{9}$$

Equation (9) shows that eigenfunctions corresponding to distinct eigenvalues are orthogonal in the interval $[a,b]$ with respect to the weight function $\rho(x)$.

An orthonormal set of Sturm–Liouville eigenfunctions, $\{u_k(x)\}$, forms a complete set of functions (Courant and Hilbert, 1953, Chap. 6, Sec. 3). This completeness property means that the following equation is valid for any function $f(x)$ that is at least piecewise continuous in the interval $[a,b]$:

$$\lim_{n\to\infty}\int_a^b\left|f(x)-\sum_{k=1}^{n}c_k u_k(x)\right|^2\rho(x)dx=0. \tag{10}$$

The notation $|\ldots|^2$ means the product of the enclosed quantity and its complex conjugate, $|z|^2 = z^*z$. Equation (10) and the orthogonality relation in Eq. (9) lead to

$$f(x)=\sum_{k=1}^{\infty}c_k u_k(x)\quad\text{where } c_k = \int_a^b f(x)u_k^*(x)\rho(x)dx \tag{11}$$

and

$$\sum_{k=1}^{\infty}|c_k|^2=\int_a^b|f(x)|^2\rho(x)dx. \tag{12}$$

Equation (12) is referred to as the completeness relation. By use of Eq. (11) with the appropriate orthogonality relation and weight, one may obtain series expansions for $f(x)$ in terms of any complete set of orthogonal polynomials (or orthogonal functions); for example, the Fourier series, Legendre series, and Hermite series may be written respectively as

$$f(x)=\sum_{n=-\infty}^{\infty}c_n e^{in\pi x/l}$$

where

$$c_n=\frac{1}{2l}\int_{-l}^{l}f(x)e^{-in\pi x/l}dx,\quad -l\le x\le l;$$

$$f(x)=\sum_{n=0}^{\infty}c_n P_n(x)$$

where

$$c_n=\frac{2n+1}{2}\int_{-1}^{1}f(x)P_n(x)dx,\quad -1\le x\le 1;$$

and

$$f(x)=\sum_{n=0}^{\infty}c_n H_n(x)$$

where

$$c_n=\frac{1}{2^n n!\sqrt{\pi}}\int_{-\infty}^{\infty}f(x)H_n(x)e^{-x^2}dx,\quad -\infty\le x\le\infty.$$

1.4 Orthogonal Polynomials and Functions

The power-series solutions of many second-order ordinary linear differential equations in mathematical physics such as the Legendre, Laguerre, and Hermite differential equations may be written as an orthogonal polynomial plus an orthogonal function. The set of real polynomials $\{f_n(x)\}$ is said to be orthogonal with respect to the weight function $\rho(x)$ over the interval $[a,b]$ if the following relations are valid:

$$\int_a^b \rho(x)f_n(x)f_m(x)dx=\begin{cases}0 & m\neq n\\ h_n^2 & m=n\end{cases}. \tag{13}$$

If $h_n^2 = 1$ for all n, then the system of orthogonal polynomials in Eq. (13) is said to be orthonormal. Note that the weight determines the system of polynomials up to a constant factor (the value of h_n) in each polynomial; the specification of this constant factor for each polynomial is referred to a standardization (or standard convention). Summarized in Table 2 are some frequently used orthogonality relations.

1.4.1 Recurrence Formula for Orthogonal Polynomials In many cases, three consecutive orthogonal polynomials f_{n+1}, f_n,

Table 2. Some orthogonality relations.

$$\int_{-1}^{1}P_n(x)P_k(x)dx=\frac{2}{2n+1}\delta_{nk}$$

$$\int_{-1}^{1}P_n^m(x)P_k^m(x)dx=\frac{2}{2n+1}\frac{(n+m)!}{(n-m)!}\delta_{nk}$$

$$\int_0^{\infty}e^{-x}L_n(x)L_m(x)dx=\delta_{nm}$$

$$\int_0^{\infty}e^{-x}x^k L_n^k(x)L_m^k(x)dx=\frac{(n!)^3}{(n-k)!}\delta_{nm}$$

$$\int_{-\infty}^{\infty}e^{-x^2}H_n(x)H_m(x)dx=2^n n!\sqrt{\pi}\delta_{nm}$$

Table 3. Recurrence relations for some polynomials.

$A_n f_{n+1}(x) = (B_n + C_n x) f_n(x) - D_n f_{n-1}(x).$

$f_n(x)$	A_n	B_n	C_n	D_n
$P_n(x)$	$n + 1$	0	$2n + 1$	n
$P_n^m(x)$	$n - m + 1$	0	$2n + 1$	$n + m$
$L_n(x)$	$n + 1$	$2n + 1$	-1	n
$L_n^k(x)$	$n + 1$	$2n + k + 1$	-1	$n + k$
$H_n(x)$	1	0	2	$2n$

and f_{n-1} satisfy a recurrence formula of the form

$$A_n f_{n+1}(x) = (B_n + C_n x) f_n(x) - D_n f_{n-1}(x). \tag{14}$$

The recurrence relations for some of the frequently used orthogonal polynomials are listed in Table 3.

1.4.2 Rodrigues Formulas Formulas involving the nth derivative of an elementary function that can be used to generate orthogonal polynomials f_n are called Rodrigues formulas. It can be shown that the Rodrigues formulas for many orthogonal polynomials may be combined into the following general Rodrigues formula:

$$f_n = \frac{1}{a_n \rho(x)} \frac{d^n\{\rho(x)[g(x)]^n\}}{dx^n}. \tag{15}$$

The quantity $g(x)$ is a polynomial whose coefficients are independent of n, and the factor a_n is determined by the standardization of the orthogonal polynomial system. The Leibnitz formula for the nth derivative of a product should be used to evaluate the right-hand side of Eq. (15); this formula is

$$\frac{d^n}{dx^n}\{A(x)B(x)\} = \sum_{s=0}^{n} \left\{ \frac{n!}{(n-s)!s!} \frac{d^{n-s}}{dx^{n-s}} A(x) \frac{d^s}{dx^s} B(x) \right\}. \tag{16}$$

The Rodrigues formulas for some important orthogonal polynomials are given in Table 4.

1.4.3 The Generating Function The function $\mathscr{G}(x,t)$ is said to be a generating function of the sequence of functions $\{f_n(x)\}$ if the $f_n(x)$ are, up to a constant, the coefficients of t^n in the expansion of $\mathscr{G}(x,t)$ in powers of t. Such an expansion is valid for orthogonal polynomials and most orthogonal functions, and it may be written in the form

$$\mathscr{G}(x,t) = \sum_{n=0}^{\infty} a_n f_n(x) t^n. \tag{17}$$

In Eq. (17), the a_n are independent of x and t. The generating functions for certain orthogonal polynomials that will be used in other parts of this article are given in Table 5.

1.5 Factorization of the Sturm–Liouville Equation

The factorization method for finding eigenfunctions and corresponding eigenvalues of a large class of Schrödinger-type equations (forms of the Sturm–Liouville equation) was introduced by Schrödinginer (1940); in a clearly written paper, Infeld and Hull (1951) further developed the method. By use of the factorization method, a second-order differential equation is factored (transformed) into a product of first-order

Table 4. Rodrigues formula for some polynomials.

$$f_n = \frac{1}{a_n \rho(x)} \frac{d^n\{\rho(x)[g(x)]^n\}}{dx^n}.$$

$f_n(x)$	a_n	$g(x)$	$\rho(x)$

$T_n(x)$	2	$1 + (1 - t^2)/R^2$

differential operators, which results in a pair of first-order differential equations that are equivalent to the original second-order differential equation. The form of the potential function determines if the factorization method will be successful. In terms of the forms of the potential function, Infeld and Hull classified factorizations into six general factorization types. Many examples of the various factorization types are presented in the paper by Infeld and Hull. We give a brief overview of the factorization method because it is

1. a useful and straightforward method for finding eigenfunctions (in many cases, involving special functions) and corresponding eigenvalues for important differential equations in mathematical physics, and
2. equivalent to a local Lie-group theoretical analysis involving differential operators that leads to a group-theoretical approach to special functions.

In this overview of the factorization method, we closely follow the Infeld–Hull approach; using a plus sign for the second term in the Sturm–Liouville equation, we find that it may be transformed (see, e.g., Courant and Hilbert, 1953, p. 292) into the following general differential equation in standard form:

$$\frac{d^2y}{dx^2} + r(x,m)y + \lambda y = 0; m = 0, 1, 2, \ldots. \tag{18}$$

In Eq. (18), the function $r(x,m)$ contains the dynamical information, such as the potential energy, that characterizes the particular problem. The basic idea of the factorization method is that Eq. (18) can be either factored directly as a single differential equation or factored into a pair of differential equations of the following forms:

$$H_{m+1}^{+}H_{m+1}^{-}y(\lambda,m) = [\lambda - L(m + 1)]y(\lambda,m) \tag{19}$$

and

$$H_m^{-}H_m^{+}y(\lambda,m) = [\lambda - L(m)]y(\lambda,m),$$
$$\text{where } H_m^{\pm} = k(x,m) \pm \frac{d}{dx}. \tag{20}$$

The condition that must be satisfied by $k(x,m)$ and $L(m)$ is obtained by carrying out the indicated operations in Eqs. (19) and (20), comparing the result with the original differential equation, and eliminating $r(x,m)$; this condition is

$$k^2(x, m + 1) - k^2(x,m) + \frac{dk(x, m + 1)}{dx}$$
$$+ \frac{dk(x,m)}{dx} = L(m) - L(m + 1). \tag{21}$$

The fundamental idea of the factorization method is established in the five theorems that we now summarize.

Theorem I: If $y(\lambda,m)$ is a solution of the original differential equation, then $y(\lambda, m + 1) = H_{m+1}^{-}y(\lambda,m)$ and $y(\lambda, m - 1) = H_m^{+}y(\lambda,m)$ are also solutions corresponding to the same λ.

Theorem II (mutual adjointness of the operators): For functions g and f satisfying the end-point conditions,

$$\int_a^b g(H_m^{-}f)dx = \int_a^b (H_m^{+}g)f dx.$$

Theorem III (satisfying the boundary conditions): If $y(\lambda,m)$ is quadratically integrable over the entire range of x and $L(m)$ is an increasing function of m $(0 < m)$, then the raising operation, $y(\lambda, m + 1) = H_{m+1}^{-} \times y(\lambda,m)$, produces a function that is also quadratically integrable and vanishes at the end points. If $L(m)$ is a decreasing function of $m (0 < m)$, then the lowering operation, $y(\lambda, m - 1) = H_m^{+}y(\lambda,m)$, produces a function that is also quadratically integrable and vanishes at the end points.

Theorem IV: Class I solutions—$L(m)$ is an increasing function of the integer m. If $0 < m \leq M$ and $\lambda \leq$ the larger of $L(M)$ and $L(M+1)$, then a necessary condition for a square integrable solution is that $\lambda = \lambda_l = L(l+1)$, where l is an integer, and $m = 0, 1, \ldots, l$ and $H_{l+1}^{-}y(\lambda,l) \equiv 0$. Other solutions are given by

$$y_l^{m-1} = [L(l+1) - L(m)]^{-1/2}\left[k(x,m) + \frac{d}{dx}\right]y_l^m.$$

Class II solutions—$L(m)$ is a decreasing function of the integer m. If $0 \leq m \leq M$ and $\lambda \leq L(0)$, then a necessary condition for square integrable solutions is that $\lambda = \lambda_l = L(l)$, where l is an integer, and $m = l, l+1, \ldots$ and $H_l^{+}y(\lambda,l) \equiv 0$. Other solutions are given by

$$y_l^{m+1} = [L(l) - L(m+1)]^{-1/2} \times \left[k(x, m+1) - \frac{d}{dx}\right]y_l^m.$$

Theorem V (normalization of solutions): The $H^{\pm}$ operators preserve the normalization of the eigenfunctions.

The basic task now is to find $k(x,m)$ and $L(m)$ corresponding to a given $r(x,m)$. Infeld and Hull have shown that finding $k(x,m)$ and $L(m)$ is accomplished by use of one of the following six operator types.

Type A solutions are related to spherical harmonic functions and other eigenfunctions that are special cases of the hypergeometric function, ${}_2F_1$; we have

$$r(x,m) = -\frac{a^2(m+c)(m+c+1) + d^2 + 2ad(m+c+\frac{1}{2})\cos a(x+p)}{\sin^2 a(x+p)},$$

$$k(x,m) = a(m+c)\cot a(x+p) + \frac{d}{\sin a(x+p)},$$

and

$$L(m) = a^2(m+c)^2$$

where a, c, d, and p are constants.

Type B solutions are related to associated Laguerre and Laguerre functions and other eigenfunctions that are special cases of the confluent hypergeometric function, ${}_1F_1$; here

$$r(x,m) = -d^2e^{2ax} + 2ad(m+c+\tfrac{1}{2})e^{ax},$$

$$k(x,m) = de^{ax} - m - c,$$

and

$$L(m) = -a^2(m+c)^2.$$

Type C solutions are related to confluent hypergeometric functions, with

$$r(x,m) = -\frac{(m+c)(m+c+1)}{x^2} - \frac{b^2x^2}{4} + b(m-c),$$

$$k(x,m) = \frac{m+c}{x} + \frac{bx}{2},$$

and

$$L(m) = -2bm + \frac{b}{2}.$$

Type D solutions are related to generalization of the Hermite polynomials; here

$$r(x,m) = -(bx+d)^2 + b(2m+1),$$

$$k(x,m) = bx + d,$$

and

$$L(m) = -2bm.$$

Type E solutions are related to hypergeometric functions, with

$$r(x,m) = -\frac{m(m+1)a^2}{\sin^2 a(x+p)} - 2aq\cot a(x+p),$$

$$k(x,m) = ma\cot a(x + p) + \frac{q}{m},$$

and

$$L(m) = a^2m^2 - \frac{q^2}{m^2}.$$

Type F solutions are related to Laguerre polynomials, with

$$r(x,m) = -\frac{2q}{x} - \frac{m(m + 1)}{x^2},$$

$$k(x,m) = \frac{m}{x} + \frac{q}{m},$$

and

$$L(m) = -\frac{q^2}{m^2}.$$

Example 1: Find the eigenvalues and eigenfunctions of the associated Legendre differential equation by use of the factorization method.

Solution: By use of the transformation $u = P \sin^{1/2}\theta$, the associated Legendre differential equation [the theta equation in spherical coordinates, Eq. (49)],

$$\frac{1}{\sin\theta}\frac{d}{d\theta}\left(\sin\theta\frac{dP}{d\theta}\right) + \left[\lambda - \frac{m^2}{\sin^2\theta}\right]P = 0, \tag{22}$$

reduces to

$$\frac{d^2u}{d\theta^2} - \frac{m^2 - \frac{1}{4}}{\sin^2\theta}u + (\lambda + \tfrac{1}{4})u = 0. \tag{23}$$

On comparing Eq. (23) with the general equation, Eq. (18), in standard form, we find that it is a Type A factorization (see Theorem IV) where the parameters are given by $a = 1$, $c = -\frac{1}{2}$, $d = 0$, $p = 0$, $x = \theta$, and $\lambda \Rightarrow \lambda + \frac{1}{4}$; the required quantities for Type A factorization reduce to $r(\theta,m) = -(m^2 - \frac{1}{4})/\sin^2\theta$, $L(m) = (m - \frac{1}{2})$, and $k(\theta,m) = (m - \frac{1}{2})\cot\theta$. Since this is a Class I problem, $\lambda + \frac{1}{4} = L(l + 1)$ or $\lambda = l(l + 1)$ for $l = 0, 1, 2, \ldots$ $l \geq m$. The corresponding eigenfunctions (solutions) of Eq. (23) are obtained by use of Theorem IV for Class I solutions, $H_l^+y(\lambda,l) \equiv 0$; for normalization constants C_l and D_{lm}, the solutions are given by

$$u_l^l = C_l\sin^{(l+1/2)}\theta \text{ and}$$

$$u_l^{m-1} = D_{lm}\left\{(m - \tfrac{1}{2})\cot\theta + \frac{d}{d\theta}\right\}u_l^m.$$

Example 2: By use of a modified factorization method, find the eigenvalues and eigenfunctions of the quantum mechanical linear harmonic oscillator.

Solution: The linear harmonic oscillator problem was used by Schrödinger in his original work on factorization; it is a Type D problem, but $r(x,m)$ does not depend on m. For the linear harmonic oscillator, it is simpler to use the modified version of factorization involving the idea of raising and lowering operators; this modified factorization method is used in many quantum mechanics textbooks and is summarized here. The time-independent Schrödinger equation for the linear harmonic oscillator with potential energy $V(x) = kx^2/2 = m\omega^2x^2/2$ is given by

$$-\frac{\hbar^2}{2m}\frac{d^2\psi}{dx^2} + \frac{m\omega^2x^2}{2}\psi = E\psi. \tag{24}$$

The change of variable $\xi = (m\omega/k)^{1/2}x$ reduces Eq. (24) to the dimensionless form

$$\frac{d^2\psi}{d\xi^2} - \xi^2\psi + \lambda\psi = 0, \quad \text{where } \lambda = \frac{2E}{\hbar\omega}. \tag{25}$$

By use of the factorization (of differential operators) method, Eq. (25) may be written as

$$H^+H^-\psi = (\lambda + 1)\psi \text{ and } H^-H^+\psi = (\lambda - 1)\psi,$$
$$\text{where } H^{\pm} = \xi \pm \frac{d}{d\xi}. \tag{26}$$

The above factored equations are equivalent to Eq. (25). The basic idea of this factorization method is that ψ_n and λ_n can be generated from known ψ_0 and λ_0. If ψ_0 satisfies the original equation (factored equations) Eq. (26) with eigenvalue λ_0, then we may write

$$\left(\frac{d}{d\xi} - \xi\right)\left(\frac{d}{d\xi} + \xi\right)\psi_0 = (-\lambda_0 + 1)\psi_0. \tag{27}$$

By use of the identity

$$\left(\frac{d}{d\xi} - \xi\right)\left(\frac{d}{d\xi} + \xi\right)\psi = 2\psi - \left(\frac{d}{d\xi} + \xi\right)\left(\xi - \frac{d}{d\xi}\right)\psi,$$

Eq. (27) reduces to

$$\left(\frac{d}{d\xi} - \xi\right)\left(\frac{d}{d\xi} + \xi\right)\psi_1 = \lambda_1\psi_1. \tag{28}$$

To obtain Eq. (28), we made the following substitutions:

$$\psi_1(\xi) = \left(\xi - \frac{d}{d\xi}\right)\psi_0 \text{ and } \lambda_1 = \lambda_0 + 1. \tag{29}$$

In a similar manner, we obtain

$$\psi_{-1}(\xi) = \left(\xi + \frac{d}{d\xi}\right)\psi_0 \text{ and } \lambda_{-1} = \lambda_0 - 1. \tag{30}$$

The operators in Eqs. (29) and (30) are referred to as raising and lowering operators, respectively. If the above process is repeated n times, we obtain

$$\psi_n(\xi) = \left(\xi - \frac{d}{d\xi}\right)^n \psi_0 \text{ for } \lambda_n = \lambda_0 + n \tag{31}$$

and

$$\psi_{-n}(\xi) = \left(\xi + \frac{d}{d\xi}\right)^n \psi_0 \text{ for } \lambda_{-n} = \lambda_0 - n. \tag{32}$$

As seen from Eqs. (31) and (32), the eigenvalue (eigenenergy) is bounded from below at λ_0, but it is an arbitrarily large negative value, as seen in Eq. (32). It is required that the negative values of λ_{-n} be terminated (Theorem IV) by setting $\psi_{-1} = 0 = (\xi - d/d\xi)\psi_0$; by use of this termination, we find that $\psi_0 = N\exp(-\xi^2/2)$ is a solution of the original differential equation, Eq. (25). The corresponding lower bound for the eigenvalue is $\lambda_0 = 1$ or $E_0 = \hbar\omega/2$. Hence, we find that the knowledge of ψ_0 and λ_0 allows us to find ψ_n and λ_n; we obtain

$$\psi_n(\xi) = N_n H_n(\xi) e^{-\xi^2/2} \text{ for } \lambda_n = 1 + n \text{ or } E_n = \hbar\omega(n + \tfrac{1}{2}). \tag{33}$$

Equation (33) results from the fact that $(\xi - d/d\xi)^n \exp(-\xi^2/2)$ produces $\exp(-\xi^2/2)$ times an nth-order polynomial, $H_n(\xi)$; this polynomial, as is shown in Sec. 2.2, is the Hermite polynomial.

1.6 Connection with Local Lie-Group Theory

Wigner, unpublished Princeton University Lecture Notes in 1955, demonstrated that large classes of special functions arise as matrix elements of the representations of Lie groups such as the groups of rotations in two, three, and four dimensions or the Euclidean groups in two and three dimensions. Talman (1968) extended the work of Wigner. The Wigner group-theoretical approach to special functions shows that

1. addition theorems for special functions result from the group multiplication rule and
2. differential equations giving rise to special functions result from limits of generators.

Other group-theoretical development of special functions exist (see, e.g. Vilenkin, 1968).

The focus in this section is on the approach by Miller (1968), which is based on the recognition of the equivalence between the Infeld–Hull factorization method and the representation theory of complex local Lie groups with the four-dimensional Lie algebras $\mathcal{G}(a,b)$ and the six-dimensional Lie algebra $\mathcal{F}_6$. Local Lie-group theory provides a unifying approach to a large class of special functions and their properties. A comprehensive treatment of group theory is given in GROUP THEORY and in the many excellent books on the subject; we simply summarize essential group concepts needed to outline the Miller group-theoretical approach to special functions.

Local Lie-group theory was developed in the nineteenth century; it is based on the use of local coordinates (needed for a discussion of special functions), and concerned with groups that are analytic only in the neighborhood of the group identity element. A global Lie group involves coordinate-free considerations and is an abstract group.

The Lie algebra (vector space) $\mathcal{G}$ of the local Lie group G is the set of all tangent vectors (generators) at the identity element together with commutation relations $[\alpha,\beta] \in \mathcal{G}$ defined for all tangent vectors α, $\beta \in \mathcal{G}$. Lie's three fundamental theorems and their converses together with the Taylor expansion theorem provide a mechanism for constructing the Lie algebra associated with a Lie group. For local transformation groups, which are important in our analysis, the commutation relations involve Lie derivatives, $[L_\alpha, L_\beta]$, or generalized Lie derivatives, $[D_\alpha, D_\beta]$.

A four-dimensional complex Lie algebra $\mathcal{G}(a,b)$ with basis $\mathcal{J}^\pm$, $\mathcal{J}^3$, and $\mathcal{E}$ is defined by the commutation relations

$$[\mathcal{J}^+,\mathcal{J}^-] = 2a\mathcal{J}^3 - b\mathcal{E};\ [\mathcal{J}^3,\mathcal{J}^\pm] = \pm\mathcal{J}^\pm;\ \text{and}\ [\mathcal{J}^\pm,\mathcal{E}] = [\mathcal{J}^3,\mathcal{E}] = 0. \tag{34}$$

The parameters a and b are a pair of arbitrary complex numbers. For the representation ρ of $\mathcal{G}(a,b)$ on the complex vector space V, we define four operators as follows:

$$J^+ = \rho(\mathcal{J}^+);\ J^- = \rho(\mathcal{J}^-);\ J^3 = \rho(\mathcal{J}^3);\ \text{and}\ E = \rho(\mathcal{E}). \tag{35}$$

The four operators in Eq. (35) obey commutation relations similar to those in Eq. (34); they are

$$[J^+,J^-] = 2aJ^3 - bE;\ [J^3,J^\pm] = \pm J^\pm;\ \text{and}\ [J^\pm,E] = [J^3,E] = 0. \tag{36}$$

The object at this stage is that of finding realizations of the irreducible representations $\rho(\alpha)$ of $\mathcal{G}(a,b)$ [where $\alpha \in \mathcal{G}(a,b)$] that form a Lie algebra of analytic differential operators acting on V. An extremely large number of possible solutions of Eq. (36) exists. By use of generalized Lie derivatives and a classification of all such solutions by differential operators in two variables, Miller (1968, Chap. 8) has shown that only generalized forms of the angular momentum operators are important in special function theory. We therefore write

$$J^3 = \frac{\partial}{\partial y};\ J^\pm = e^{\pm y}\left[\pm\frac{\partial}{\partial x} - k(x)\frac{\partial}{\partial y} + j(x)\right];\ \text{and}\ E = \mu. \tag{37}$$

In Eq. (37), μ is a complex constant; the functions $k(x)$ and $j(x)$ are to be determined. The equations in Eq. (37) satisfy all the commutation conditions for the operators in Eq. (36), except $[J^+,J^-] = 2aJ^3 - bE$, which is satisfied when $k(x)$ and $j(x)$ are solutions of the differential equations

$$\frac{dk(x)}{dx} + k(x)^2 = -a^2\ \text{and}\quad \frac{dj(x)}{dx} + k(x)j(x) = -\frac{d\mu}{2}. \tag{38}$$

The connection of the group-theoretical analysis with the Infeld–Hull factorization method is related to finding the various solutions of the equations in Eq. (38); these various solutions will now be summarized.

$\mathcal{G}(1,0)$ yields

Type A: $k(x) = \cot(x + p)$ and $j(x) = \dfrac{q}{\sin(x + p)}$;

and

Type B: $k(x) = i$ and $j(x) = qe^{-ix}$.

$\mathcal{G}(0,1)$ yields

Type C′: $k(x) = \dfrac{1}{x + p}$ and $j(x) = -\dfrac{\mu(x + p)}{4} + \dfrac{q}{x + p}$;

and

Type D′: $k(x) \equiv 0$ and $j(x) = -\dfrac{\mu x}{2} + q$.

$\mathcal{G}(0,0)$ yields

Type C″: $k(x) = \dfrac{1}{x + p}$ and $j(x) = \dfrac{q}{x + p}$;

and

Type D″: $k(x) \equiv 0$ and $j(x) = q$.

The quantities p and q are complex constants, and $i = \sqrt{-1}$. In the Infeld–Hull notation, Types C′ and C″ are combined and called Type C, and Types D′ and D″ are combined to form Type D. The six-dimensional complex Lie algebra $\mathcal{F}_6$, with generators $\mathcal{P}^\pm$, $\mathcal{P}^3$, $\mathcal{J}^\pm$, and $\mathcal{J}^3$, is defined by appropriate commutation relations for these generators. Because of the difficulty involved in computing matrix elements in the representation theory of $\mathcal{F}_6$, the task of obtaining all of the special-function identities implied by $\mathcal{F}_6$ is incomplete. Some results are obtained by noting that the elements $\mathcal{J}^{\pm}$ and $\mathcal{J}^3$ generate a subalgebra of $\mathcal{F}_6$ that is isomorphic to $sl(2)$, and the elements $\mathcal{P}^{\pm}$ and $\mathcal{P}^3$ generate a three-dimensional abelian subalgebra of $\mathcal{F}_6$. Type A and B operators forming a realization of $sl(2)$ can be extended to Type E and F operators, respectively, forming a realization of $\mathcal{F}_6$ (Miller, 1968, Chap. 6). The connection of these eight types of solutions of Eq. (32) with special functions is now summarized.

$\mathcal{G}(1,0)$: Type A solutions are related to hypergeometric functions, and Type B solutions are related to confluent hypergeometric functions and generalized associated Laguerre functions.

$\mathcal{G}(0,1)$: Type C′ solutions are closely related to confluent hypergeometric functions, Laguerre and associated Laguerre functions. Type D′ solutions are related to parabolic cylinder functions and Hermite polynomials.

$\mathcal{G}(0,0)$: Type C″ solutions are related to Bessel functions, and Type D″ solutions are related to simple transcendental functions, $e^{\pm i\omega x}$.

$\mathcal{F}_6$: Type E solutions are related to hypergeometric functions. Types A and E solutions have different recurrence relations and the same eigenfunctions. Type F solutions are related to confluent hypergeometric functions. Types B and F solutions have different recurrence relations and the same eigenfunctions.

2. THE HYPERGEOMETRIC FUNCTION, $_2F_1(a,b,c;z)$

2.1 Properties of the Hypergeometric Differential Equation

Important members of a large subset of special functions are related to a class of functions called hypergeometric functions, which are solutions of the hypergeometric differential equation (also known as Gauss's differential equation). The hypergeometric differential equation has three regular singular points, and it can be shown that any second-order ordinary linear differential equation with three regular singular points can be transformed (reduced) to the hypergeometric differential equation form. The solutions of many physical problems involve special functions that result from solving second-order ordinary linear differential equations with regular singular points. It is, therefore, natural to expect a connection among hypergeometric functions and certain special functions. The hypergeometric differential equation has the form

$$z(1-z)\frac{d^2w}{dz^2} + [c-(a+b+1)z]\frac{dw}{dz} - abw = 0. \tag{39}$$

Note that Eq. (39) has regular singular points at $z = 0, 1, \infty$. In Eq. (39), parameters a, b, and c are arbitrary complex constants. The hypergeometric differential equation can be solved by use of the Frobenius–Fuchs power series method (see, e.g., ANALYTIC METHODS),

$$w = \sum_{\lambda=0}^{\infty} a_\lambda z^{\lambda+k}, \text{ where } a_0 \neq 0.$$

At the three regular singular points, the respective solutions of the indicial equations are, at $z = 0$: $k = 0$ and $1 - c$; at $z = 1$: $k = 0$ and $c - a - b$; and at $z = \infty$: $k = a$ and b. In general, the solutions of Eq. (39) are the various forms of the Gauss hypergeometric series; they are $[w(z) = {}_2F_1(a,b,c;z) = F(a,b,c;z)]$

$$_2F_1(a,b,c;z) = \sum_{n=0}^{\infty} \frac{(a)_n(b)_n}{n!(c)_n} z_n. \tag{40}$$

The factorial function in Eq. (40) is defined by

$$\begin{aligned}(\lambda)_n &= \prod_{k=1}^{n} (\lambda + k - 1)\\ &= \lambda(\lambda+1)(\lambda+2)\ldots(\lambda+n-1)\\ &= \frac{\Gamma(\lambda+n)}{\Gamma(\lambda)}\end{aligned} \tag{41}$$

for $\lambda = a$, b, and c, respectively. This notation for the factorial function is called a Pochhammer symbol. The notation $_2F_1$ means that there are two factorial functions in the numerator of the series and one factorial function in the denominator of the series in Eq. (40). The gamma function $\Gamma(\lambda)$ is defined in Sec. 5.2.

For convenience, we will write $F(a,b,c;z)$

for ${}_2F_1(a,b,c;z)$ since the three parameters in the parentheses are sufficient to avoid confusion with the notation for the confluent hypergeometric function. Originally, the notation ${}_2F_1(a,b;c;z)$ was used to represent the hypergeometric function. One, however, finds a variety of combinations of commas and/or semicolons used in the literature to represent the hypergeometric function. We will use a comma to separate constants and a semicolon to separate the variable from the constants.

The hypergeometric series $F(-m,b,-n;z)$ is not defined if $n < m$. The hypergeometric series converges if $|z| < 1$ and diverges if $|z| > 1$. For $z = 1$, the series converges if $c > a + b$, and it converges for $z = -1$ if $c > a + b - 1$. The hypergeometric series becomes a polynomial of degree n in z when a or b equals a negative integer.

Note that $F(a,b,c;0) = 1$ and $F(a,b,c;z) = F(b,a,c;z)$. Also, note that many elementary transcendental functions may be expressed in terms of a hypergeometric series; two examples are $\ln(1 + z) = zF(1,1,2;-z)$ and $(1 + z)^a = F(-a,b,b;-z)$. The geometric series is a special case of the hypergeometric series since

$$F(1,1,1;z) = \sum_{n=0}^{\infty} z^n.$$

The numerous properties of $F(a,b,c;z)$ summarized in this article as well as in many other places were developed by Euler and Gauss.

2.2 Properties of $F(a,b,c;z)$

If none of the numbers c, $c - a - b$, or $a - b$ equals an integer, then two linearly independent solutions of the hypergeometric differential equation exist, and each of the six solutions (two at each of three singular points) may be written in four equivalent forms. These 24 forms are referred to as Kummer's 24 solutions of the Gauss hypergeometric differential equation. One of these forms in each case is as follows:

$$w_1(0) = F(a,b,c;z),$$

$$w_2(0) = z^{1-c}F(a - c + 1, b - c + 1, 2 - c; z),$$

$$w_1(1) = F(a, b, a + b + 1 - c; 1 - z),$$

$$w_2(1) = (1 - z)^{c-a-b} \times F(c - b, c - a, c - a - b + 1; 1 - z),$$

$$w_1(\infty) = z^{-a}F(a, a - c + 1, a - b + 1; z^{-1}),$$

and

$$w_2(\infty) = z^{-b}F(b, b - c + 1, b - a + 1; z^{-1}).$$

The functions $F(a \pm 1, b, c; z)$, $F(a, b \pm 1, c; z)$, and $F(a, b, c \pm 1; z)$ are said to be contiguous to $F(a,b,c;z)$. Numerous relations between $F(a,b,c;z)$ and any two contiguous functions, of a form similar to

$$(c - a)F(a - 1, b, c; z) + (2a - c - az + bz) \times F(a,b,c;z) + a(z - 1)F(a + 1, b, c; z) = 0,$$

were developed by Gauss.

When $|z| < 1$, $F(a,b,c;z)$ is analytic, and $F(a,b,c;z)$ has a branch point at $z = 1$ (see Whitaker and Watson, 1947, Sec. 14.53); if a cut is made from 1 to infinity along the real axis, $F(a,b,c;z)$ is analytic throughout the cut plane. Formulas for $F(a,b,c;x)$ for $z = x + iy$ may be obtained from those involving $F(a,b,c;z)$ by use of the following replacements in the cut interval $(-1,1)$: $z - 1$ by $(1 - x)e^{\pm i\pi}$, $z^2 - 1$ by $(1 - x^2)e^{\pm i\pi}$, and $z + 1$ by $x + 1$.

The following differentiation and integration relations are valid for ${}_2F_1$.

A differentiation relation for $F(a,b,c;z)$:

$$\frac{d^nF(a,b,c;z)}{dz^n} = \frac{(a)_n(b)_n}{(c)_n} \times F(a + n, b + n, c + n; z).$$

Fundamental integral relation: The form of the fundamental integral relation for the hypergeometric function is

$$F(a,b,c;z) = \frac{\Gamma(c)}{\Gamma(b)\Gamma(c - b)} \times \int_0^1 t^{b-1}(1 - t)^{c-b-1}(1 - tz)^{-a}dt$$

$$\text{for } \mathrm{Re}(c) > \mathrm{Re}(b) > 0.$$

Solutions of the hypergeometric differential equation that are orthogonal polynomials are of particular interest in this article, and polynomial solutions occur when a or b is a negative integer. Examples of the connections of $F(a,b,c;x)$ with some special polynomials of interest are as follows:

$$F(-n,n,\tfrac{1}{2};x) = T_n(1-2x)\text{—Chebyshev;}$$

$$F(-n,n+1,1;x) = P_n(1-2x)\text{—Legendre;}$$

$$F(-n,n+2\alpha,\alpha+\tfrac{1}{2};x) = \frac{n!}{(2\alpha)_n}C_n^{(\alpha)}(1-2x)\text{—Gegenbauer,}$$

and

$$F(-n,\alpha+1+\beta+n,\alpha+1;x) = \frac{n!}{(\alpha+1)_n}P_n^{(\alpha,\beta)}(1-2x)\text{—Jacobi.}$$

The Gegenbauer (also known as ultraspherical), Legendre and associated Legendre, and Chebyshev polynomials are special cases of the Jacobi polynomial (sometimes called hypergeometric polynomial). Chebyshev (Tschebyscheff, Tchebichef, and Tchebicheff are other spellings found in the literature) polynomials involve solutions of separated equations in spherical, parabolic, and prolate and oblate spheroidal coordinates. Chebyshev polynomials converge rapidly and have the special property that $\mathrm{Max}T_n(x) = +1$ and $\mathrm{Min}T_n(x) = -1$; because of this property, Chebyshev polynomials are useful in numerical analysis. Gegenbauer functions result from separated equations in circular cylinder and spherical coordinates with two regular singular points at ± 1 rather than at 0 and 1.

We now summarize some of the basic properties of the solutions of the Jacobi differential equation (see Table 1 in Sec. 1.1.) and express these solutions in terms of ${}_2F_1$. The solutions of the Jacobi differential equation may be written as

$$y = c_1P_n^{(\alpha,\beta)}(x) + c_2Q_n^{(\alpha,\beta)}(x).$$

The quantity $P_n^{(\alpha,\beta)}(x)$ is a polynomial and is called Jacobi polynomial of the first kind. The quantity $Q_n^{(\alpha,\beta)}(x)$ is not a polynomial and is called Jacobi function of the second kind. In terms of hypergeometric functions, we write

$$P_n^{(\alpha,\beta)}(x) = \frac{(\alpha+1)_n}{n!} \times F\left(-n, n+\alpha+\beta+1, \alpha+1; \frac{1-x}{2}\right)$$

and

$$Q_n^{(\alpha,\beta)}(x) = \frac{C(\alpha,\beta)}{(x-1)^{n+\alpha+1}(x+1)^{\beta}} \times F\left(n+1, n+\alpha+1, 2n+\alpha+\beta+2; \frac{2}{1-x}\right).$$

The symbol $C(\alpha,\beta)$ in the above equation represents the quantity

$$C(\alpha,\beta) = \frac{2^{n+\alpha+\beta}\Gamma(n+\alpha+1)\Gamma(n+\beta+1)}{\Gamma(2n+\alpha+\beta+2)(x-1)^{n+\alpha+1}}.$$

The standardization for the Jacobi polynomial is given by

$$P_n^{(\alpha,\beta)}(1) = (\alpha+1)_n/n!.$$

Rodrigues's formula and the generating function for the Jacobi polynomial are given in Tables 4 and 5, respectively. The form of the recursion formula for the Jacobi polynomial is

$$\begin{aligned}&2(n+1)(n+\alpha+\beta+1)(2n+\alpha+\beta)P_{n+1}^{(\alpha,\beta)}(x)\\&= (2n+\alpha+\beta+1)\\&\quad\times[(2n+\alpha+\beta)(2n+\alpha+\beta)x+\alpha^2-\beta^2]\\&\quad\times P_n^{(\alpha,\beta)}(x) - 2(n+\alpha)(n+\beta)\\&\quad\times(2n+\alpha+\beta+2)P_{n-1}^{(\alpha,\beta)}(x).\end{aligned}$$

The integral representation of the Jacobi polynomial may be written as

$$P_n^{(\alpha,\beta)}(x) = \frac{1}{2\pi i}\oint_c \frac{1}{2}\left(\frac{t^2-1}{t-x}\right)^n \times\left(\frac{1-t}{1-x}\right)^{\alpha}\left(\frac{1+t}{1+x}\right)^{\beta}dt;\ x \neq \pm 1. \tag{42}$$

The contour in Eq. (42) is a simple closed contour in a positive sense around $t = x$; the points $t = \pm 1$ are outside of the contour. In Eq. (42), the quantities raised to the α and β power are defined to be unity when $t = x$. Graphical illustrations of Jacobi, Chebyshev, and Gegenbauer polynomials are given in Figs. 1–3.

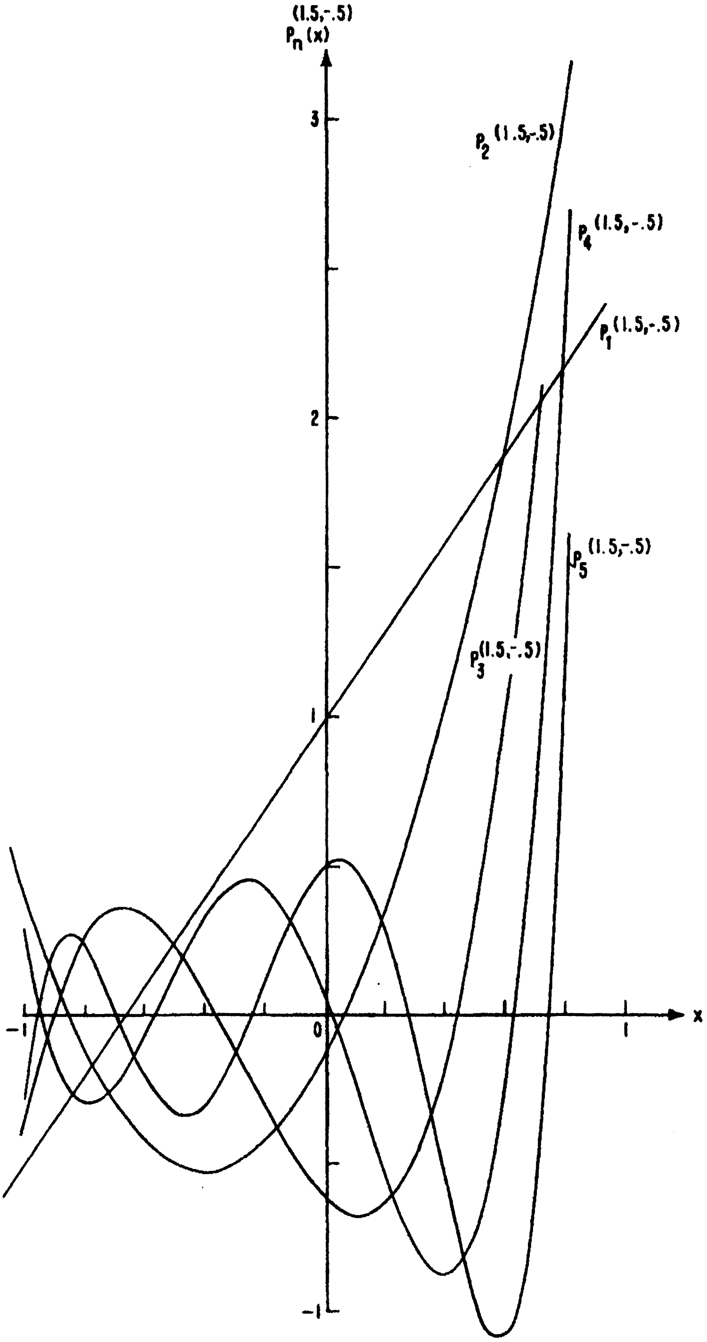

FIG. 1. Jacobi polynomials, $P_n^{(1.5,-0.5)}(x)$ (Abramowitz and Stegun, 1964).

2.3 Helmholtz's Differential Equation in Spherical Coordinates

The Laplacian operator in spherical coordinates (r,θ,ϕ) has the form

$$\nabla^2 = \nabla_r^2 + \frac{1}{r^2}\nabla_{\theta,\phi}^2.$$

The radial and angular parts of the Laplacian are given respectively by

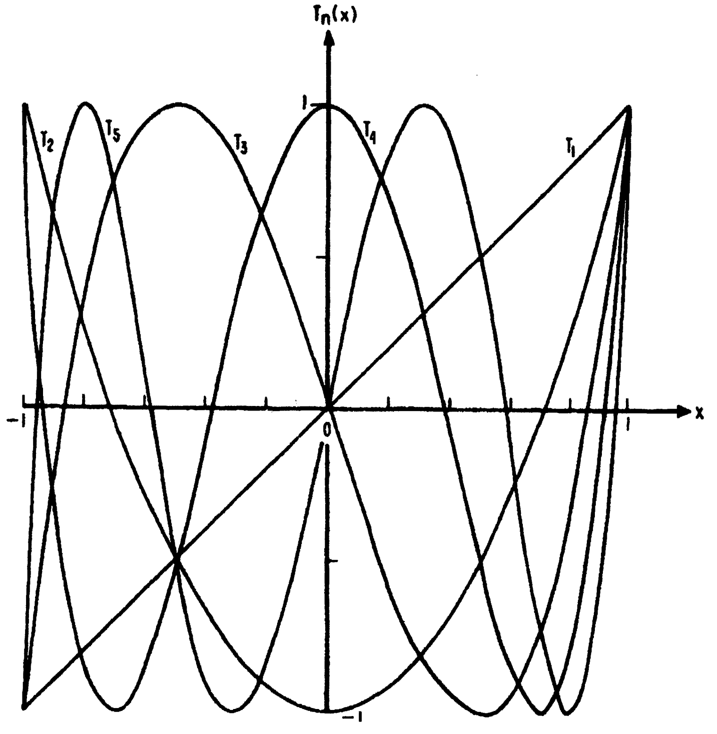

FIG. 2. Chebyshev polynomials, $T_n(x)$ (Abramowitz and Stegun, 1964).

$$\nabla_r^2 = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) \tag{43}$$

and

$$\nabla_{\theta,\phi}^2 = \frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}\right) + \frac{1}{\sin^2\theta}\frac{\partial^2}{\partial\phi^2}. \tag{44}$$

The Helmholtz differential equation in spherical coordinates has the form

$$\left\{\nabla_r^2 + \frac{1}{r^2}\nabla_{\theta,\phi}^2\right\}u + k^2u = 0. \tag{45}$$

The solution of Eq. (45) involves symmetry-type information in terms of the angular parts θ and ϕ, which are common to all problems with spherical symmetry, and dynamical information in terms of the radial part, which characterizes the particular problem under investigation. In this connection, the Helmholtz differential equation reduces to the Laplace differential equation for $k^2 = 0$, to the time-independent heat-conduction (diffusion) or time-independent mechanical wave differential equations for $k^2 =$ constant, and to the time-independent Schrödinger wave equation for $k^2 = (2m/\hbar^2)\{E - V(r)\}$. On separating the angular parts from the radial part in Eq. (45) for $u(r,\theta,\phi) = R(r)Y(\theta,\phi)$, the corresponding differential equations for $R(r)$ and $Y(\theta,\phi)$ with separation constant λ are

$$\nabla_r^2 R(r) + \left\{k^2 - \frac{\lambda}{r^2}\right\}R(r) = 0 \tag{46}$$

and

$$\nabla_{\phi,\phi}^2 Y(\theta,\phi) + \lambda Y(\theta,\phi) = 0. \tag{47}$$

Note that the general solutions of Eq. (47) are independent of the specific problem under investigation but are common to all problems that involve the Laplacian operator in spherical coordinates. The solutions of Eq. (47) with separation constant $-m^2$ are called spherical harmonics (also known as surface harmonics of the first kind), $Y_\lambda^m(\theta,\phi)$. For square integrable solutions, a replacement of the form $\lambda = n(n + 1)$ is required. Tesseral harmonics is the name given to $Y_n^m(\theta,\phi)$ when $m < n$, and the term sectoral harmon-

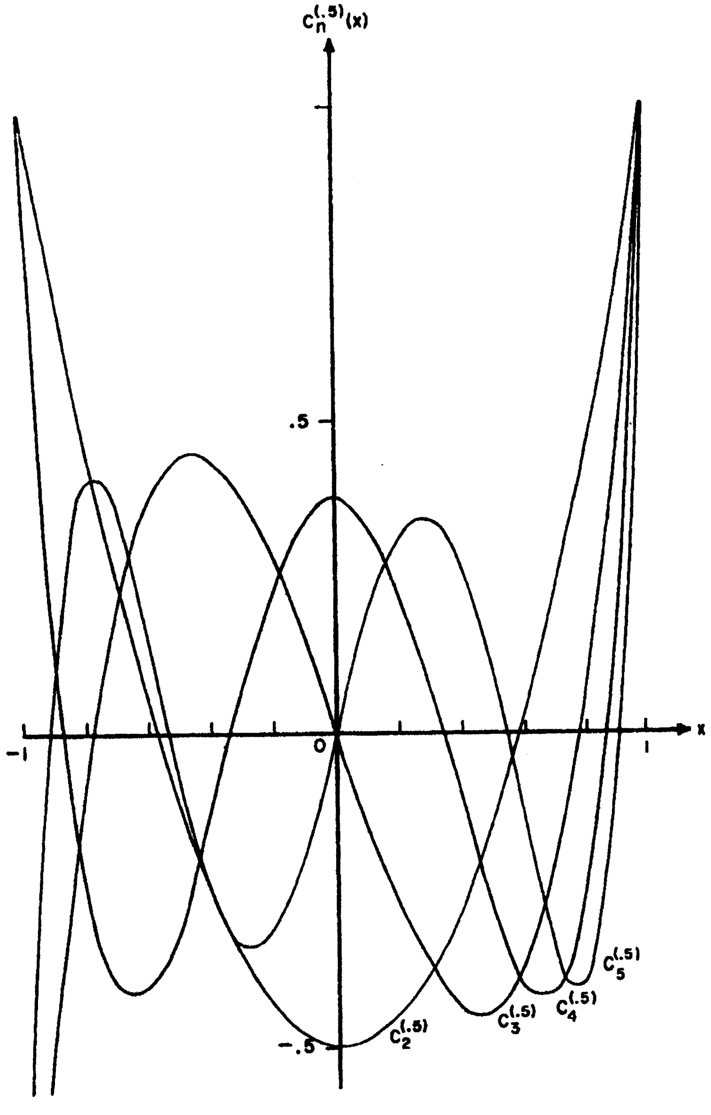

FIG. 3. Gegenbauer polynomials, $C_n^{(0.5)}(x)$ (Abramowitz and Stegun, 1964).

ics is used when $m = n$. Tesseral and sectoral harmonics may be written as $C_n e^{im\phi} P_n^m(\cos\theta)$, where $P_n^m(\cos\theta)$ are associated Legendre functions of the first kind. When $m = 0$, the spherical functions are called Legendre polynomials of the first kind (also known as zonal harmonics and Legendre coefficients).

On substituting Eqs. (43) and (44) into Eqs. (46) and (47), respectively, and separating the variables in Eq. (47) $[Y(\theta,\phi) = \Theta(\theta)\Phi(\phi)$ with separation constant $-m^2]$, we obtain the following three ordinary differential equations: radial equation,

$$\frac{1}{r^2}\frac{d}{dr}\left(r^2\frac{dR}{dr}\right) + \left[k^2 - \frac{n(n+1)}{r^2}\right]R = 0; \qquad (48)$$

theta equation,

$$\frac{1}{\sin\theta}\frac{d}{d\theta}\left(\sin\theta\frac{d\Theta}{d\theta}\right) + \left[n(n+1) - \frac{m^2}{\sin^2\theta}\right]\Theta = 0; \qquad (49)$$

and azimuthal equation,

$$\frac{d^2\Phi}{d\phi^2} + m^2\Phi = 0. \qquad (50)$$

The general solution of the azimuthal equation is $\Phi = c_1 e^{im\phi} + c_2 e^{-im\phi}$. In solving physical problems, the requirement that $\Phi(\phi)$ be a single-valued function is imposed. That is to say, we require that $\Phi(\phi) = \Phi(\phi + 2\pi)$, which leads to the following acceptable values for m: $m = 0, \pm 1, \pm 2, \ldots$; the solution may be written in the form $\Phi(\phi) = Ae^{im\phi}$. In quantum mechanics, the single-valued function requirement is referred to as Born's periodic boundary condition, and m is the magnetic quantum number.

2.4 Associated Legendre Functions and Legendre Polynomials

Solutions of the theta equation, Eq. (49), involve the Legendre polynomials and associated Legendre functions. The traditional treatment of the theta equation involves introducing a new independent variable x by use of the transformation $x = \cos\theta$; here x is not the usual Cartesian coordinate. The associated Legendre differential equation results from this transformation,

$$(1 - x^2)\frac{d^2\Theta}{dx^2} - 2x\frac{d\Theta}{dx} + \left\{n(n + 1) - \frac{m^2}{1 - x^2}\right\}\Theta = 0. \tag{51}$$

The Legendre differential equation is the result when m equals zero in Eq. (51); it is given by

$$(1 - x^2)\frac{d^2\Theta}{dx^2} - 2x\frac{d\Theta}{dx} + n(n + 1)\Theta = 0. \tag{52}$$

The Legendre and associated Legendre differential equations can be solved by use of the Frobenius–Fuchs power series method, factorization method, and hypergeometric functions. The two linearly independent solutions of the associated Legendre differential equation are

$$\Theta_n^m(x) = AP_n^m(x) + BQ_n^m(x).$$

The quantities $P_n^m(x)$ and $Q_n^m(x)$ are associated Legendre functions of the first and second kind, respectively; they are related to the hypergeometric functions as follows:

$$P_n^m(z) = \frac{1}{\Gamma(1 - m)}\left(\frac{z + 1}{z - 1}\right)^{m/2} \times F\left(-n, n + 1, 1 - m; \frac{1 - z}{2}\right), \quad |1 - z| < 2,$$

and

$$Q_n^m(z) = C^{nm} \times F\left(1 + \frac{n}{2} + \frac{m}{2}, \frac{1}{2} + \frac{n}{2} + \frac{m}{2}, n + \frac{3}{2}; \frac{1}{z^2}\right); \quad |z| > 1.$$

The factor C^{nm} in the above equation is given by

$$C^{nm} = e^{im\pi}2^{-n-1}\pi^{1/2} \times \frac{\Gamma(n + m + 1)}{\Gamma(n + \frac{3}{2})} z^{-n-m-1}(z^2 - 1)^{m/2}.$$

Also, the associated Legendre functions $P_n^m(x)$ result when the Legendre polynomials are differentiated m times. That is to say,

$$P_n^m(x) = (1 - x^2)^{m/2}\frac{d^m P_n(x)}{dx^m}.$$

The orthogonality relation, recurrence relation, and Rodrigues formula for the associated Legendre functions are given in Tables 2, 3, and 4, respectively. Graphical illustrations of associated Legendre functions are given in Fig. 4.

The Legendre polynomials of the first kind, $P_n(x)$, and Legendre functions of the second kind, $Q_n(x)$, are related to the Jacobi functions as follows:

$$P_n^{(0,0)}(x) = P_n(x) \text{ and } Q_n^{(0,0)}(x) = Q_n(x).$$

In series form, the Legendre polynomials may be written as

$$\Theta_n(x) \equiv P_n(x) = \sum_{r=0}^{N}\frac{(-1)^r(2n - 2r)!x^{n-2r}}{2^n r!(n - r)!(n - 2r)!}.$$

In the above sum, $N = n/2$ for n even and $N = (n - 1)/2$ for n odd. The general solution of the Legendre differential equation has the form $\Theta_n(x) = C_1P_n(x) + C_2Q_n(x)$; Legendre functions of the second kind, $Q_n(x)$, are not polynomials. The orthogonality relation, recurrence relation, Rodrigues formula, and

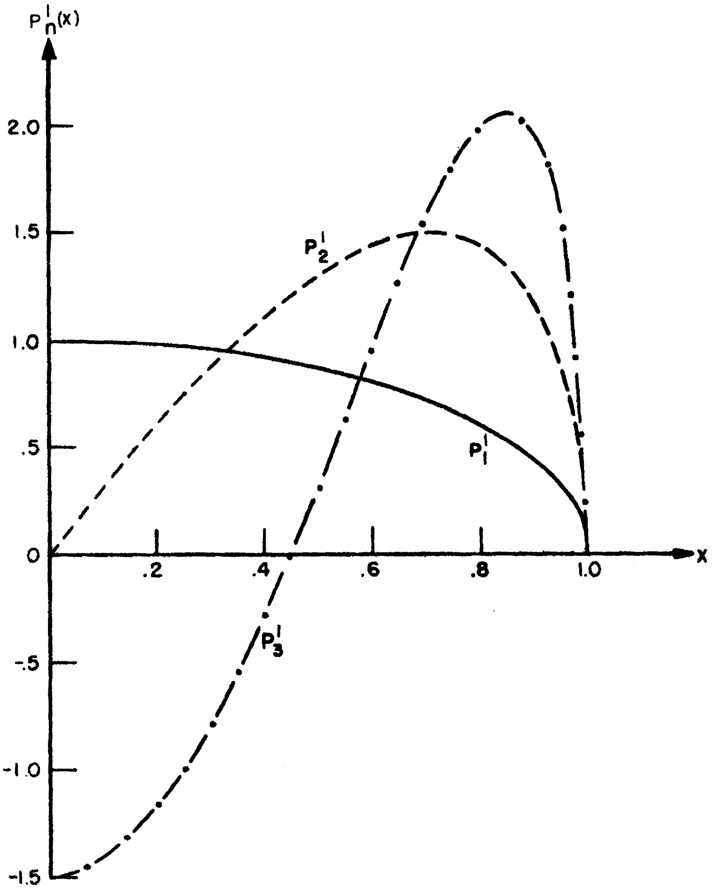

FIG. 4. Associated Legendre functions, $P_n^1(x)$ (Abramowitz and Stegun, 1964).

generating function for the Legendre polynomials are given in Tables 2, 3, 4, and 5, respectively.

The Legendre functions of the second kind, $Q_n(x)$, satisfy a recursion relation of the same form as the one for $P_n(x)$. Graphical illustrations of Legendre polynomials are given in Figs. 5–7, and Legendre functions of the second kind are illustrated in Figs. 8 and 9.

2.5 The Radial Equation

The radial equation, Eq. (48), characterizes the dynamical information of specific problems or classes of problems. The Laplace equation results when $k^2 = 0$; for this case, the solution characterizes such steady-state problems as potentials in electrostatics and temperatures in heat conduction. The time-independent Schrodinger equation results when $k^2 = 2\mu[E - V(r)]/\hbar^2$ for a class of two-body central-force problems; the reduced mass of such a system is given by $\mu = m_1m_2/(m_1 + m_2)$, where m_1 and m_2 are the masses of constituent particles one and two, respectively.

Example 3: Calculate the steady-state temperature distribution $T(r,\theta)$ within a sphere of radius b when the temperature over the surface of the sphere is independent of ϕ. That is to say, $T(b,\theta) = f(\theta)$, where $f(\theta)$ is a known function.

Solution: The general solution of Laplace's differential equation of this problem is independent of ϕ (circular symmetry) and has the form $T(r,\theta) = R(r)\Theta(\theta)$. The radial and theta equations for this problem reduce to

$$r^2R'' + 2rR' - n(n + 1)R = 0$$

and

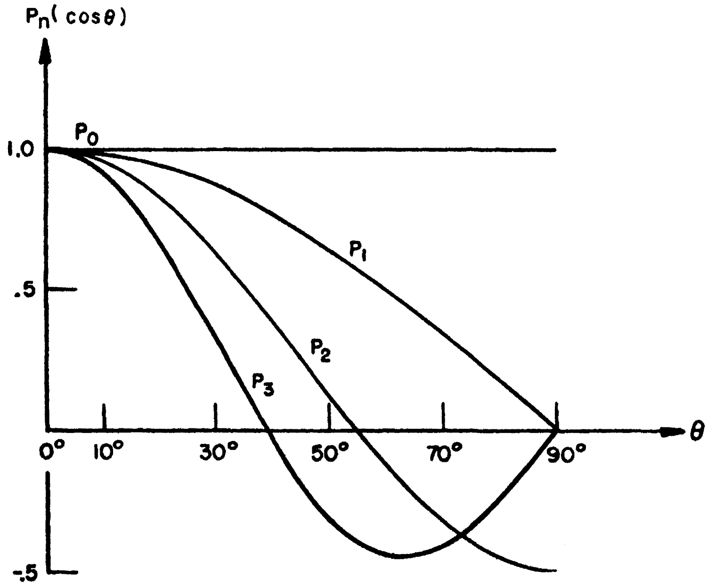

FIG. 5. Legendre polynomials, $P_n(\cos\theta)$ (Abramowitz and Stegun, 1964).

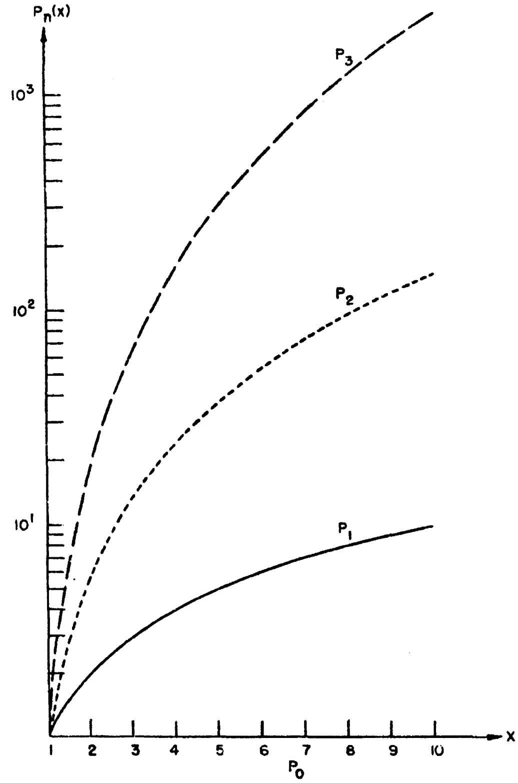

FIG. 6. Legendre polynomials, $P_n(x)$ (Abramowitz and Stegun, 1964).

$$\sin\theta\Theta'' + \cos\theta\Theta' + n(n + 1)\sin\theta\Theta = 0.$$

The general solution of the radial equation is

$$R(r) = Ar^n + B/r^{n+1}.$$

Constants A and B are arbitrary, and the general solution of the theta equation (the Legendre differential equation) is $P_n(\cos\theta)$. We set the coefficient B equal to zero since a solution finite at every point within the sphere is required. The general solution of the problem is a superposition of products of radial and theta solutions; we write

$$T(r,\theta) = \sum_{n=0}^{\infty} A_n r^n P_n(\cos\theta).$$

The coefficients A_n are obtained by use of the boundary condition $T(b,\theta) = f(\theta)$ and the orthogonality relations for the Legendre polynomials. The specific form for $f(\theta)$ must be given if the specific values for A_n are required.

3. THE CONFLUENT HYPERGEOMETRIC FUNCTION, ${}_1F_1(a,c;x)$

The confluent hypergeometric differential equation (also called the Kummer differential equation) has the form

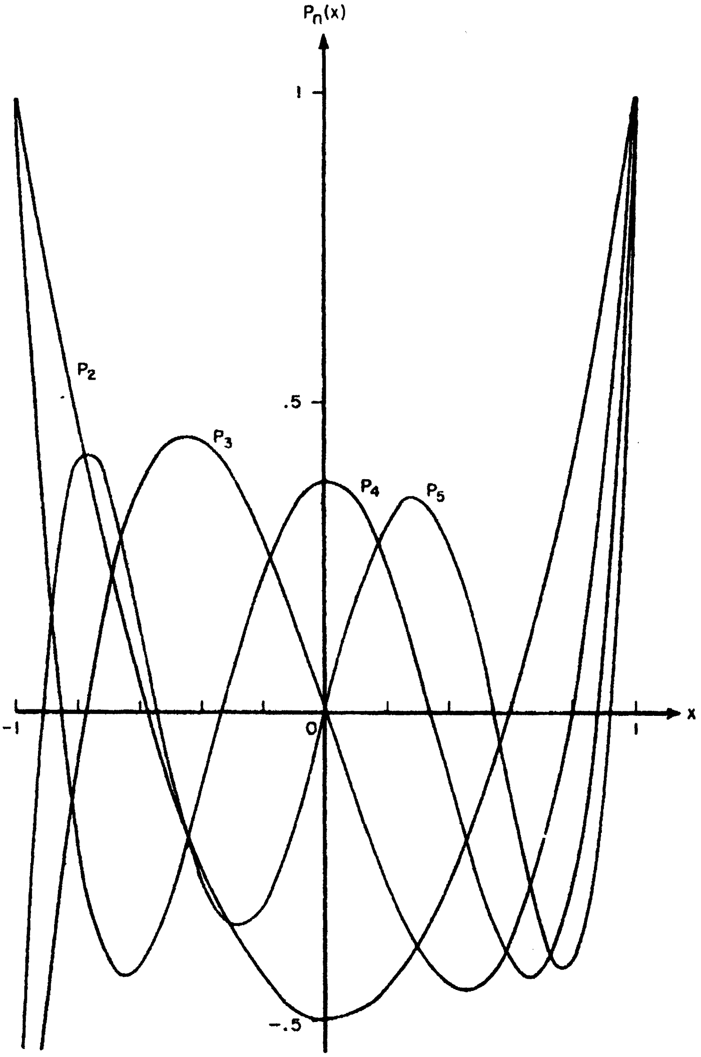

FIG. 7. Legendre polynomials, $P_n(x)$ (Abramowitz and Stegun, 1964).

$$xy'' + (c - x)y' - ay = 0. \tag{53}$$

Equation (53) is obtained from the hypergeometric differential equation by substituting $z = bx$ and letting b approach infinity; this substitution causes a merging or confluence of the two upper singular points. In the confluent hypergeometric differential equation, there is a regular singularity at $x = 0$ and an irregular singularity at $x = \infty$. By use of the power-series method in the neighborhood of $x = 0$, we find that one solution of Eq. (53) has the form (confluent hypergeometric functions or Kummer functions)

$$y(x) \equiv {}_1F_1(a,c;x) = 1 + \frac{ax}{c} + \frac{a(a+1)x}{2!c(c+1)} + \dots$$
$$= \sum_{n=0}^{\infty} \frac{(a)_n x^n}{(c)_n}.$$

The confluent hypergeometric series converges for all values of x.

The Bessel functions and modified Bessel functions in terms of ${}_1F_1$ are respectively given by

$$J_n(x) = \frac{e^{-ix}}{n!}\left(\frac{x}{2}\right)^n {}_1F_1(n + \tfrac{1}{2}, 2n + 1; 2ix)$$

and

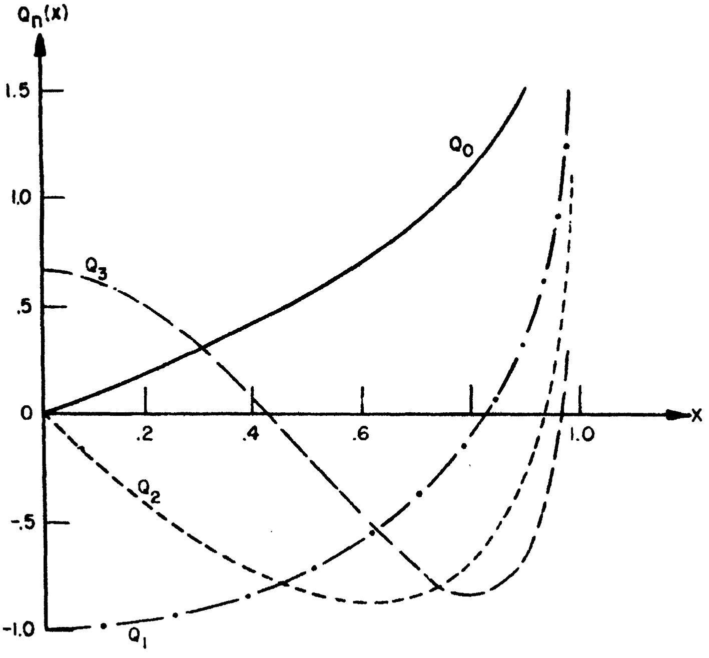

FIG. 8. Legendre functions of the second kind, $Q_n(x)$ (Abramowitz and Stegun, 1964).

$$I_n(x) = \frac{e^{-x}}{n!}\left(\frac{x}{n!}\right)^n {}_1F_1(n + \tfrac{1}{2}, 2n + 1; 2x).$$

The Laguerre and associated Laguerre polynomials in terms of ${}_1F_1$ are respectively given by

$$L_n(x) = {}_1F_1(-n,1;x)$$

and

$$L_n^m(x) = \frac{(n + m)!}{n!m!}\, {}_1F_1(-n, m + 1; x).$$

Hermite polynomials in terms of ${}_1F_1$ have the form

$$H_{2n}(x) = (-1)^n \frac{(2n)!}{n!}\, {}_1F_1(-n, \tfrac{1}{2}; x^2).$$

The error function and complementary error function are respectively defined by

$$\operatorname{erf}(x) = \frac{2}{\sqrt{\pi}}\int_0^x e^{-t^2}dt, \text{ where } \operatorname{erf}(\infty) = 1$$

and

$$\operatorname{erfc}(x) = 1 - \operatorname{erf}(x) = \frac{2}{\sqrt{\pi}}\int_x^\infty e^{-t^2}dt.$$

The Hermite polynomials may be obtained from derivatives of the error function as follows:

$$\frac{d^{n+1}\operatorname{erf}(x)}{dx^{n+1}} = (-1)^n \frac{2}{\sqrt{\pi}} H_n(x)e^{-x^2}.$$

In addition, the error function is related to the confluent hypergeometric function by use of the following equation:

$$\operatorname{erf}(x) = \frac{2x}{\sqrt{\pi}}\, {}_1F_1(\tfrac{1}{2},\tfrac{3}{2}; -x^2).$$

3.1 More on Hermite Polynomials

The Hermite differential equation,

$$y'' - 2xy' + 2ny = 0 \quad \text{for } n = \text{constant},$$

is a special case of the Sturm–Liouville differential equation and a special case of the confluent hypergeometric differential equation. The polynomial solution $H_n(x)$ of the Hermite differential equation may be ob-

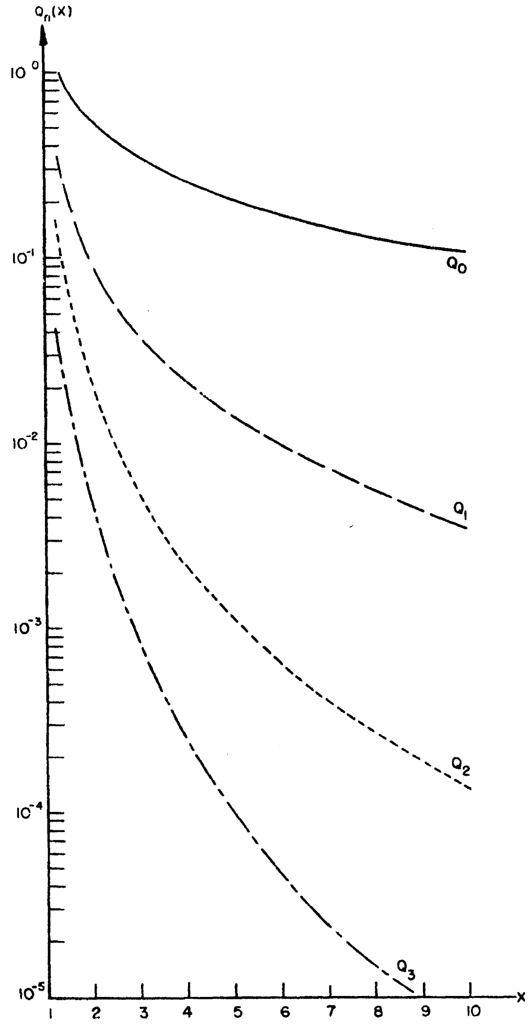

FIG. 9. Legendre functions of the second kind, $Q_n(x)$ (Abramowitz and Stegun, 1964).

tained by use of the Frobenius–Fuchs power-series method,

$$y = \sum_{r=0}^{\infty} a_r x^{k+r}, \text{ where } a_0 \neq 0.$$

For standardization $a_n = 2^n$, the solution has the form

$$y_n \equiv H_n(x) = \sum_{j=0}^{N} \frac{(-1)^j n!(2x)^{n-2j}}{j!(n-2j)!}. \tag{54}$$

Equation (54) is the series form of the Hermite polynomials. In Eq. (54), $N = n/2$ for n even and $N = (n-1)/2$ for n odd. The orthogonality relation, recurrence relation, Rodrigues formula, and generating function for $H_n(x)$ are respectively given in Tables 2, 3, 4, and 5. A representative sketch of $H_n(x)$ is given in Fig. 10.

Example 4: More on the quantum mechanical linear harmonic oscillator.

Solution: The problem of describing the small oscillation of a mass m attached to the end of a spring with force constant k and potential energy $V(x) = kx^2/2$ can be solved exactly in both classical and quantum theory. This system is referred to as a linear harmonic oscillator and is used to represent and analyze more complex physical systems such as vibrations of individual atoms in molecules and in crystals, and classical and quantum theories of radiation. The solution of Schrodinger's wave equation for the linear harmonic oscillator is expressed in terms of Hermite polynomials $H_n(x)$. The equation to be solved is the one-dimensional wave equation for the linear harmonic oscillator, which has the form

$$-\frac{\hbar^2}{2m}\frac{d^2\psi}{dx^2} + \frac{kx^2\psi}{2} = E\psi. \tag{55}$$

Note that Eq. (55) is just the one-dimensional Helmholtz equation for which k^2 equals $2m(E - kx^2/2)/\hbar^2$. Solving a problem in quantum mechanics involves finding the wave functions ψ_n and the corresponding eigenenergies E_n. In dimensionless form, Eq. (55) becomes

$$\begin{aligned} &\frac{d^2\psi}{d\xi^2} + (\lambda - \xi^2)\psi = 0, \\ &\quad \text{where } \xi = \left(\frac{m\omega}{\hbar}\right)^{1/2} x,\ \omega^2 = \frac{k}{m}, \\ &\quad \text{and } \lambda = \frac{2E}{\hbar\omega}. \end{aligned} \tag{56}$$

On substituting $\lambda = 1 + 2n$ into Eq. (56), we obtain the Weber differential equation, and the transformation $\psi = \exp(-\xi^2/2)y(\xi)$ reduces the Weber differential equation to the Hermite differential equation. The transformation equation leading to Hermite's differential equation is motivated by use of the Sommerfeld (1949) polynomial method for solving certain differential equations. According to the Sommerfeld method, the so-

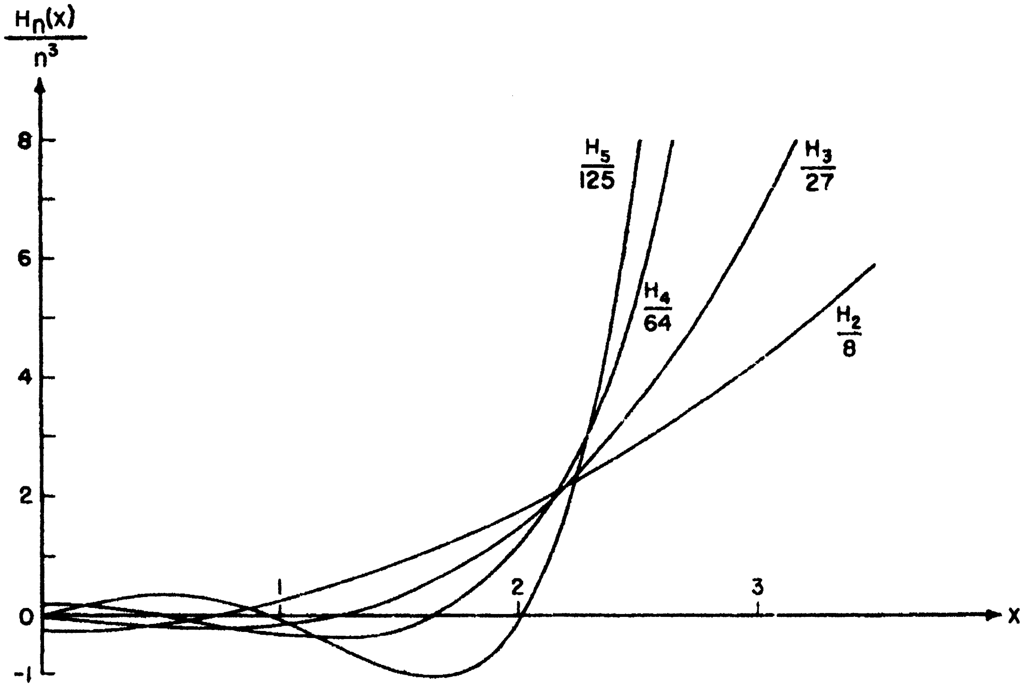

FIG. 10. Hermite polynomials, $H_n(x)/n^3$ (Abramowitz and Stegun, 1964).

lution of Eq. (56) is the product of the physically acceptable asymptotic solution times a polynomial. The resulting asymptotic ($|\xi|$ approaches infinity) differential equation is $\psi'' - \xi^2\psi = 0$, and the physically acceptable solution of this differential equation is given by $\exp(-\xi^2/2)$. In this case, the polynomial part of the solution of Eq. (56) comes from solving Hermite's differential equation. The eigenfunctions and eigenenergy for the linear harmonic oscillator, Eq. (56), are respectively given by

$$\psi_n(\xi) = Ne^{-\xi^2/2}H_n(\xi) \text{ and}$$
$$\lambda_n = 1 + 2n = 2E_n/\hbar\omega \text{ or}$$
$$E_n = \hbar\omega(n + \tfrac{1}{2}).$$

The behavior of $\psi_n(\xi)$ for the first six values of n is illustrated in the sketches in Fig. 11.

3.2 More on the Laguerre and Associated Laguerre Polynomials

The Laguerre differential equation, $xy'' + (1 - x^2)y' + ny = 0$ for n = constant, is a special case of the Sturm–Liouville differential equation as well as a special case of the confluent hypergeometric differential equation; its solution may be obtained by relation to ${}_1F_1$ or by use of the Frobenius–Fuchs power-series method,

$$y(x) = \sum_{\lambda=0}^{\infty} a_\lambda x^{k+\lambda} \text{ for } a_0 \neq 0.$$

The indicial equation in the power-series method has a double root at $k = 0$, and the power-series method yields only one of the two linearly independent solutions of the Laguerre differential equation; this solution is extremely important in mathematical physics. The finite solutions of the Laguerre differential equation, $L_n(x)$, are called Laguerre polynomials. The solution in series form is

$$L_n(x) = \sum_{\lambda=0}^{n} \frac{(-1)^\lambda n! x^\lambda}{(n - \lambda)!(\lambda!)^2};$$
$$a_0 \equiv 1 \text{ (standardization).}$$

The orthogonality and recurrence relations for the Laguerre polynomials are given in Tables 2 and 3, respectively; the generating

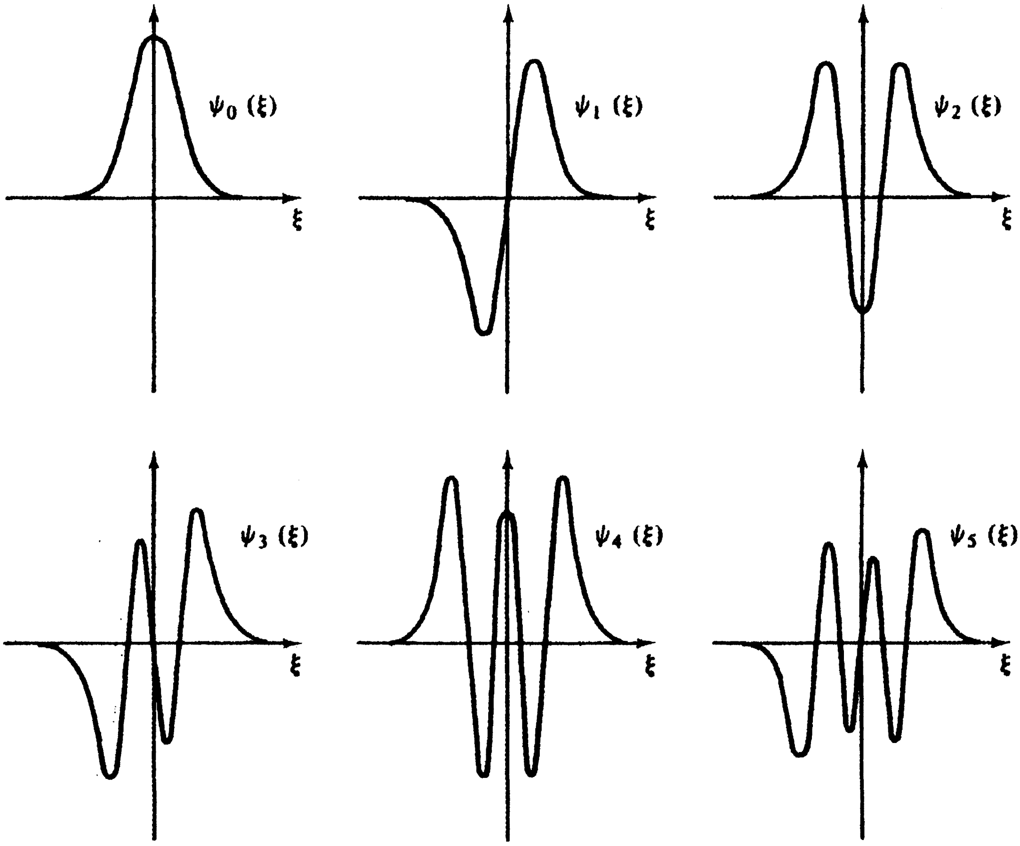

FIG. 11. Linear harmonic oscillator wave functions, $\psi_n(\xi)$.

function and Rodrigues formula are respectively given by

$$\frac{\exp[-xt/(1-t)]}{(1-t)} = \sum_{n=0}^{\infty} \frac{L_n(x)t^n}{n!}$$

and

$$L_n(x) = \frac{1}{n!} e^x \frac{d^n}{dx^n} (x^n e^x).$$

Note that $L_n(0) = 1$, $L_0(x) = 1$, $L_1(x) = 1 - x$, and $L_2(x) = 2 - 4x + x^2$. A sketch of Laguerre polynomials is given in Fig. 12.

Note that the kth derivative of the Laguerre differential equation yields the associated Laguerre differential equation,

$$x \frac{d^2L_n^k(x)}{dx^2} + (k + 1 - x) \frac{dL_n^k(x)}{dx} + (n - k)L_n^k(x) = 0. \qquad (57)$$

In obtaining Eq. (57), the Leibnitz formula, Eq. (16), for finding the kth derivative of a product was used, and we note that the associated Laguerre polynomials $L_n^k(x)$ are related to the Laguerre polynomials by

$$L_n^k(x) = \frac{d^kL_n(x)}{dx^k}.$$

The orthogonality relation, recurrence relation, Rodrigues formula, and generating function for associated Laguerre polynomials are respectively given in Tables 2, 3, 4, and 5.

Example 5, a central-force problem in quantum mechanics.

Solution: The time-independent Schrödinger wave equation is used to study the mechanics of two microscopic particles moving under the influence of a central force (that is to say, the force and potential de-

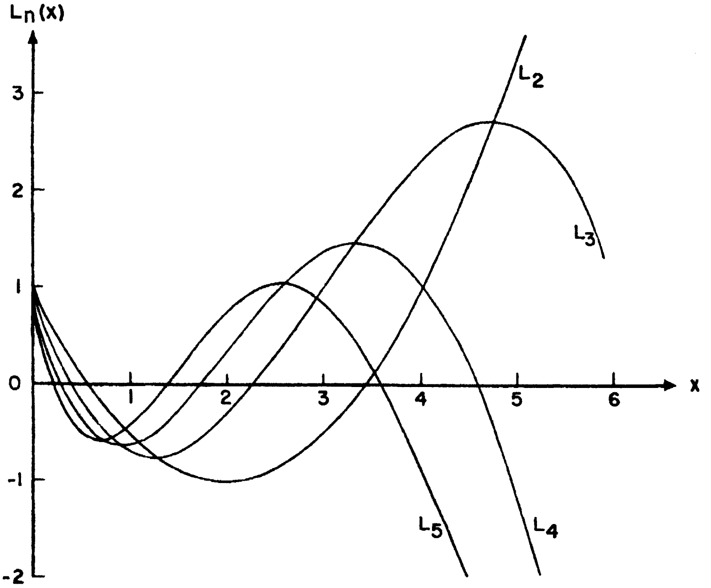

FIG. 12. Laguerre polynomials, $L_n(x)$ (Abramowitz and Stegun, 1964).

pend only on the distance between the two particles). This problem provides the basis for the quantum mechanical treatment of a fundamental class of problems such as the rigid rotator, which is of considerable importance in the study of the spectra of diatomic molecules; the theory of the hydrogen atom; and the nonrelativistic theory of the deuteron. For an attractive inverse-square force law, we substitute $k^2 = 2\mu(E - A/r)/\hbar^2$ into the radial equation; the quantity A is a positive constant. Anticipating use of the well-known solution of the associated Laguerre differential equation, the following substitutions are made in the radial equation for inverse-square force problems:

$$\xi = \beta r,\ \beta^2 \equiv \frac{8\mu|E|}{\hbar^2},\ \text{and}\ \gamma \equiv \frac{2\mu A}{\beta\hbar^2} = \frac{A}{\hbar}\left(\frac{\mu}{2|E|}\right)^{1/2}. \tag{58}$$

By use of the substitutions in Eq. (58), the radial equation, Eq. (48), reduces to

$$\xi\frac{d^2R}{d\xi^2} + 2\frac{dR}{d\xi} + \left\{\gamma - \frac{\xi}{4} - \frac{l(l+1)}{\xi}\right\}R = 0. \tag{59}$$

The symbol l represents the angular momentum quantum number; it is used instead of n in Eq. (48) since n denotes principal quantum number for this problem. Equation (59) is reduced to the associated Laguerre differential equation by use of the transformation

$$R_{nl}(\xi) = \exp(-\xi/2)\xi^l L_{n+1}^{2l+1}(\xi).$$

The desired solution of the equation to be solved, Eq. (59), is a normalization constant times $R_{nl}(\xi)$. A polynomial solution of the associated Laguerre differential equation is obtained when $\gamma = n = l + k + 1$ for $k = 0, 1, 2, \ldots, n - 1$.

Example 6, the hydrogen atom: Obtain the eigenfunction and eigenenergy for the hydrogen atom.

Solution: The hydrogen atom represents a two-body central-force problem in quantum mechanics, where the electron and proton are the two particles under investigation. The Coulomb potential is the central potential for the hydrogen atom. Here, the total energy is negative for bound states, $E < 0$, and the attractive potential energy is given by $V = -e^2/4\pi\epsilon_0 r = -A/r$. The eigenenergy E_n is obtained from Eq. (58); we obtain the usual Bohr result,

$$E_n = -\mu A^2/2\hbar^2 n^2.$$

The corresponding steady-state wave function is the product of solution of the radial part and the angular part, which is $Y_l^m(\sigma,\phi)$ times a normalization constant, C_{nl}; the result is

$$\psi(r,\theta,\phi) = -C_{nl}R_{nl}(\xi)Y_l^m(\theta,\phi). \qquad (60)$$

The eigenfunction solution, Eq. (60), is given in most quantum mechanics books, and the normalization constant is obtained in the usual manner.

4. HELMHOLTZ'S DIFFERENTIAL EQUATION IN CYLINDRICAL COORDINATES

Problems in mathematical physics that involve cylindrical geometry are, in general, simpler to solve in cylindrical coordinates (ρ,ϕ,z) than in Cartesian coordinates. The Helmholtz differential equation in cylindrical coordinates has the form

$$\rho\frac{\partial^2 u}{\partial\rho^2} + \frac{\partial u}{\partial\rho} + \frac{1}{\rho}\frac{\partial^2 u}{\partial\phi^2} + \rho\frac{\partial^2 u}{\partial z^2} + k^2\rho u = 0.$$

By use of the separation-of-variables method for $u(\rho,\phi,z) = P(\rho)\Phi(\phi)Z(z)$ with separation constants $-\lambda^2$ and $-n^2$, the following three ordinary differential equations are obtained:

$$\frac{1}{Z}\frac{d^2 Z}{dz^2} = -\lambda^2$$

with solution $Z(z) = A\cos(\lambda z) + B\sin(\lambda z)$,

$$\frac{1}{\Phi}\frac{d^2\Phi}{d\phi^2} = -n^2$$

with solution $\Phi(\phi) = C\cos(n\phi) + D\sin(n\phi)$, and

$$\xi^2\frac{d^2P}{d\xi^2} + \xi\frac{dP}{d\xi} + (\xi^2 - n^2)P = 0 \text{ for } \xi = \alpha\rho$$
$$\text{and } k^2 - \lambda^2 \equiv \alpha^2. \qquad (61)$$

4.1 Solutions of Bessel's Differential Equation

Equation (61) is Bessel's differential equation, and its solutions are called Bessel (or cylindrical) functions. Bessel's differential equation is solved by use of the power-series method,

$$P(\xi) = \sum_{\lambda=0}^{\infty} a_\lambda \xi^{k+\lambda} \text{ for } a_0 \neq 0.$$

The general solutions of Bessel's differential equation when n is an integer are

$$P(\xi) = AJ_n(\xi) + BN_n(\xi);\ n = \text{integer}.$$

The functions $J_n(\xi)$ and $N_n(\xi)$ are explained in the following sections.

4.2 Bessel Functions of the First Kind

The functions $J_n(\xi)$ are called Bessel functions of the first kind; the series representation, generating function, and recurrence relation for $J_n(\xi)$ are respectively given by

$$J_n(\xi) = \sum_{j=0}^{\infty}\frac{(-1)^j(\xi/2)^{2j+1}}{j!\Gamma(n+j+1)}$$
$$\text{for standardization } a_0 \equiv \frac{1}{2^n\Gamma(n+1)}, \qquad (62)$$

$$\exp\left\{\tfrac{1}{2}\xi\left(t - \frac{1}{t}\right)\right\} = \sum_{n=-\infty}^{\infty} J_n(\xi)t^n,$$

and

$$J_{n-1}(\xi) + J_{n+1}(\xi) = \frac{2n}{\xi}J_n(\xi).$$

Note that $J_{-n}(\xi) = (-1)^n J_n(\xi)$ results from use of Eq. (62). The gamma function Γ is defined in Sec. 5.2. The orthogonality relation for the interval $[0,a]$ may be written in the form

$$\int_0^a J_n\left(\beta_{ni}\frac{\xi}{a}\right)J_n\left(\beta_{nj}\frac{\xi}{a}\right)\xi d\xi = \begin{cases} 0, i \neq j, \\ \dfrac{a^2}{2}[J_{n+1}(\beta_{nj})]^2, \ i = j. \end{cases} \qquad (63)$$

In Eq. (63), $n > -1$, the parameter β_{ni} is the ith zero of J_n, and $0 \leq \xi \leq a$.

The general solutions of Bessel's differential equation when n is not an integer are

$$P(\xi) = CJ_n(\xi) + DJ_{-n}(\xi);\quad n \neq \text{integer}.$$

Sketches of several Bessel functions of the first kind are given in Fig. 13.

4.3 Neumann Functions

The Neumann functions are defined by

$$Y_n(\xi) = N_n(\xi)$$
$$\equiv \frac{J_n(\xi)\cos n\pi - J_{-n}(\xi)}{\sin n\pi};\quad n = \text{integer}.$$

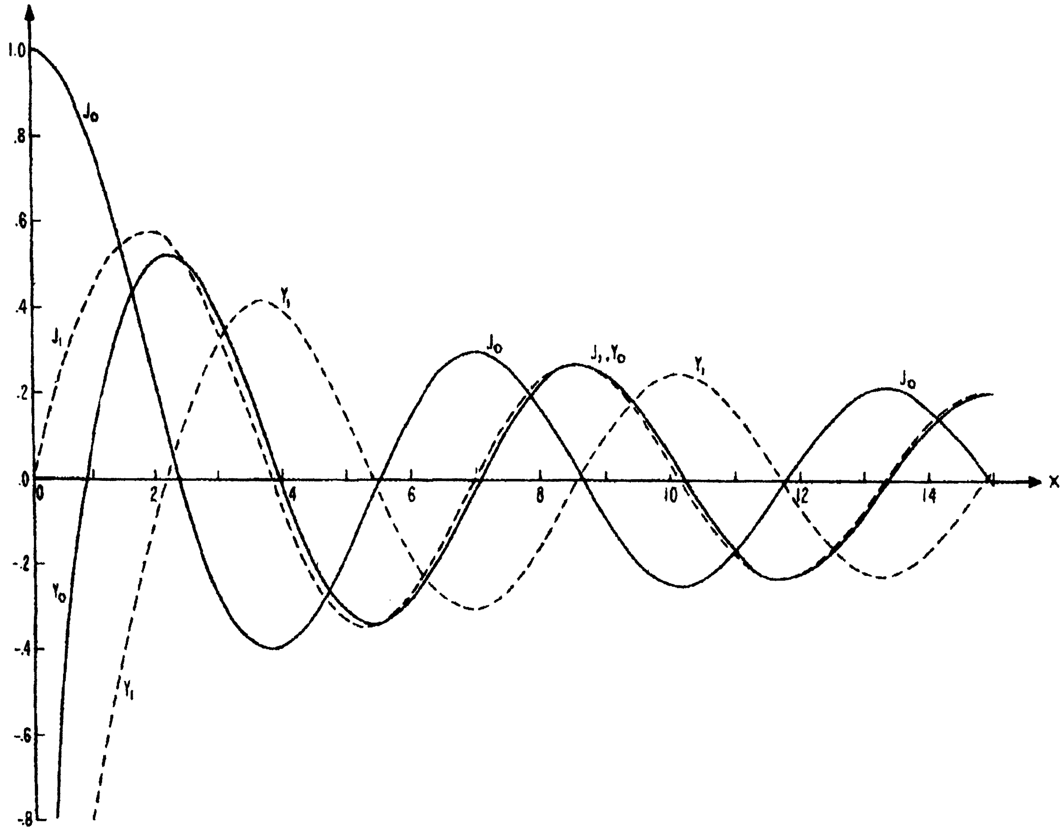

FIG. 13. Bessel functions of the first and second kinds, $J_n(x)$ and $Y_n(x)$ (Abramowitz and Stegun, 1964).

The Neumann functions are called Bessel functions of the second kind. L'Hospital's rule should be used to evaluate $N_n(\xi)$. Sketches of several Neumann functions are given in Fig. 13.

4.4 Hankel Functions

Hankel functions of the first and second kind are respectively defined by

$$\begin{aligned} H_n^{(1)}(\xi) &\equiv \frac{i}{\sin n\pi}\left[e^{-n\pi i}J_n(\xi) - J_{-n}(\xi)\right] \\ &= J_n(\xi) + iN_n(\xi) \end{aligned}$$

and

$$\begin{aligned} H_n^{(2)}(\xi) &\equiv -\frac{i}{\sin n\pi}\left[e^{n\pi i}J_n(\xi) - J_{-n}(\xi)\right] \\ &= J_n(\xi) - iN_n(\xi). \end{aligned}$$

The Hankel functions are independent solutions of the Bessel differential equation, and they are useful in connection with their behavior for large values of ξ since they are infinite at $\xi = 0$. Hankel functions are sometimes referred to as Bessel functions of the third kind.

4.5 Modified Bessel Functions

The modified Bessel differential equation is obtained when ξ is replaced with it in Eq. (61); the result is

$$t^2\frac{d^2P}{dt^2} + t\frac{dP}{dt} - (t^2 + n^2)P = 0. \tag{64}$$

The solutions of Eq. (64) are called modified Bessel functions of the first kind and are denoted by $I_n(\xi)$; they are given by

$$I_n(\xi) = i^{-n}J_n(i\xi) = \sum_{\lambda=0}^{\infty}\frac{(\xi/2)^{2\lambda+n}}{\lambda!(\lambda+n)!}; \quad n = \text{integer}.$$

When n is not an integer, $I_n(\xi)$ and $I_{-n}(\xi)$ are linearly independent solutions of the modified Bessel differential equation, Eq. (64). When n is an integer, $I_n(\xi) = I_{-n}(\xi)$. The modified Bessel functions of the second kind, $K_n(\xi)$, are defined by

$$K_n(\xi) \equiv \frac{\pi}{2}\left\{\frac{I_n(\xi) - I_{-n}(\xi)}{\sin n\pi}\right\}.$$

The modified Bessel functions of the second kind are well behaved for all values of n. Sketches of several modified Bessel functions are given in Fig. 14.

4.6 Spherical Bessel Functions

Solutions of the radial equation, Eq. (48), for k^2 = constant are obtained by comparing the radial equation with the Bessel differential equation; these solutions are called spherical Bessel functions and have the form

$$R(\xi) = Aj_n(\xi) = \left(\frac{\pi}{2\xi}\right)^{1/2} J_{n+1/2}(\xi) \text{ for } \xi = kr.$$

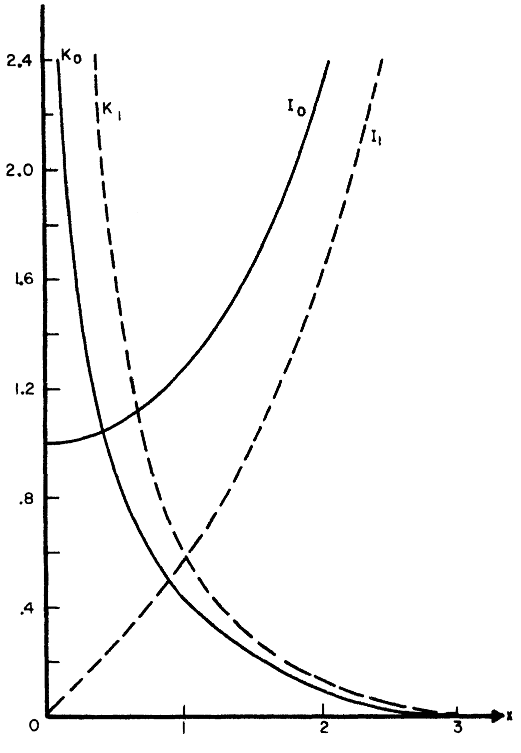

FIG. 14. Modified Bessel functions, $K_n(x)$ and $I_n(x)$ (Abramowitz and Stegun, 1964).

Spherical Bessel functions are often used in quantum mechanics and in other areas of physics. Sketches of several spherical Bessel functions, spherical Neumann functions, and spherical modified Bessel functions are respectively given in Figs. 15, 16, and 17.

Example 7, vibrations of a circular membrane: The displacement $u(r,\theta,t)$ of a stretched circular membrane with mass per unit area μ and under tension T satisfies the two-dimensional mechanical wave equation in plane polar coordinates (r,θ), which may be written in the following form:

$$\frac{1}{r}\left\{\frac{\partial}{\partial r}\left(r\frac{\partial u}{\partial r}\right) + \frac{\partial}{\partial \theta}\left(\frac{1}{r}\frac{\partial u}{\partial \theta}\right)\right\} = \frac{1}{v^2}\frac{\partial^2 u}{\partial t^2}.$$

The speed of the wave motion is defined by $v = \sqrt{T/\mu}$. Develop the solution of this equation for a vibrating drum head.

Solution: Separating the variables $u(r,\theta,t) = R(r)\Theta(\theta)T(t)$ with separation constants $-\alpha^2$ and $-n^2$ yields the following three ordinary differential equations:

$$\frac{d^2T}{dt^2} + \omega^2 T = 0,$$

with solution $T(t) = A\cos\omega t + B\sin\omega t$, where $\omega^2 \equiv v^2\alpha^2$;

$$\frac{d^2\Theta}{d\theta^2} + n^2\Theta = 0,$$

with solution $\Theta(\theta) = C\cos n\theta + D\sin n\theta$; and

$$\xi^2\frac{d^2R}{d\xi^2} + \xi\frac{dR}{d\xi} + (\xi^2 - n^2)R = 0,$$

where $\xi \equiv \alpha r$. The solution of the last equation is $R(\xi) = EJ_n(\xi) + FN_n(\xi)$ since it is the Bessel differential equation. In addition, it is required that the solution be finite at $\xi = 0$; hence, F is set equal to zero since $N_n(\xi)$ approaches infinity as ξ approaches zero. The general solution for the motion of the drum head is therefore given by

$$u = [A\cos\omega t + B\sin\omega t] \times [C\cos n\phi + D\sin n\phi]EJ_n(\xi).$$

Since the membrane is fixed (no vibration, $u = 0$) around the edge where $r = b$ (radius of

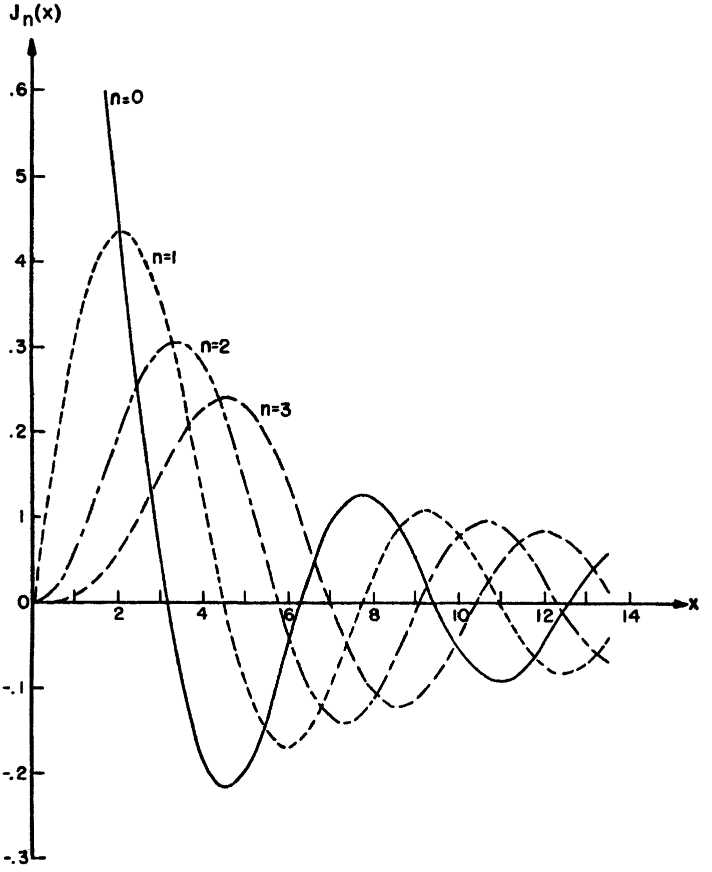

FIG. 15. Spherical Bessel functions of the first kind, $j_n(x)$ (Abramowitz and Stegun, 1964).

the head), the drum head vibrates in circular modes such that $EJ_n(\xi) = 0$. The nodes are located at $\alpha r = \xi_k$, where ξ_k are the values of ξ for which $J_n(\xi)$ has a zero. A single term in the solution corresponds to a standing wave whose modes are concentric circles, and the complete solution is obtained by summing over all such modes of vibration.

5. OTHER SPECIAL FUNCTIONS USED IN MATHEMATICAL PHYSICS

As explained in the Introduction of this article, the list of special functions is extensive. The *Handbook of Mathematical Functions* (Abramowitz and Stegun, 1964) contains a fairly comprehensive list of special functions. The focus in this article has been on special functions that are widely used in mathematical physics to solve classes of problems whose formulations involve special cases of the Helmholtz differential equation. In general, special functions may be classified as Type 1, those special functions that satisfy a differential equation, or Type 2, special functions that do not satisfy a differential equation; for example, the gamma function is a Type 2 special function. In Secs. 5.1 and 5.2, we summarize some other special functions that are used in mathematical physics.

5.1 Some Other Special Functions—Type 1

Some other special functions that satisfy a differential equation are the following:

1. Airy functions are solutions of the Airy differential equation, which has the form $y'' - xy = 0$; the Airy differential equation characterizes constant-force–type problems in quantum mechanical and in elementary particle physics.

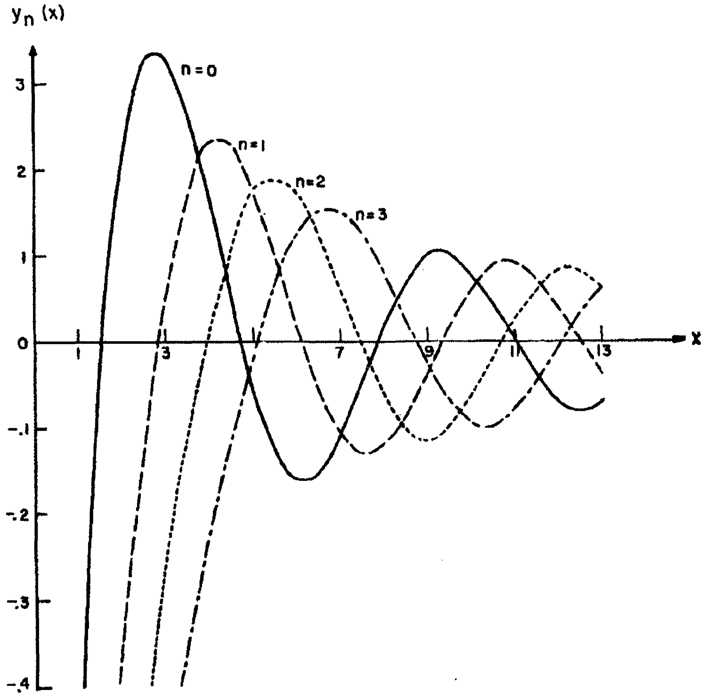

FIG. 16. Spherical Bessel functions of the second kind, $y_n(x)$ (Abramowitz and Stegun, 1964).

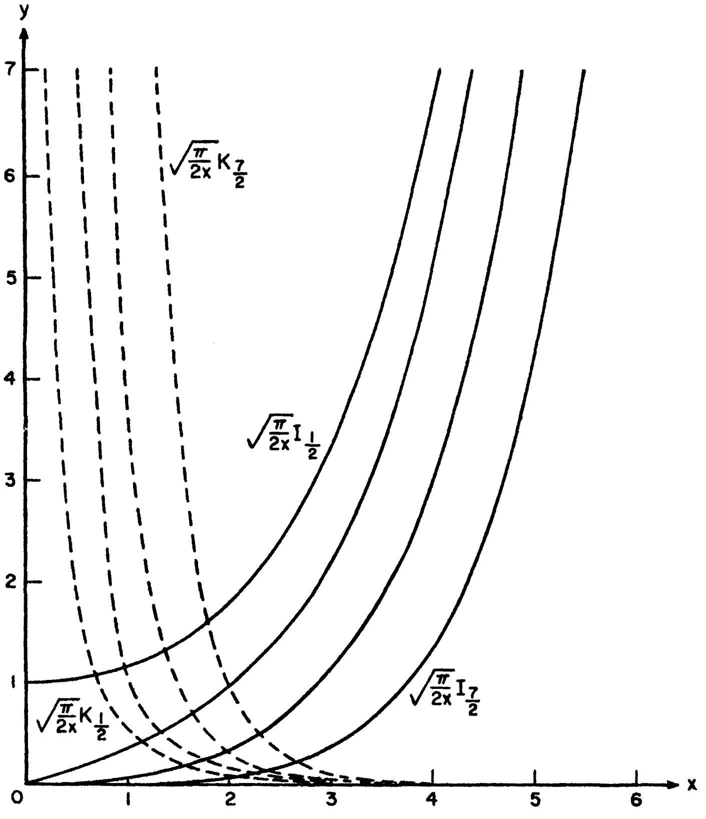

FIG. 17. Modified spherical Bessel functions of the first and second kinds (Abramowitz and Stegun, 1964).

2. Mathieu functions are solutions of the Mathieu differential equation, which has the form $y'' + (a - 2b\cos 2x)y = 0$; the Mathieu differential equation results when a cosine-type potential is substituted into the one-dimensional time-independent Schrödinger wave equation.
3. Parabolic cylinder functions are connected with confluent hypergeometric functions and with Hermite polynomials; they are solutions of differential equations of the form $y'' + (ax^2 + bx + c)y = 0$.

Many bound-state and collision problems in classical and quantum mechanics as well as in other areas of physics involve integrals of the form

$$\int R(x,y)dx. \tag{65}$$

When $R(x,y)$ is a rational function of x and y and $y^2 = a_0 + a_1x + a_2x^2 + a_3x^3 + a_4x^4$, where $a_4 \neq 0$ or $a_4 = 0$ and $a_3 \neq 0$, the integral in Eq. (65) is called an elliptic integral. Complete elliptic integrals of the first and second kind are respectively defined as

$$K(m) = \int_0^{\pi/2} (1 - m\sin^2\theta)^{-1/2}d\theta$$

and

$$E(m) = \int_0^{\pi/2} (1 - m\sin^2\theta)^{1/2}d\theta.$$

Analyzing the motion of a simple pendulum involves an elliptic integral of the first kind. Elliptic integrals can be evaluated directly by use of series expansions or computers. Their importance in mathematical physics, however, is related to their appearance in the solution of physical problems involving certain nonlinear differential equations. Elliptic integrals are special cases of the hypergeometric functions since

$$K(m) = \frac{\pi}{2}F(\tfrac{1}{2},\tfrac{1}{2},1;m) \text{ and}$$

$$E(m) = \frac{\pi}{2}F(-\tfrac{1}{2},\tfrac{1}{2},1;m).$$

The *Handbook of Mathematical Functions* (Abramowitz and Stegun, 1964) is a good reference for additional information on elliptic integrals.

5.2 Some Other Special Functions—Type 2

Some special functions used in mathematical physics that do not satisfy a differential equation are Einstein and Debye functions, which are used in representing the specific heats of solids due to lattice vibrations; error function (defined in Sec. 3.1); gamma function; and beta function. The last two functions are widely used in many areas of mathematical physics and are now summarized.

The factorial, $n!$, is defined as

$$n! = n(n-1)\ldots 2\cdot 1 = \int_0^\infty e^{-t}t^n dt$$

for integer values of n. Note that $0! = 1$, and $n! = \pm\infty$ if n equals a negative integer. The gamma function, Γ, is a generalization of the factorial to cases of noninteger values for n. The Euler definition of the gamma function is

$$\Gamma(z) = \int_0^\infty e^{-t}t^{z-1}dt \quad \text{for } \mathrm{Re}(z) > 0. \tag{66}$$

In Eq. (66), $\mathrm{Re}(z)$ denotes the real part of $z = x + iy$. Note that $\Gamma(\tfrac{1}{2}) = \pi^{1/2}$. Evaluating the integral in Eq. (66) by parts yields the recurrence relation for the gamma function, $\Gamma(z+1) = z\Gamma(z)$. If z is a positive integer n, then $\Gamma(z+1)$ equals $n!$.

The gamma function is used to express, in compact form, solutions of many problems of mathematical physics. The gamma function, however, does not satisfy a differential equation that is related to a physical problem; in fact, the gamma function does not satisfy any differential equation with rational coefficients. A sketch of $\Gamma(x)$ for some positive and negative values is given in Fig. 18.

The beta function, $B(x,y)$, is defined by use of an integral, and it involves a simple and useful combination of gamma functions; it has the form

$$B(p,q) \equiv \int_0^1 t^{p-1}(1-t)^{q-1}dt = \frac{\Gamma(p)\Gamma(q)}{\Gamma(p+q)} \text{ for } \mathrm{Re}(p) > 0,\ \mathrm{Re}(q) > 0.$$

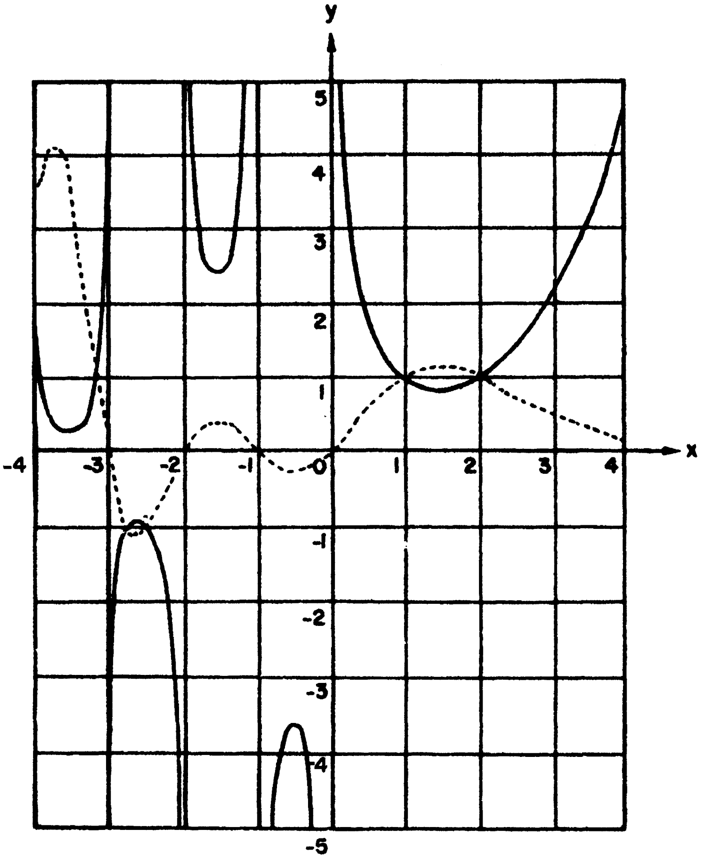

FIG. 18. Gamma function: solid curve, $\Gamma(x)$; dashed curve, $1/\Gamma(x)$ (Abramowitz and Stegun, 1964).

Note that $B(p,q) = B(q,p)$. The beta function is frequently used in high-energy particle physics as well as other areas of mathematical physics.

GLOSSARY

Confluent Hypergeometric Function: A solution of the confluent hypergeometric differential equation, which is a second-order ordinary differential equation with a regular singularity at $x = 0$ and an irregular singularity at $x = \infty$. Laguerre and associated Laguerre polynomials and Hermite polynomials are special cases of the confluent hypergeometric function.

Gamma Function: A generalization, to noninteger values of n, of the factorial $n!$.

Generating Function: A function $\mathcal{G}(x,t)$ that, when expanded in a power series with respect to t, contains the functions (set of polynomials) to be generated as coefficients of the parameter t.

Hypergeometric Function: A generalized geometric series that is the solution of the hypergeometric differential equation, which is a second-order ordinary differential equation with regular singular points at 0,1, and infinity. For example, the Legendre polynomials and associated Legendre functions are special cases of the hypergeometric function.

Rodrigues Formula: A formula used to generate an orthogonal polynomial by taking the nth derivative of an elementary function.

Special Functions: Higher transcendental functions used in mathematical physics.

Sturm–Liouville Theory: The theory devoted to determining the dependence of eigenfunctions on eigenvalues and the dependence of eigenvalues on boundary conditions imposed on eigenfunction solutions of the Sturm–Liouville equation.

INTRODUCTION

Charged-particle analyzers are nowadays applied in numerous fields of research to give detailed information about the spectral distributions of electrons and ions emitted from materials under irradiation of various kinds. Such analyzers have long been used extensively to study the radiation from radioactive species. In surface science precise measurements of energies and emission directions of photoelectrons can supply basic and detailed information about electronic structures. Normally such experiments are performed under ultrahigh-vacuum conditions. Similar studies can be performed on free molecules or clusters of atoms or molecules preferably in the form of adiabatically cooled jet beams. Even liquids can be studied if adequate measures are taken for differential pumping of the vapor phase and if arrangements for continuous renewing of the liquid surface exposed to vacuum are made. A range of suitable detectors and electronics has been developed to meet the needs for various experimental situations. Channel-plate detectors are highly efficient tools for these purposes and can be adopted to record particles simultaneously over an extended area. In the following review the basic properties of the various types of analyzers are discussed. Within the scope of this survey, no attempts have been made to include applications in different fields of research.

1. BASIC CONCEPTS, DEFINITIONS, AND RELATIONS

1.1 Liouville's Theorem

It is assumed that the charged particles to be transported, analyzed, and detected are under the action of conservative forces only (due to, e.g., static magnetic and electric fields). Each particle then can be characterized by a point in a six-dimensional phase space, where two three-coordinates represent

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

its geometric position and the components of its momentum vector, respectively. Liouville's theorem, which is fundamental for electron and ion optics, states that in these circumstances the density of points in phase space remains constant throughout the motion of the particles.

As a consequence, the volume of the phase space occupied by the particles does not change, since their number is constant, so that in their phase space these particles behave like an incompressible fluid. For a beamlike particle ensemble, the limits of the area it occupies in the phase subspace containing coordinates perpendicular to the beam direction is the *emittance* of the beam and is an invariant property as a consequence of Liouville's theorem (its shape and orientation, of course, can change) assuming a constant axial momentum component. When the axial momentum is varying along the trajectory, then the emittance varies in inverse proportion. In the case of a paraxial beam having cylindrical symmetry, the emittance is the product of the maximum transverse displacement from the symmetry axis and the angular divergence or aperture angle. The limiting area in the same phase subspace is the *acceptance* of an optical system. For achieving an optimum efficiency for transport or imaging, the matching of the respective emittance and acceptance is necessary.

In the case of small aperture angles, the *Lagrange–Helmholtz equation* holds:

$$\sqrt{E_1}l_1\alpha_1 = \sqrt{E_2}l_2\alpha_2, \tag{1}$$

where E_1 and E_2 are the energy values of the particles in the planes 1 and 2 perpendicular to the beam direction, while l_i and α_i are the respective transverse displacements and aperture angles. This equation is fundamental for focusing of paraxial rays of charged particles.

From Liouville's general theorem one can derive a useful relationship between the source width s, the spectrometer angular acceptance interval α, and the electron energy E:

$$s\alpha\sqrt{E} = \text{const.}$$

Thus, if the electrons are retarded before being analyzed in a given spectrometer, the Lagrange–Helmholtz equation regulates the consequences for the three parameters. This is a frequently occurring case when high resolution is aimed at.

1.2 Motion of Charged Particles in Static Fields

A particle with charge q and velocity v moving in a homogeneous magnetic field B in a plane perpendicular to the lines of force describes a circular path with a radius of curvature ρ. The equation of motion is

$$Bqv = mv^2/\rho, \tag{2}$$

where $m = m_0/\sqrt{1 - v^2/c^2}$. Thus, the momentum is given by

$$p = mv = qB\rho. \tag{3}$$

Because the momentum of the focused particles is proportional to the magnetic field of the spectrometer, it is convenient to express the momentum of a particle (e.g., electron) by means of its $B\rho$ value, which gives information about the magnitude of the magnetic field and spectrometer dimension required in a given experiment. The relationship between the relative energy change $\Delta E/E$ and a respective relative change in the momentum of the particle is

$$\frac{\Delta E}{E} = \left(1 + \frac{\mu}{\mu + E}\right)\frac{\Delta(B\rho)}{B\rho}, \tag{4}$$

where μ denotes the rest-mass energy of the particle. In the case of electrostatic spectrometers, however, it is the energy of the particles that is proportional to the deflecting voltage, and equations similar to (3) and (4) are presented in Secs. 1.3 [Eq. (6)] and 3.1 [Eq. (21)].

1.3 General Nomenclature of Parameters Describing the Properties of Electron and Ion Spectrometers

In this section, the most important parameters specifying and describing electron and ion spectrometers are listed, focusing on the dispersive types. The following definitions contain the energy of the particles, E; similar relations are used in the case of momentum-dispersive devices (magnetic spectrometers), where E should be replaced by the respective momentum values p or $B\rho$.

A charged-particle spectrometer provides a selective transport of the particles emitted from a geometrically well-defined source to the similarly well-defined position detector. The energy interval over which particles are accepted is the *energy range* of the spectrometer, while the *solid angle* Ω of the spectrometer defines the angular region from which particles leaving the source are entering the spectrometer. In the case of sources having a finite *source area,* Ω usually means the solid angle averaged over this area.

The fraction of all monochromatic particles leaving the source and entering the spectrometer that is detected is called the *transmission* of the spectrometer. For a point source, the *point transmission* is the solid angle over which the particles are accepted by the spectrometer multiplied by a factor of less than unity, expressing the intensity loss inside the spectrometer. The *efficiency* of the spectrometer is given by the ratio of the total current detected to the total particle current emitted from the monochromatic source. Characteristic for a specific dispersive spectrometer is the *"central"* or *"main" particle trajectory,* along which a particle entering the spectrometer in a direction tangential to this trajectory moves when the spectrometer is set to the energy of the particle, E. The source is centered on the point where the central trajectory crosses the source plane, and the detector (exit slit) should be positioned (or centered) on the point where this trajectory crosses the plane of the image of the source produced by the spectrometer. On increasing the energy (momentum) of the particle moving in the central trajectory by a small amount dE (dp), the corresponding image point will be shifted by a small displacement dx. The measure of this energy (momentum) dispersive property is the *dispersion* D of the spectrometer, expressed as

$$D = E\frac{dx}{dE}\left(\text{or}\; p\,\frac{dx}{dp}\right). \tag{5}$$

Usually, D is related to the characteristic distance of the spectrometer (focal length or path length along the central trajectory), and this ratio is called *relative dispersion.*

Because of spherical aberrations and other possible imaging errors of the electron or ion optical system of the spectrometers, monochromatic particles emitted from a source (with a constant number of particles emitted per unit time from unit source area within unit solid angle, i.e., with constant *brightness*) and entering the spectrometer will have an apparent energy distribution at the detector in the image plane. The shape and intensity of this distribution depends on different factors (including E, Ω, source size, and type of focusing), and it can be defined as the *spectrometer function* S. For a particle energy E, the energy width (full width at half maximum, FWHM, or base width) of $S(E)$ is the *absolute energy resolution* ΔE of the spectrometer. The *relative energy resolution* $\Delta E/E$ for energy-dispersive (electrostatic) spectrometers can be expressed as a function of the absolute image magnification M, the widths of the inlet and exit slits of the spectrometer (s_1 and s_2), and the dispersion D:

$$\frac{\Delta E}{E} = \frac{Ms_1 + s_2 + \Sigma}{D}, \tag{6}$$

where Σ denotes the contribution coming from the aberrations (here ΔE means base width). Analogous expressions (see later) can be found for the *relative momentum resolution* $\Delta p/p$ in the case of momentum-dispersive spectrometers. A similarly often-used quantity is the *resolving power* $E/\Delta E$ (ΔE usually defined as FWHM, which is about half of the base width, depending on the shape of the spectrometer function), or $p/\Delta p$. For most high-transmission spectrometers, the resolution is 1% or worse, while in the case of high-resolution devices, its value is better than 0.01%.

In the case of extended sources, as an alternative to the transmission used as a measure of the sensitivity for a finite-dimension source, the *luminosity* is applied:

$$L = \Omega\sigma, \tag{7}$$

where σ is the source area. It should be noted here that the luminosity can be increased considerably by increasing the number of detectors in the focal surface (energy or momentum multidetection), or—e.g., in the case of electrostatic spectrometers—by applying pre-retardation of particles before energy analysis.

Spectrometers are often classified on the basis of their focusing properties. When the image width of a point source, expressed as an expansion in powers of the angle, does not contain the first n powers, the spectrometer has nth-order focusing. Focusing in a single direction (nth order) produces a line image of a point, while if the same order of focus exists in the perpendicular direction, the spectrometer is *double focusing*, and for stigmatic focusing (producing images in the same plane in each direction) it provides a point image of a point source.

2. MAGNETIC SPECTROMETERS

Magnetic spectrometers have a long and extended use in the separation and analysis of charged particles. Comprehensive reviews are available (Siegbahn, 1965; Mladjenovic, 1979; Dragoun, 1983) in this field, providing detailed descriptions of the basic principles, theory, design, and applications of these experimental instruments. A classical field where magnetic spectrometers have been of great importance is nuclear structure analysis including the alpha- and beta-ray spectroscopy of radioactive samples, as well as the (in-beam) spectroscopy of particles emitted from the interaction of a target with a high-energy ion beam produced by a particle accelerator. High-resolution spectrometers are used for the spectroscopy of electrons emitted following the decay of excited nuclear states. Applications of devices based on magnetic particle transport or analyzer systems are expanding in the field of analysis of molecular and solid surface structures. Here we should limit ourselves to mentioning only some examples of characteristic types and uses of these devices.

The various magnetic spectrometers can be grouped into four classes (Mladjenovic, 1979):

momentum-dispersive spectrometers for high-performance use or for coincidence measurements;

magnetic transport spectrometers, where the requirement of the good momentum resolution is relaxed and the energy spectra are measured with semiconductor [Si(Li)] detectors;

magnetic guides, for simply transporting particles from the source to the detector, having an input solid angle in some cases nearly 2π (4π) sr and providing a guide for almost the whole spectrum, except usually the low-energy part, in order to avoid the overloading of the detector from the high background produced by the low-energy secondaries (e.g., delta electrons); and

nondispersive focusing magnets for focusing a wider momentum band into a narrow cone at the detector far from the target and stray radiation.

The latest developments in the field of magnetic spectrometers are strongly influenced by the increased ability of performing precise calculation of more sophisticated field distributions, the improved technology in the production of magnetic materials, and the availability of superconducting solenoids (making possible the production of very strong fields while keeping the size of the device relatively small), as well as by the extended application of the modern position-sensitive detectors, making possible the use of the spectrometers as spectrographs, with simultaneous detection of a considerable part of the whole spectrum, and the development of the performance of the semiconductor detectors.

2.1 Momentum-Dispersive Spectrometers

In order to get an impression of the magnitude of the different aberration errors of geometrical nature, it is useful to consider first the *semicircular* focusing principle. Figure 1 shows the paths of monochromatic electrons, emitted from a point source, in a plane perpendicular to the applied magnetic field. Here φ is the pencil angle (defined by a slit) of the electrons emitted, and ρ is the radius of curvature in all cases. The focusing is not perfect; the spherical aberration causes a broadening of the image to width Δx. With a source having a width of x, the full image width is given by

$$\Delta x = s + 2\rho(1 - \cos\varphi), \tag{8}$$

while, assuming small φ and with $\Delta x = \Delta 2\rho$, the base resolution R^0 is

$$R^0 = \frac{\Delta\rho}{\rho} = \frac{s}{2\rho} + \frac{\varphi^2}{2}, \tag{9}$$

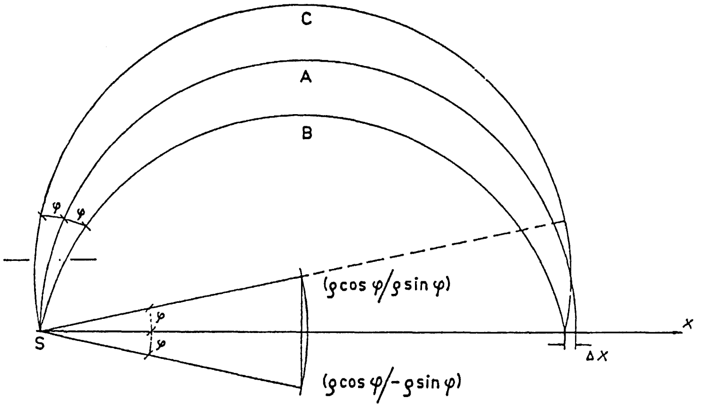

FIG. 1. The semicircular focusing principle (Siegbahn, 1965, by courtesy of Elsevier Science B. V.).

the first term depending upon the width of the source and the radius of curvature and the second upon the angular aperture. For optimum conditions, the two terms should give about equal contributions to the resolving power.

Among the magnetic spectrometers with high momentum dispersion, the best known and most widespread are the double-focusing $\pi\sqrt{2}$ types, combining features of one-dimensional semicircular focusing and two-dimensional helical or lens focusing. These spectrometers have a field of rotational symmetry, decreasing as $1/\sqrt{\rho}$ in the vicinity of the central path ($\rho = \rho_0$). In the symmetry plane of the field, electrons starting from a point on this central circle having angles φ_0 and ψ_0 in the radial and axial directions, respectively, will return to the central circle after focusing angles Φ_ρ and Φ_z. The focusing angles are related as

$$\frac{1}{\Phi_\rho^2} + \frac{1}{\Phi_z^2} = \frac{1}{\pi^2}\,. \tag{10}$$

An anastigmatic focusing is taking place when $\Phi_\rho = \Phi_z = \pi\sqrt{2} = 254°56$. Figure 2 shows the principle of the $\pi\sqrt{2}$ focusing.

Expanding $B_z(\rho,0)$ in a series gives

$$B_z(\rho,0) = B_0(1 + \alpha\eta + \beta\eta^2 + \ldots\ldots), \tag{11}$$

where $\eta = (\rho - \rho_0)/\rho_0$. The first expansion coefficient α is related to the focusing angles by

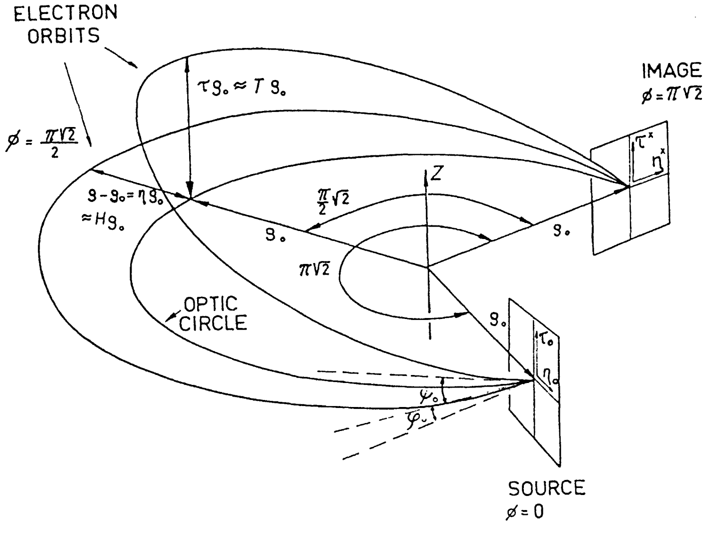

FIG. 2. The principle of $\pi\sqrt{2}$ focusing (Siegbahn, 1965, by courtesy of Elsevier Science B. V.).

$$\Phi_\rho = \pi/(1 - \alpha)^{1/2},\ \Phi_z = \pi/(-\alpha)^{1/2}, \qquad (12)$$

while β is connected with the aberrations influencing the width and height of the image. The focusing is the same for noncentral rays as well.

For the double-focusing case, the relative momentum dispersion of the spectrometer is $D_p = 4$, twice the dispersion compared to that for the homogeneous field. For a source with dimensions of width s and height h, and with a detector width w, the resolution R_0 is (at the base)

$$R_0 = \frac{s}{4\rho} + \frac{w}{4\rho} + \frac{4\beta - 3}{48\rho^2} h^2 + f(\beta, \varphi_0^2, \psi_0^2). \qquad (13)$$

It can be seen that the source height contributes to the resolution with a term of second order, which allows a typical height of 10 mm even for very high resolution. On account of the small applicable axial apertures, $\pi\sqrt{2}$ spectrometers usually work with solid angles smaller than 1%. The luminosity can be considerably improved by applying the method of Bergquist (Siegbahn, 1965), adding two electrostatic correctors, compensating for the source width and for the spherical aberration, respectively. The extended electron source is positioned with its plane at an angle of ~43° relative to the radius of the central circle in the $\pi\sqrt{2}$ magnetic field and by the help of an electric field gradient along the source, using vertical equipotential wires. The difference in ρ coordinates of the source points can be compensated for, enabling use of very extended sources. Compensating for the spherical aberration, a conveniently shaped grid system is placed symmetrically between the spectrometer and the detector, ensuring the achievement of a very high degree of cancellation of the aberration.

The spectrometer magnetic field can be produced either by a coil system only or by using iron for field shaping. The highest attainable precision was obtained by iron-free instruments first designed in Uppsala (Siegbahn, 1965). Present double-focusing systems with position-sensitive semiconductor detectors for multienergy detection can provide a momentum resolution of $\Delta p/p = 0.005$–0.3% in the electron energy range of 300–1000 keV. In coincidence spectroscopy and in the case of in-beam experiments, where a good access is requested to the source and detector, *sector field* devices are often used, in order to place the source and detector outside the field. By using curved pole boundaries, it is possible to achieve simultaneous double and second-order focusing (aberration coefficients depending on φ_0^2 and ψ_0^2 vanish simultaneously) with magnetic sector spectrometers, while the attainable resolution and transmission are comparable to those in the case of the double-focusing $\pi\sqrt{2}$-type spectrometer. An important law for sector-type spectrometers is "Barber's rule," according to which the center of the circle corresponding to the central trajectory in the sector with a homogeneous magnetic field is collinear with the source and focus points, independent of the sector angle. This rule can be generalized for the case of sectors with inhomogeneous field.

2.2 Magnetic Transport Spectrometers

Although some types of magnetic spectrometers (e.g., lens or toroidal types) can provide rather good resolution, they will be mentioned here because of their recent use mostly as particle transporters. These systems have large entrance solid angle and at the same time ensure the elimination of the high background from γ photons or unwanted particles (e.g., positrons), providing optimum conditions for coincidence measurements.

If magnetic sector analyzers are arranged in such a way that the pole pairs (with gaps between them) are situated along a circle, the center of which is collinear with the common source and focal points, a *toroidal* or *"orange"-type* spectrometer is obtained. At a resolution characteristic of sector field types and limited by the fringing fields, much higher transmission ranging between 10% and 20% can be obtained. Toroidal spectrometers with coils containing iron cores usually have 6–8 gaps, while the number of poles in the case of iron-free systems may be one order of magnitude higher. Most of the orange spectrometers are symmetrical, having the same pole profiles at the source and the detector side. Applying different air gaps, this type of spectrometer can be used for angular distribution measurements as well. The background is greatly reduced compared to the lens-type systems. Small, simple, and inexpensive toroidal transport spectrometers can be constructed by using permanent magnets and Si(Li) detectors ("mini oranges"). The characteristic sizes of such a system (source-detector distance, diameter of the magnet configuration) are in the order of 10 cm, and the transmission has a maximum that depends on the field strength and geometry. Figure 3 shows the scheme of a mini orange spectrometer.

The *magnetic lens-type spectrometers* are based on the focusing action of axial fields in long or short solenoids. The simplest case is a long solenoid with homogeneous field parallel to an axis containing the source and the detector. Its focusing properties can be treated completely analytically, which is not possible in the case of more complicated fields. The particle trajectories have a cylindrical symmetry, and the focusing is two dimensional. Particles from the source enter the spectrometer at an angle usually between 10° and 60°, defined by the entrance baffle (no axial rays can reach the detector separated from the source by a long lead absorber). For the case of a long lens with a homogeneous axial field B, the focusing properties are characterized as in the following description (Mladjenovic, 1976).

Dispersion $D = p\,dr/dp$, when measuring the radial displacement of the electron trajectory in the ring focus and when the momentum p is changed by dp, is given by

$$D = r_F/\sin^2\gamma^2, \tag{14}$$

where r_F is the radius of the ring focus and γ is the mean angle of the entering beam, related to the spectrometer axis and defined by the entrance aperture. The resolution (base width) for a point source is given by

$$R = (\Delta\gamma)^2(\beta + \cos^2\gamma\tan^2\beta), \tag{15}$$

where $\Delta\gamma$ is the semiaperture angle and β is defined by

$$\tan\beta/(\pi - \beta) = \tan^2\gamma, \tag{16}$$

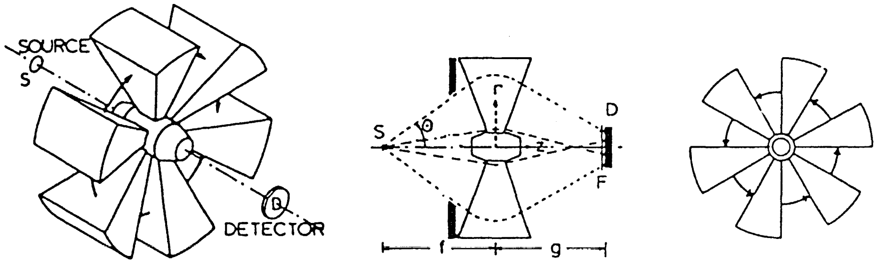
while the acceptance solid angle Ω, defined by the entrance solid angle, is given by

$$\Omega = 4\pi\Delta\gamma\sin\gamma. \tag{17}$$

In the case of *short lenses,* the source and the detector are in field-free regions and the magnetic field distribution along the axis has a strong maximum. The solid angle of the lens spectrometers is usually 1–2%.

In order to increase the transmission and reduce the spherical aberrations, Siegbahn and Slätis (Siegbahn, 1965) designed a lens type with magnetic field weaker in the middle, forming an intermediate ring focus after which focusing the particles again at the end to a point focus on the axis. Such an *intermediate-image focusing lens* can be used for electron–electron coincidence measurements. The transmission of this type of spectrometer can reach 8%, and it is most often used for in-beam applications.

When a high-resolution semiconductor spectrometer is used as a particle detector, only the high-efficiency collection of the particles, as well as their transport to the detector, is of importance. To achieve this, *axial magnetic guides* or *solenoid transports* are



Stereoscopic plane Y plane Z

FIG. 3. The scheme of a permanent magnet "mini-orange" spectrometer (Van Klinken *et al.*, 1975, by courtesy of Elsevier Science B. V.).

used. The homogeneous field of a solenoid represents the guiding channel between the source and the detector on the axis, and when a sufficiently strong field is applied, the particles emitted from the source in 2π solid angle will spiral toward the detector. In order to limit the transport to the particles that can reach the detector surface of a definite size, field gradients are introduced at both the source and detector sides, inducing a magnetic mirror effect for reflecting the particles emitted at angles larger than a maximum angle relative to the axis, while circular baffles can be placed on the axis between the source and the detector to cut off the low-energy part of the spectra, thus saving the detector from the high load. A modulation of the field can improve the efficiency reduced by the baffle or, e.g., reduce the background due to particles with opposite charge (e.g., positrons in the case of electron focusing). If absorbers had been placed on the axis for preventing photons from being detected, the efficiency would have been considerably decreased. The cross section of a superconducting solenoid transport system, used for in-beam experiments (internal conversion spectroscopy), can be seen in Fig. 4 (Árvay *et al.*, 1980). A different concept is realized in the *trochoidal spectrometers and guides,* where the particles, in a cylindrically symmetric field (e.g., having r^{-n} dependence) between two pole pieces, are moving in circles, the centers of which drift along a much

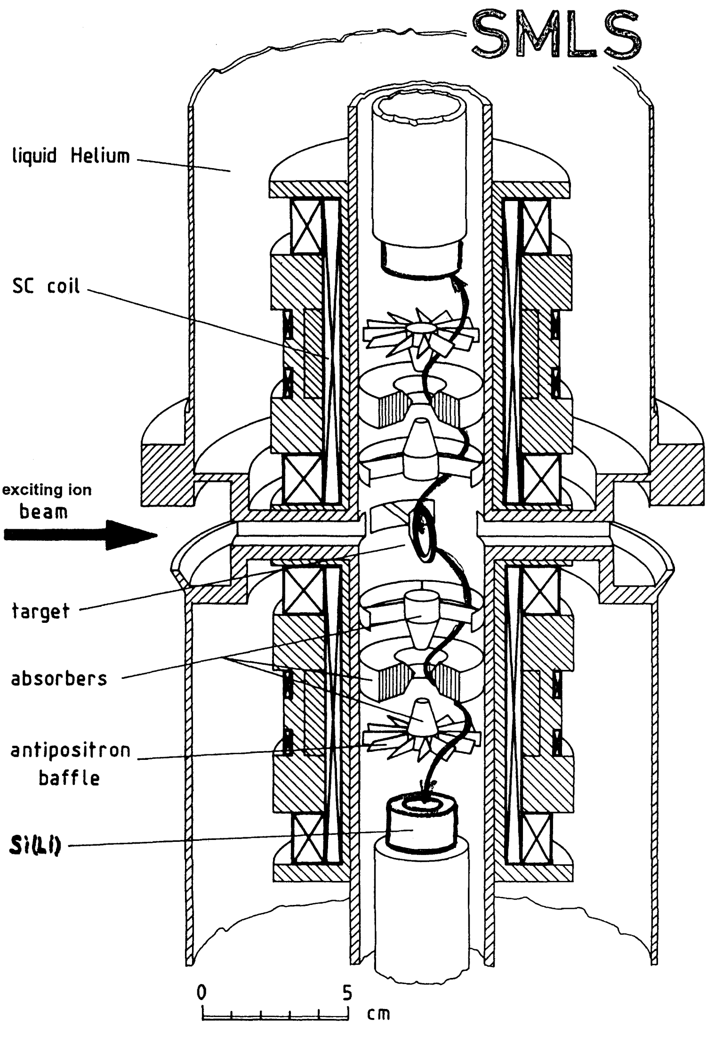


FIG. 4. A superconducting solenoid transport system (modified for lens working mode) for in-beam experiments (Árvay *et al.*, 1980, by courtesy of T. Fényes, 1994).

larger radius circle due to the inhomogeneity of the field. The transmission of the trochoidal systems is independent of the particle energy.

The *nondispersive focusing magnets* collect particles from a source into a converging beam after momentum selection. Figure 5 illustrates the principle of such a system. Here a baffle can be positioned at the intermediate plane of dispersion, while the detector is placed at the converging part of the beam. These instruments ensure a very low background and a good momentum bandwidth. They have, however, a low transmission (usually well below 1%).

2.3 New Applications

Without any attempt for completeness, we mention here some recent applications of magnetic devices, providing an insight into future directions. High-performance time-of-flight spectrometers can be developed using magnetic guides combining high luminosity with high energy resolution. An example is the trochoidal electron spectrometer (Norell *et al.*, 1984), where the electrons are moving in a magnetic field of rotational symmetry with $1/r^2$ dependence. This field ensures very long flight paths within small physical dimensions. The trochoidal spectrometer was successfully applied to studying resonance excitation in He^-, reaching an energy resolution less than 0.2% at an acceptance solid angle of almost 20% of 4π sr (Norell *et al.*, 1984).

A different solution for combining high sensitivity and reasonably high resolution is the *magnetic bottle* device, which can be used as a spectrometer as well as for image magnification and projection. The principle can be understood from Fig. 6. Electrons emitted from a source in a very strong homogeneous magnetic field are forced to follow a spiral around a field line, and they follow the same field line into a region of low and uniform field. Since the total velocity is constant, the axial velocity component increases when go-

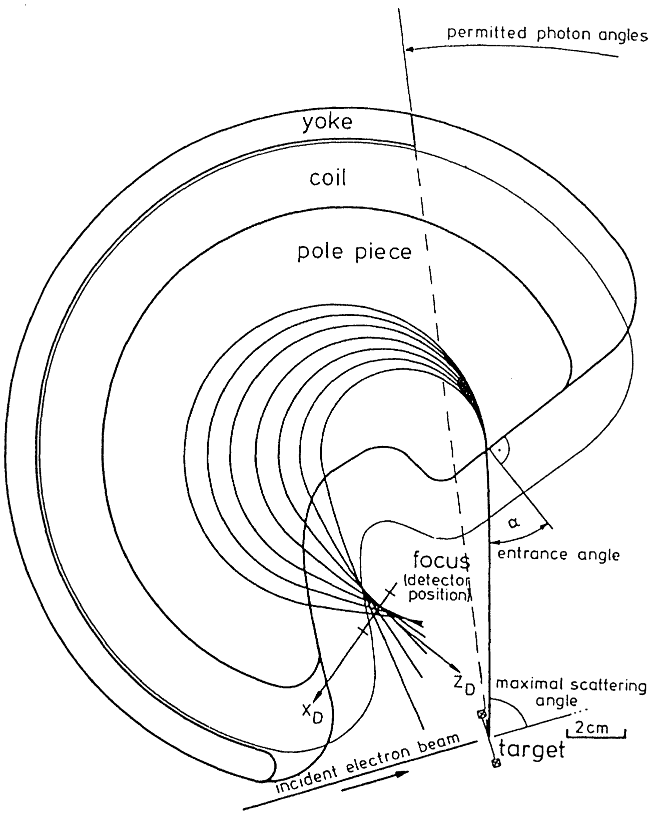

FIG. 5. The principle of operation of a nondispersive focusing magnet (Komma and Ruoff, 1981, by courtesy of Elsevier Science B. V.).

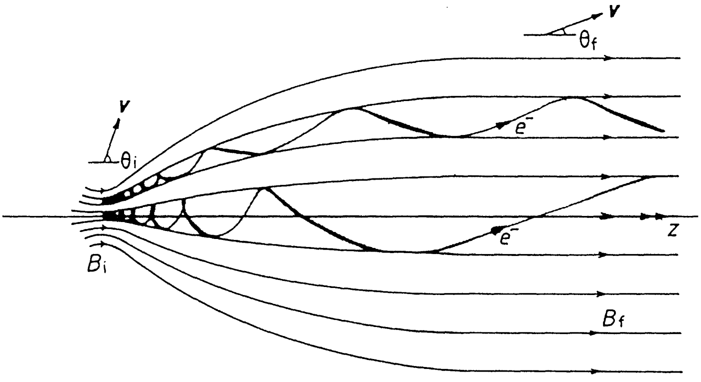

FIG. 6. Magnetic field lines and electron trajectories in a "magnetic bottle." The magnetic field changes gradually from a strong field B_i to a weaker field B_f. (Kruit and Read, 1983, by courtesy of IOP Publishing Ltd.)

ing from the high-field to low-field regions, while the transverse component decreases, leading to the parallelization and unspiralling of the electrons. (Beamson *et al.*, 1980; Kruit and Read, 1983). If the ratio of the field strengths in the high- and low-field region is high enough, electrons follow trajectories parallel to the field lines in the low-field region, even if emitted nearly perpendicularly to the field lines, and can be subjected to the different methods of energy analysis. When the field experienced by an electron changes negligibly in the course of one revolution of the helical motion, the angular momentum is constant, and the angle θ_f of the helical motion in the low-field (B_f) region can be obtained from (Kruit and Read, 1983)

$$\frac{\sin\theta_f}{\sin\theta_i} = \left(\frac{B_f}{B_i}\right)^{1/2}, \tag{18}$$

where the index i refers to the initial parameters at emission. Similarly, the lateral linear magnification M of the orbital motion is given by

$$M = (B_i/B_f)^{1/2}. \tag{19}$$

Assuming that electrons originate from the source with an angular spread 2π sr and energy E, the total possible relative energy spread is

$$\Delta E/E = B_f/B_i, \tag{20}$$

representing an intrinsic limit of the resolution, which is strongly dependent on the initial angular distribution of the emitted electrons. In most cases the magnetic bottle is used as a time-of-flight spectrometer with pulsed sources. Applications are in the low–electron-energy (around 10 eV) region and concern spectroscopy of photoelectrons induced by laser multiphotoionization or UV photoionization processes of atoms, molecules, or cluster ions and also energy-loss spectroscopy of inner-shell excited states. As the diverging magnetic field lines act as guiding tracks for electrons emitted from a solid surface, a good image projection is possible at a high magnification (Beamson *et al.*, 1980), ensuring at the same time high collection efficiency. Combining this magnifier with proper energy selectors [i.e., time-of-flight (TOF) spectrometers, band-pass image filters, or energy analyzers], high-performance photoelectron spectromicroscopes can be developed. Using superconducting solenoids and tunable synchrotron photon sources, submicron lateral resolution can be reached by the help of a special angular selection scheme (Keenlyside and Pianetta, 1993).

Another field of growing interest where magnetic spectrometers can be utilized is the ion-beam analysis of surfaces and interfaces. Here the energy and angular as well as the mass distribution of the ions scattered or recoiling from a solid surface are measured. The design of a magnetic spectrograph connected to a particle accelerator and developed for the analysis of surfaces and thin layers with Rutherford backscattering and recoil spectroscopy (Boerma *et al.*, 1990) is shown in Fig. 7. The main elements of the system are the ultrahigh-vacuum scattering chamber, with a precision three-axis manipulator where the sample is mounted, and the

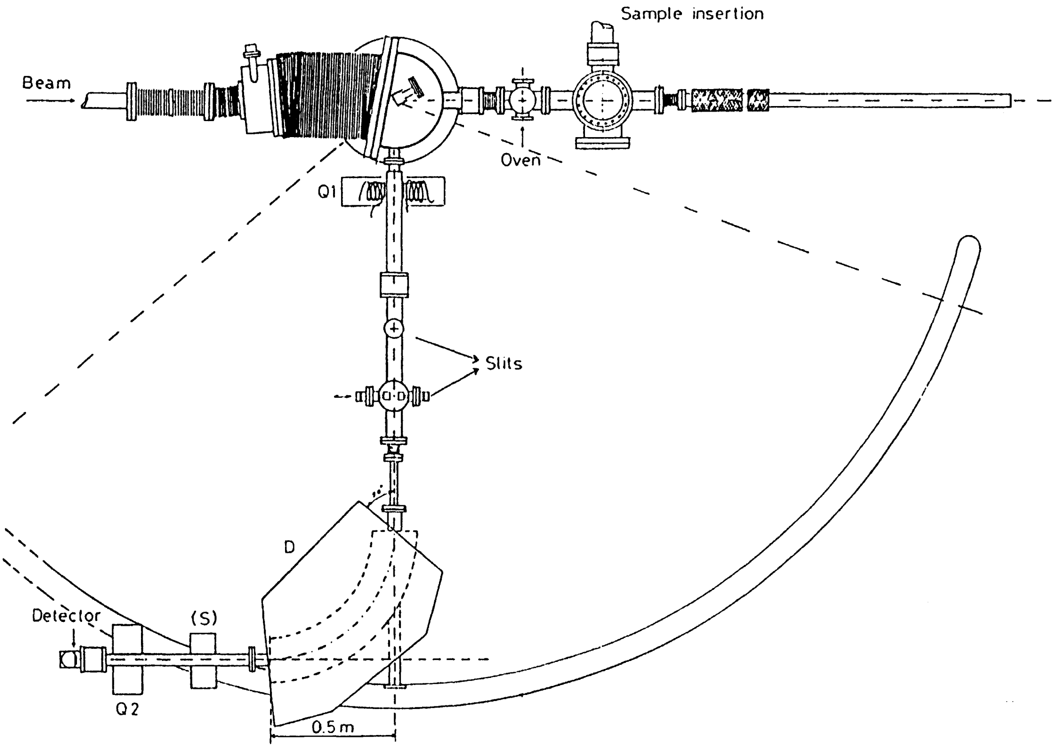

FIG. 7. The design of a magnetic spectrograph for surface and thin-layer analysis using a particle beam from an accelerator in ion-scattering experiments (Boerma *et al.*, 1990, by courtesy of Elsevier Science B. V.).

spectrograph, consisting of two quadrupole magnets and a dipole sector magnet bending the ions in the horizontal plane, equipped with a two-dimensional position-sensitive detector. Together with the chamber, the spectrograph is rotatable around a vertical axis, ensuring a scattering angle variable between 20° and 140°. In the horizontal plane, ions can be measured simultaneously within an energy window of 2% relative width at an energy resolution of 2×10^{-4}, while in the vertical direction their angular distribution can be detected with an angular window of 5° and an angular resolution of 0.1°. The depth resolution is close to one monolayer near the surface, while the mass discrimination of the spectrograph makes possible the background-free detection of light atoms recoiling from a heavier substrate. Providing optimum conditions for surface analysis using the channeling-blocking technique, the magnetic spectrograph provides an important extension of ion-beam analysis through its unique features in applications for recoil spectroscopy and in lattice-site location of light atoms in thin layers.

3. ELECTROSTATIC SPECTROMETERS

In the low–particle-energy region (from a few eV to several keV), the application of the electrostatic spectrometers is the most common. There are many comprehensive reviews available of these systems (Afanas'ev and Yavor, 1976; Granneman and Van der Wiel, 1983). Critical reports on design considerations and recent developments appeared recently (Leckey, 1987; Roy and Tremblay, 1990; Ibach, 1991). Electrostatic spectrometers have been used extensively for a few decades in the fields of analysis of atomic, molecular, and cluster structures, collision processes, and surface and interface analysis through a variety of photoelectron and Auger-electron spectroscopic, electron and ion energy-loss spectroscopic, and electron-diffraction and ion-scattering spectroscopic methods. Further expansion in applications of electrostatic spectrometers is seen in experiments connected with phenomena of molecular and surface dynamics (including processes induced by multiply-charged–particle beams, laser beams, and synchrotron radiation) or with phenomena and structures of microscopic (even molecular) localization. The main advantages of electrostatic spectrometers are their suitability for energy analysis and the simpler way of attaining high stability and precision in forming the field. An electron or ion spectrometer consists of a vacuum (in the case of surface analysis, UHV) system with a sample or scattering chamber, an irradiating unit for exciting the target, and an analyzer including the detector. The analyzer and sample chambers are shielded against even weak external magnetic fields. We restrict ourselves to discussing analyzers and detectors only, while detailed information on component materials, magnetic shielding, working modes, calibration, etc. can be learned from available reports (Granneman and Van der Wiel, 1983; Rivière, 1990). Most electrostatic spectrometers can be grouped into two classes: energy-dispersive and -nondispersive types. Many designs, however (e.g., of display type, TOF spectrometers, or band-pass filters), important for specific applications, fall outside these groups. The latest developments regarding electrostatic spectrometers are motivated by the need for multienergy and multiangle detection in order to increase the speed of information important from the point of view of state and structure analysis, and by the strong requirement of spectromicroscopy for state imaging and the possibility for doing time-resolved spectroscopy at high resolution.

3.1 Dispersive-Type Analyzers

Dispersive analyzers can be of either the mirror or the deflector type. In deflectors the particles follow trajectories close to the equipotentials, while in mirrors the trajectories cross the equipotentials, and the velocity component of the particles perpendicular to these lines decreases to zero and changes to the opposite direction after reflection. In electrostatic dispersive analyzers, the pass energy E is proportional to the potential difference (ΔV) of the electrodes producing the dispersive field:

$$E = qk\Delta V, \tag{21}$$

where q is the charge of the particles with energy E and k is the *spectrometer constant.*

3.1.1 Electrostatic Mirror Analyzers

Among the electrostatic mirror spectrometers, the simplest is the *parallel-plate analyzer,* the scheme of which is shown in Fig. 8. The field between the two parallel plane electrodes is uniform, and the equipotential surfaces are also parallel to the electrodes. In most cases the source (aperture) and the detector are positioned symmetrically relative to the electrodes, in the field-free region. The particles enter into the field at an angle α (Fig. 8) and are focused symmetrically in a plane (in the case of a source at the entrance slit and $\alpha = 45°$, this plane coincides with the plate containing the entrance and exit slits). This property is advantageous from the point of view of simultaneous detection of different energy particles (energy multidetection). At $\alpha = 30°$ beam angle, it is possible to achieve second-order focusing if $h_1 + h_2 = d/(3\sqrt{3})$ (see Fig. 8), where $h_1 + h_2$ is the sum of the distance of the source and detec-

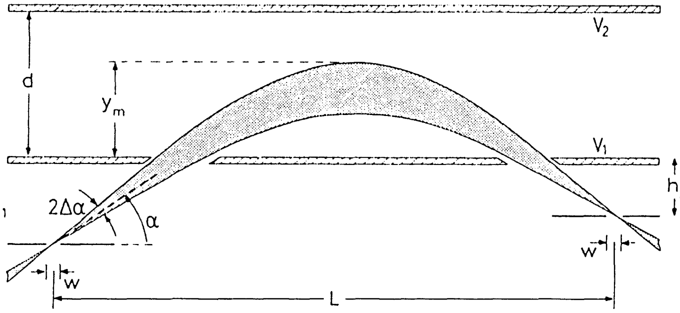

FIG. 8. The scheme of the parallel plate analyzer (Granneman and Van der Wiel, 1983, by courtesy of Elsevier Science B. V.).

tor apertures placed at the focal length d from each other. The energy dispersion in this case is

$$D = \tfrac{2}{3}d. \tag{22}$$

The parallel-plate mirror analyzer has a very simple construction and is often applied in coincidence or in angular distribution measurements. Because of the unidirectional focusing, however, its luminosity is low at high resolution.

One of the most often used electrostatic analyzers is the *cylindrical-mirror analyzer* (CMA). Its scheme is shown in Fig. 9. It consists of two coaxial cylinders with inner radius R_1 and outer radius R_2. The radial logarithmic field between the cylinders reflects the charged particles, which start from the common axis in the field-free region and enter the field through the entrance slit on the inner cylinder, and return to the axis after traveling one focal length (which is dependent on the energy of the particles). Although the focusing in the CMA is unidirectional on account of the cylindrical symmetry, it is equivalent to a two-directional focus (i.e., a point source is imaged to a point). In many applications the point source and the detector are situated on axis (point-to-point focusing); however, either the source or the detector aperture (or both) can be selected to be ring-shaped, providing a considerable flexibility in the design. The focal length L is dependent on the beam entrance angle α, the sum of the radial projection of the central trajectory in the field-free region, $n = h_1 + h_2$ (see Fig. 9), and the spectrometer constant $k = E/q(V_2 - V_1) \times \ln(R_2/R_1)$ (Zashkvara *et al.*, 1966):

$$\frac{L}{R_1} = \left(n + 4pe^{p^2}\int_0^p e^{-x^2}dx\right)\cot\alpha, \tag{23}$$

where $p = \sqrt{k'}\,\sin\alpha$.

When both the source and image are on the axis, first-order focusing can be obtained at practically any beam entrance angle. Second-order focusing can also be achieved at any value of n with properly chosen values for the other parameters. For example, in the case of (second-order) axial point-to-point focusing, $\alpha = 42.3°$ and $k = 1.31$, while $D = 5.6R_1$. The focal surface is a cone centered on the axis with an apex pointing toward the position of the detector. Calculated values of the respective parameters for first- or second-order focusing are available (Risley, 1972) with various combinations of α, n, and k. The point transmission of the CMA is high, and using second-order focusing, the accepted angular range ($2\Delta\alpha$) around the beam angle can be considerably increased at a given resolution. At larger beam angles α, the dispersion is larger, and at a given luminosity, a better resolution can be achieved even for first-order focusing—a practical limit is $\alpha = 60°$. Finite radial dimension of

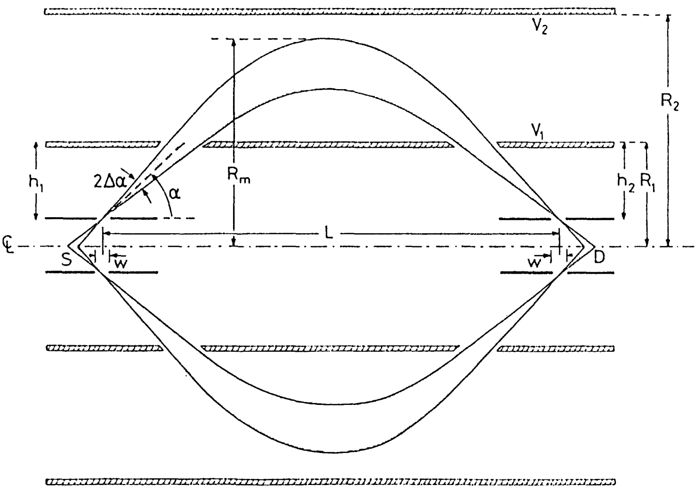

FIG. 9. Cross section of the cylindrical-mirror analyzer (Granneman and Van der Wiel, 1983, by courtesy of Elsevier Science B. V.).

the sample leads to image broadening, and the effective source area is much smaller than the actual one in the case of a radially extended source (Afanas'ev and Yavor, 1976). The "classical" (point-to-point focusing) CMA has the disadvantage of its focusing and spectrometer function (line shape and width) being very sensitive to the axial and radial position of the source (Rivière, 1990). Unfortunately, this property, including the small effective source area, largely undermines the advantage of the high transmission, resulting in low luminosity for extended samples. Therefore, the application of the CMA is most suitable for small-area excitation, e.g., for scanning Auger microscopy, where only point transmission is important. More advantageous are, from the point of view of analysis of particles emitted from extended sources, the double-pass CMA, i.e., CMA applied in series (Palmberg, 1974), with the exit aperture of the first CMA representing the entrance aperture to the second. This arrangement ensures a much better source definition, higher energy dispersion, and a considerable reduction of the spectral background by preventing the greater part of the particles scattered on constructional elements of the analyzer (as well as secondaries) from reaching the detector. Besides this, pre-retardation (e.g., by using spherical grids in front of the entrance slits) makes possible improvement of the energy resolution as well as maintaining a high luminosity by opening the slits of the second stage. For extended sources, the most favorable solution is to position the entrance (source) aperture of the first stage at the entrance slit on the inner cylinder (Varga *et al.*, 1978). A further possible application of the double-pass CMA is for angle-resolved experiments, in combination with a position-sensitive detector for angular multidetection. Figure 10 shows the arrangement of such a double-pass CMA, with the option of pre-retardation (Bosch *et al.*, 1984). By tilting the sample, angular information can be obtained both in azimuthal and in polar directions. One of the disadvantages of the cylindrical mirrors, difficult to improve, is connected with the endings of the cylinders. It is necessary to ensure the correct field distribution at the ends of the analyzer and at the same time to provide a good accessibility of the sample for irradiation. A possible solution, different from the application of equipotential electrodes or conical-shaped endings with a resistive layer (Palmberg, 1974), is the utilization of a distorted field, near the simply closed ends. The scheme of such a second-order focusing *distorted-field* CMA is shown in Fig. 11 (Varga *et al.*, 1985). Here the source and detector are situated well outside the spectrometer, thus providing an increased dispersion and, at the same time, a considerably improved accessibility of the sample and detector (an important advantage when irradiating the sample or in the case of multidetection). This type of analyzer can be easily arranged along a common axis as a double- (or triple-) pass system, with the further advantage of positioning the source between two modules for coincidence experiments or applying different potentials on the inner cylinders of the independent stages facilitating the retardation between two modules. Similar results can be obtained with conical-shaped endings, which further improves the accessibility of the sample, while keeping the second-or-

der focusing properties for the cases of point source, ring focus and ring source, ring focus as well (Tőkési *et al.*, 1994). A considerable improvement of the performance of CMAs can be achieved by applying a similar, axially inhomogeneous field that can be described by an analytical expression, adding a hyperbolic term to the formula giving the potential distribution Φ for the "classical" CMA (Siegbahn *et al.*, 1996):

$$\Phi = \Phi_0[\ln(r/l) - \tfrac{1}{2}(r/l)^2 + (z/l)^2 + \text{const}], \tag{24}$$

where r and z are cylindrical coordinates, l is the linear dimension of the analyzer, and Φ_0 is a constant. The axial potential makes possible the transformation of a large-angle input cone of the beam at the entrance slit into a small-angle output cone at the exit slit of the analyzer. This large input angle ensures a large energy dispersion and a large acceptance solid angle at the same time. A further attractive property of this type of CMA is the applicability as a mass filter with a periodically varying analyzer voltage component, or as a mass reflector with good time dispersion.

Finally, among electrostatic mirrors the *spherical-mirror analyzer* (SMA) should be mentioned most of all because of the increasing interest in its application. First described by Sar-El (1966), the SMA provides an aberration-free image of the source, without linear energy dispersion in the plane of the source and image. In most cases the source and image are located symmetrically on the diameter and inside of the inner sphere (a spherical grid). The particles start from the source in the field-free region, cross this inner spherical surface, and are then reflected by the field between the concentric inner and outer spheres. Energy separation can be made (by using baffles or an exit slit) at an intermediate focus point between the two spherical electrodes (Roy and Tremblay, 1990). Figure 12 shows the application of a hemispherical mirror for energy and angular distribution measurements (Daimon, 1988). The particles, emitted from the sample surface with the same kinetic energy, converge at the small exit aperture *A*. Their angular distribution is detected by a position-sensitive detector. Theoretically, the angular pattern obtained is distortion free, and the solid angle of acceptance is 2π sr (4π sr). The main disadvantages of the SMA are the moderate energy resolution and the difficult accessibility of the sample for irradiation. Recent improvements in the performance

(application of retarding grids at the source and the detector, and introduction of corrector electrodes) have made possible the successful application of the display-type SMA for studying the band structure of single crystals (Nishimoto *et al.,* 1993).

The combination of different types of electrostatic mirrors can result in a considerable improvement of the overall performance of the spectrometer, compensating the individual disadvantages. An example is shown in Fig. 13 for the combination of a SMA and a double-pass CMA in order to perform simultaneous measurements of high-resolution electron spectra at different angles in ion–atom collision experiments (Kövér *et al.,* 1983; Varga *et al.,* 1992).

3.1.2 Deflectors Electrostatic fields in toroidal capacitors can be used for deflection and imaging of particles entering tangentially to the equipotential surfaces. Energy dispersion occurs at the image in the plane of deflection. The equipotentials of the toroidal field are curved in two perpendicular directions having different radii of curvature. Containing the main path of particles, the main equipotential has a curvature with radius R in the radial direction (in the plane orthogonal to the symmetry axis) and r in the perpendicular (or axial) direction (in planes containing the symmetry axis). When $R = r$, the *spherical-deflector analyzer* (SDA), and in the case of $R = \infty$, the *cylindrical-deflector analyzer* (CDA) are obtained, while for the general case we speak about the *toroidal-deflector analyzer* (TDA). All reviews on electrostatic analyzers mentioned before, as well as the references therein, discuss various aspects of these types in detail, due to their widespread fields of application. The three deflectors can be used as sectors, however, with the condition for zero object and image distances (from the sector) resulting in a sector angle of 127.3° for the CDA (without focusing in the axial direction) and in a sector angle of 180° for the SDA (with the coincidence of the images in both directions). The sector angle for point-to-point focusing, as a function of the ratio of the respective radii of the toroidal deflector, exhibits two asymptotic cases at 127° and 180° (Leckey, 1987).

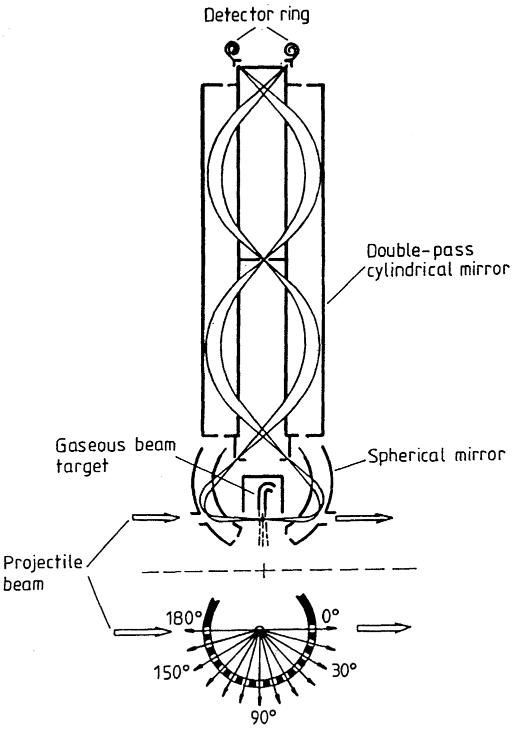

FIG. 13. Combination of spherical-mirror and double-pass CMA analyzers for simultaneous measurements of angular and energy distribution of particles (Kövér *et al.*, 1983; Varga *et al.*, 1992, by courtesy of IOP Publishing Ltd).

The radial dispersion at the focus can be expressed as

$$D = \frac{2r}{2 - r/R}, \tag{25}$$

which gives $D = 2r$ for the SDA and $D = r$ for the CDA. TDAs were recently used for obtaining good angular resolution while keeping the energy resolution and the luminosity high. They take advantage of the possibility of angular multidetection for a ring-shaped focus by using position-sensitive detectors (Roy and Tremblay, 1990; Leckey, 1987), as is shown in Fig. 14. The design, consisting of TDA sectors, is an example of the application of simultaneous energy and angular multidetection (Hellings *et al.,* 1989). The particles, scattered into different angles from the sample, preserve their angular directions and are dispersed by their energy in the radial direction in the plane of the position-sensitive detector.

One of the most popular electrostatic analyzers is the spherical deflector, with its two-directional focusing and its circular cen-

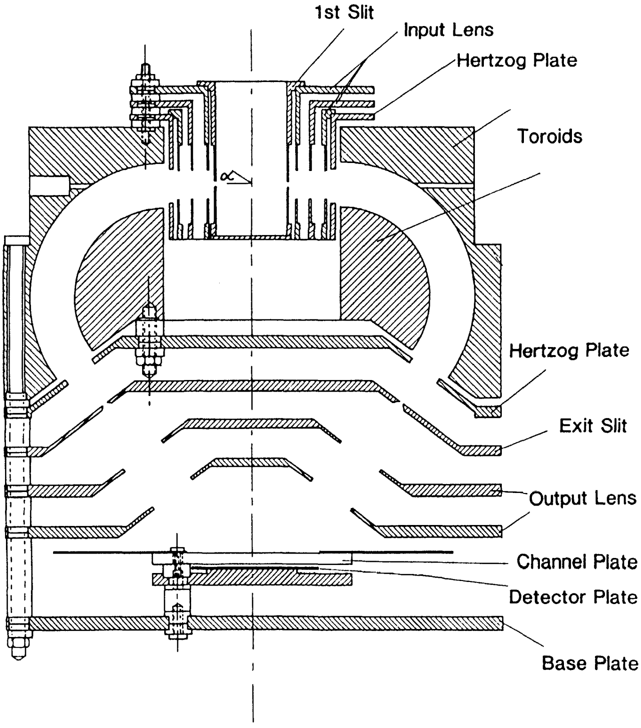

FIG. 14. Toroidal analyzer for simultaneous energy and angular multidetection (Leckey, 1987, by courtesy of Elsevier Science B. V.). The "Hertzog plates" are used for correcting the effects of the fringing fields by introducing electrode-free space between the electrode fringe and the entrance or exit slit (Nishigaki and Kanai, 1986).

tral trajectory. For practical reasons, in order to ensure the necessary space for sample irradiation and the detector, many types of spherical sectors have been developed so far, but to obtain minimal aberrations, the sector angle closest to 180° is preferred. The scheme of the 180° SDA is shown in Fig. 15, illustrating that the object and image points are located in the entrance and exit planes of the analyzer. This arrangement requires the minimization of the fringe fields (Granneman and Van der Wiel, 1983, and references therein). Spherical deflectors are often used for beam definition as particle monochromators, as well as for high-resolution energy analysis. Their space focusing and high luminosity compensates for the low entrance solid angle for point sources and the first-order focus. Because the focal surface is a plane, energy multidetection is facilitated, providing further possibilities for obtaining high-resolution lateral or angular information in the direction perpendicular to the energy dispersion in the image plane. The CDA focuses only in the radial direction and provides a line focus of a point source; therefore, its luminosity is much smaller than that of the SDA; however, it offers the advantage of the simple construction. In the case of a symmetric voltage supply ($V_1 = -V_2$), the radius of the main trajectory in a CDA sector is the geometric mean of the cylinder radii.

3.2 Nondispersive-Type Analyzers

Regarding nondispersive electrostatic analyzers, the *retarding-field* types have been used extensively for a long time, mainly in low-energy diffraction experiments (Granneman and van der Wiel, 1983). Usually these systems consist of several high-transmission, concentric spherical grids and a spherical collector. After traveling in a field-free region, retardation of particles from a sample in the center of the spheres takes place between the first two grids. Only particles having kinetic energy exceeding the retarding potential are transmitted through the grids. Therefore, varying the potential difference between the sample and collector leads to an integrated energy spectrum, the differentiation of which with respect to the retarding potential gives the spectrum itself. In order to decrease the influence of lens effects, the retarding grid is constructed of two equipotential grids, while another grid is applied in front of the collector (equipotential with the sample, the first grid and the collector) for avoiding disturbing effects from reflected particles and secondaries. Retarding-field analyzers (RFA) have very large luminosity, while being capable of high energy resolution. Due to the energy-integrating measuring mode as well as to the secondary electrons created on the grids, the level of noise is rather high and the signal-to-noise ratio is low. Improved versions of RFAs contain a cylindrical grid (and a pair of focusing spherical grids) deflecting the particles onto a small collector on the axis, converting the analyzer from a high-pass to a band-pass filter (Huchital and Rigden, 1972; Staib and Dinklage, 1977). In Fig. 16 can be seen the arrangement of Staib. Combining the advantages of retardation with energy-dispersive deflection and completed by a proper input lens, this analyzer is competitive with the dispersive-type devices (no angular information is available in this case). The direct display of the angular distribution can be achieved within a wide cone of acceptance by the help of the ellipsoidal mirror analyzer, shown in Fig. 17. Here the ellipsoidal mirror acts as a low-pass filter and reflects the pre-retarded particles into a variable aperture (preserving the original angular distribution). The energy analysis is then performed by a five-grid high-pass filter, and the image obtained by the position-sensitive detector correlates with the angular distribution of the particles emitted from the sample (Eastman *et al.*, 1980).

With pulsed sources providing a sharp time definition of the emission of (very low-energy) particles from the sample, the dispersion of their velocities can be analyzed by TOF spectrometers. Figure 18 shows the scheme of a paraboloidal electrostatic mirror adapted for this purpose (Trevor *et al.*, 1989), as a typical example. Electrons are created

by a laser pulse in the focal point of a parabolic mirror consisting of two closely spaced grids with a reflection potential on the outer grid. The parabolic shape of the mirror forces all electron trajectories to travel the same total distance to the detector along collimated paths. The flight time is dependent on the energy of the electrons at a given angle of emission, besides geometrical parameters. It is possible to achieve a good energy and angular resolution by using a position-sensitive detector.

Having a tunable, pulsed source for exciting electrons very close to the ionization threshold, the zero–kinetic energy (ZEKE) electrons can be separated from the near-ZEKE ones by the help of a delayed voltage pulse extracting the electrons created in the sample following ionization under field-free conditions. The basic principle of the

method and the scheme of a ZEKE spectrometer is shown in Fig. 19. After a given (~1 μs) delay following the ionization, the near-ZEKE electrons are separated from the electrons with zero velocity, and when the pulsed field is applied, the electrons are extracted into the drift tube and later detected by the TOF detector (Schlag *et al.*, 1993). Small differences are "time amplified" by being converted into a large difference in flight time. Moreover, while the transmission is 100% for the ZEKE electrons, a strong reduction is observed for the near-ZEKE ones.

3.3 Auxiliary Electron and Ion Optics for Transport, Retardation, and Imaging

Important elements of electrostatic spectrometers are the various lenses in front of or after the analyzer, representing an electron- or ion-optical interface between the sample and the analyzer or between the analyzer and the detector. These elements often determine the essential feature of the application (e.g., angular measurements or spectromicroscopy) as well as improving the performance of the spectrometer considerably (i.e., improving resolution and luminosity by retardation or providing optimal conditions for various kinds of sample excitation). Energy or angular multidetection also motivates the design of auxiliary lenses. The principles, types, design, and application of various lens systems are treated in the comprehensive review of Granneman and Van der Wiel (1983). Instead of dealing with details of these devices, here some examples are given for the different functions they can serve.

The arrangement shown in Fig. 20 illustrates how a CMA can scan over polar angles (20°–70°) by the help of a six-element cylindrical angle-selection lens, while simultaneously detecting electrons leaving the sample at different azimuthal angles using a position-sensitive detector (Van Hoof and Van der Wiel, 1980; Van Hoof, 1981).

A good example of the key role for additional electron optics in extending the capability of an electron spectrometer is the case of the lens system of a hemispherical deflection analyzer equipped with a two-dimensional position-sensitive detector. Separating the sample area from the analyzer and ensuring good access for handling and irradiation (as well as the possibility of differential pumping of the sample chamber), the long input lens has to provide the option of retardation of the electrons in order to improve the resolution and the luminosity, while keeping the focus always at the entrance slit of the analyzer (zoom effect) and matching the electron-emitting area on the sample to the area accepted by the analyzer (optimum efficiency). In the direction perpendicular to the direction of the energy dispersion, a wide (limited only by the length of the detector, due to the unit magnification) angular aperture at the entrance of the analyzer leads to a considerable gain in intensity at a given resolution. At the same time, however, in

this direction, as a result of the double focusing in the analyzer, the image of the source (entrance slit) can be obtained. By improving the imaging performance of the lens at high (20–25) magnification, very high (several microns) spatial resolution can be achieved (Gelius *et al.,* 1990). The five-element retarding and imaging zoom lens is provided with an exchangeable auxiliary einzel lens close to the lens entrance slit (Gelius *et al.,* 1984; Siegbahn, 1989). In order to scan over the sample surface and direct the beam accurately to a given small entrance slit at the analyzer, an octopole electric deflector is mounted inside the long central section of the lens system, surrounded by two concentric layers of magnetic shielding. While the einzel lens increases the magnification, the five-element part acts as two decoupled three-element lenses.

A completely different idea is followed in the electron optical arrangement of the ESCASCOPE instrument. The diagram of Fig. 21 shows the principle of operation of the lens system (Coxon *et al.,* 1990). There are two additional lens elements (lens 3 and lens 5) in front of the entrance and after the exit of the analyzer compared with a standard transfer lens. Lenses 1 and 2 present a magnified real image of the sample surface in the object plane of lens 3, which, converting the electrons originating from a given point of the surface within a given range of angles into a parallel beam inclined at a particular angle to the object plane of the analyzer, provides the Fourier transform of the surface image at the entrance of the analyzer. Passing through the analyzer, an energy-selected, Fourier-transformed real image is obtained at the image plane of the analyzer, and lens 5 inverts this image into a real, magnified, energy-selected image of the surface, which

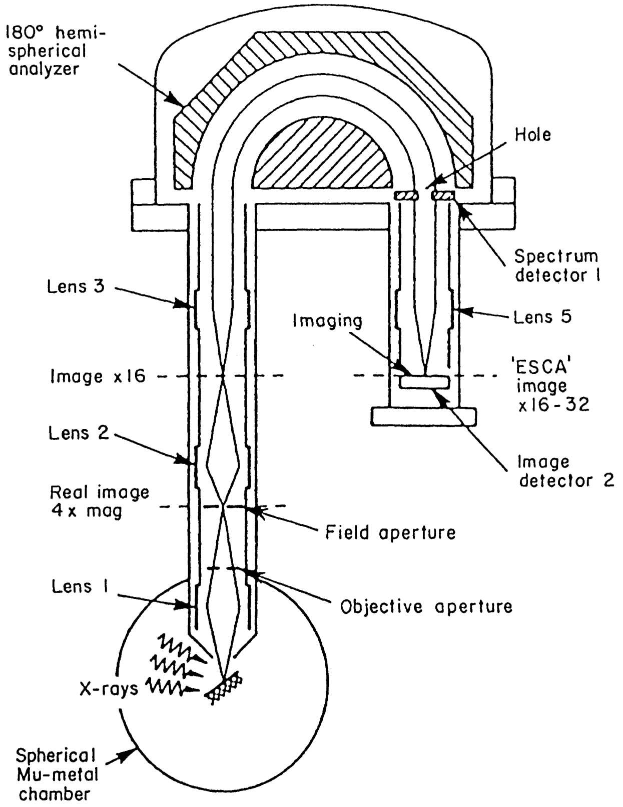

FIG. 21. The principle of operation of the lens system of the ESCASCOPE instrument (Coxon *et al.*, 1990, by courtesy of Elsevier Science B. V.).

is detected by a position-sensitive detector. A spatial resolution approaching 1–2 μm can be achieved in this way.

3.4 New Trends in Applications

Since the first period of the development of high-resolution electron spectroscopy (Siegbahn *et al.*, 1967, 1971), the proliferation of the application of electrostatic spectrometers in various fields continues. Some directions of the evolution carry promises for opening a new era in getting a direct insight into the finest details of the state and dynamic structure of atoms, molecules, and condensed systems.

Tunable laser-induced spectroscopy of excited species has reached an unprecedented level in resolution and sensitivity. In the case of resonant emission multiphoton-ionization photoelectron (or mass) spectroscopy (REMPI-PES), a photoexcited atom or molecule is photoionized, and the respective photoelectron or ion spectra are measured by using mostly TOF or ZEKE techniques, capable, e.g., of resolving the molecular rotation levels. Short-lived interface states in the band gaps between the valence and the conduction bands of semiconductors can be populated optically and photoionized by the help of picosecond or femtosecond pulse-width lasers via the "pump and probe" method, and the energy and angular distribution of the emitted photoelectrons can be measured by a TOF analyzer with angular multidetection (Haight, 1989).

Recent developments in high-resolution electron energy-loss spectroscopy (HREELS, used for obtaining information on surface vibrations and surface phonon dispersion), especially the considerable reduction of the angular aberration of the spherical deflector analyzer by applying deflection plates of optimized shape and voltage, allow attainment of a resolution below 1 meV, making HREELS competitive in this respect with infrared spectroscopy or with inelastic scattering of He atoms (Ibach, 1991, 1993). The scheme of Ibach's spectrometer is shown in Fig. 22. With a careful design, in the case of

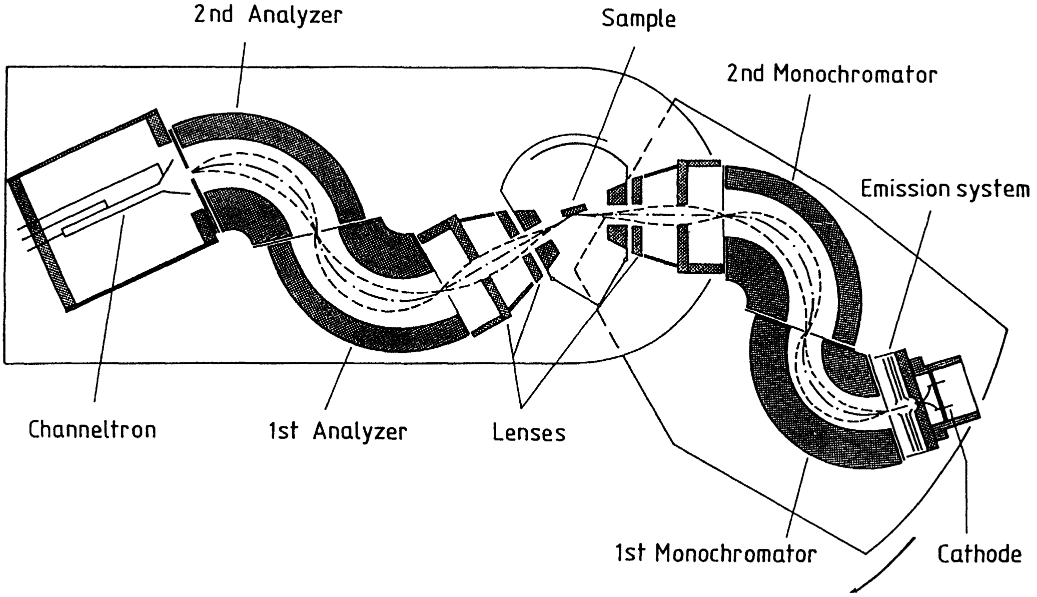

FIG. 22. A typical electron spectrometer for high-resolution electron energy-loss spectroscopy (HREELS) (Ibach, 1991, by courtesy of Springer Verlag). The electron beam emitted from the cathode is monochromatized in the monochromator system and scattered on the sample surface, while the energy spectrum of the scattered electrons is analyzed by the analyzer system with high energy resolution.

this spectrometer (measuring the monochromatic current at the sample as a function of the resolution of the monochromator and comparing to the values obtained from theoretical calculations), no indication of any extra broadening of the energy distribution due to the electron–electron scattering in dense beams known as the Boersch effect (Knauer, 1979) was found (Ibach, 1991). This effect otherwise can be minimized, and as a consequence, the energy resolution can be improved by applying thermal field (Schottky) electron emitters consisting of zirconiated tungsten tips.

The recently elaborated technique of obtaining real-space images around photoemitters by the help of direct Fourier transformation of photoelectron or Auger-electron diffraction data, collected from single-crystal surfaces (*photoelectron holography*), quickly increased the need for devices able to produce full hemispherical angular distribution (electron diffraction) data. One possibility is to scan over the polar and azimuthal angular range by an automated two-axis goniometer, fitted to a commercial hemispherical spectrometer (Naumovic *et al.,* 1993). Utilizing the scanning method and improved correction methods, atomic images with 0.2–0.3 Å (0.02–0.03 nm) accuracy can be obtained even in the case of the determination of adsorbate structures on surfaces (Trevuthasan *et al.,* 1993). Another solution is using a display-type analyzer (Fig. 17) for rapid and straightforward measurements of holograms, permitting a spatial resolution of better than 0.1 Å in transverse planes, due to the large solid angle (Petersen *et al.,* 1993).

As has been discussed in the previous sections, *chemical-state–resolved spectromicroscopy* represents a major trend in the development of electron spectroscopic instruments. There are excellent recent reviews available in this field (e.g., Margaritondo and Cerrina, 1990), reflecting the decisive impact of the development in soft-x-ray optics and of the high-brightness, third-generation synchrotrons. As an illustration, where a different concept using electrostatic lenses is followed, a photoelectron microscope is shown in Fig. 23. Combining the accelerating field of the objective and the small aperture in it and in the focal plane results in a low-pass energy filter reducing the transmission of electrons with more than 1–2 eV energy (Harp *et al.,* 1990). The magnified image is

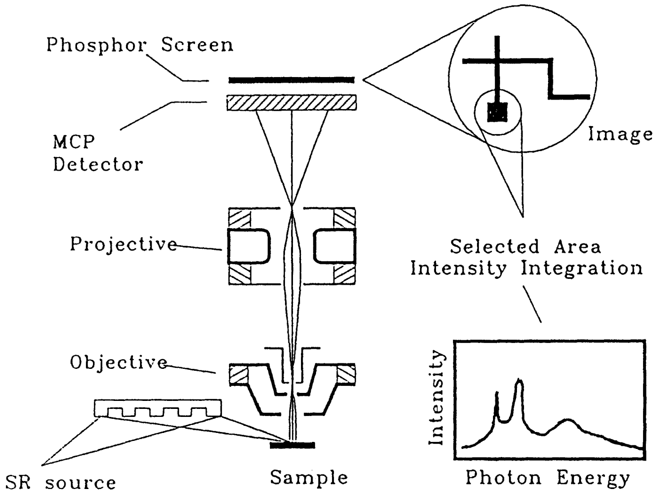

FIG. 23. Photoelectron microscope based on x-ray absorption near edge spectroscopy (XANES) (Harp *et al.*, 1990, by courtesy of The Royal Swedish Academy of Sciences). Here MCP means multichannel plate; SR, synchrotron radiation.

formed primarily by the secondary electrons, whose yield is proportional to the photoabsorption coefficient for the photon energy tuned close to the ionization threshold, applying synchrotron radiation (x-ray absorption near edge spectroscopy, XANES). The achievable spatial resolution is in the micron range.

4. SPECTROMETERS WITH COMBINED ELECTRIC AND MAGNETIC FIELD

With crossed uniform electric and magnetic fields oriented perpendicularly to each other and to the particle trajectory, it is possible to adjust the ratio of these fields to null the Lorentz force on the particle having a particular velocity, while particles with slightly deviating velocities are dispersed and can be filtered out from the beam (*Wien filter*). Minimizing the angular aberration and applying a proper deceleration/acceleration method, the combination of a Wien filter with a scanning transmission electron microscope (STEM) can lead to a high–energy-resolution electron energy-loss spectrometer with a spatial resolution of 1 nm (Batson, 1985). Figure 24 shows the approximate electron-optical ray diagram for the two orthogonal median planes in the spectrometer.

Perpendicularly crossed magnetic and electric fields can be utilized for obtaining energy dispersion of the particles in *trochoidal magnetic guides* of cylindrical symmetry, accepting particles having velocity parallel to the axial magnetic field and being deflected at the end of the guide through a distance dependent on their energy (Granneman and Van der Wiel, 1983).

For operating in a magnetically collimated spectromicroscope (Beamson *et al.*, 1980) and to make use of its axial magnetic field, an electron (positron) energy analyzer has been developed, which acts as a band-pass filter maintaining the spatial integrity of the electron image (Turner and Plummer, 1989). The analyzer design (Fig. 25) is based on a combination of electron image mirrors operating as low- or high-pass filters. In the first stage of the analyzer, the high-energy electrons are filtered out from the electron image through successive reflections by the electron mirrors in this stage, and between reflections the electrons are guided by the crossed field, finally into a high-pass filter, where the electrons having energy lower than a given value are rejected. The second stage of the analyzer, which is similar to the first one except for operating in the opposite direction, corrects the distortion of the image in the first stage. Recent improvements (Turner and Plummer, 1989) achieve a bandwidth of <10 meV for photoelectrons with energy less than 20 eV.

5. ELECTRON AND ION DETECTION SYSTEMS

Except for the direct registration by the help of a Faraday cup, electrons and ions are usually detected through secondary-electron

multiplication or by electron–hole multiplication in a surface-barrier material or counting diode. For techniques using electron multiplication, recent reviews are available (Granneman and Van der Wiel, 1983; Jede *et al.*, 1992). Detectors based on the principle of electron–hole multiplication are preferred for detecting high-energy (above 10 keV) particles, e.g., in spin analyzers; however, with rapid development of technology, they can provide a promising alternative for high-resolution multidetection.

Electron multipliers can be either *discrete anode* (CuBe or AgMg) or *channeltron* types,

providing a gain in the 10^6–10^8 range and being able to work in pulse-counting mode for low particle currents. A channeltron is a curved glass tube with an inner surface layer of a high-resistance, high–secondary-emission–coefficient material representing continuously distributed dynodes. With a high voltage applied between the ends of a channeltron, an incoming particle creates a secondary cascade leading to a gain saturable because of space charge and positive charging of the channel wall. At saturation, a narrow peak occurs in the pulse-height distribution, facilitating the discrimination of the signals from the noise after amplification. The curvature of the channeltron prevents positive feedback from the ions generated from the wall. Because of the recovery time required following a pulse, the maximum count rate is limited to about 10^7 cps. Typical pulse durations are in the range of 10 ns. Although operating only in a good vacuum like discrete anodes, channeltrons are usually less sensitive to venting or to the composition of the residual gas. The efficiency of channeltrons depends on the polarity, charge, and mass of the particles, as well as on the energy (decreasing for higher energies). When higher dynamic range is needed, secondary electrons, induced by ions from a high-voltage metallic electrode, can be accelerated to impinge onto a phosphor screen placed in the window of a photomultiplier (Daly converters: Jede *et al.*, 1992).

Position-sensitive charged-particle detectors are key elements in energy or angular multidetecting systems, as well as in image registration, and are mostly based on the application of *microchannel plates.* Such a device consists of a bundle of short capillary glass tubes, having about a 10-μm inner diameter each, ensuring a large length-to-diameter ratio. Because of the lower (10^3–10^4) gain, at least two plates should be used in series. The maximum count rate is also limited to about 10^6 cps/cm^2. The chevron-type array of the microchannels prevents positive feedback effects. Pulse durations are in the order of 1 ns, due to the small (0.5–2 mm) thickness of the plates, being an important advantage in applications for time-resolved experiments. For position-sensitive detection, various methods can be used. First, *discrete collectors* can be placed behind the channel plates. This solution ensures the highest count rate and signal-to-noise ratio; however, the size of the discrete anodes limits the lateral resolution, and sophisticated electronics are required. Another way is to apply a *fluorescent screen* on top of a fiber-optic faceplate to

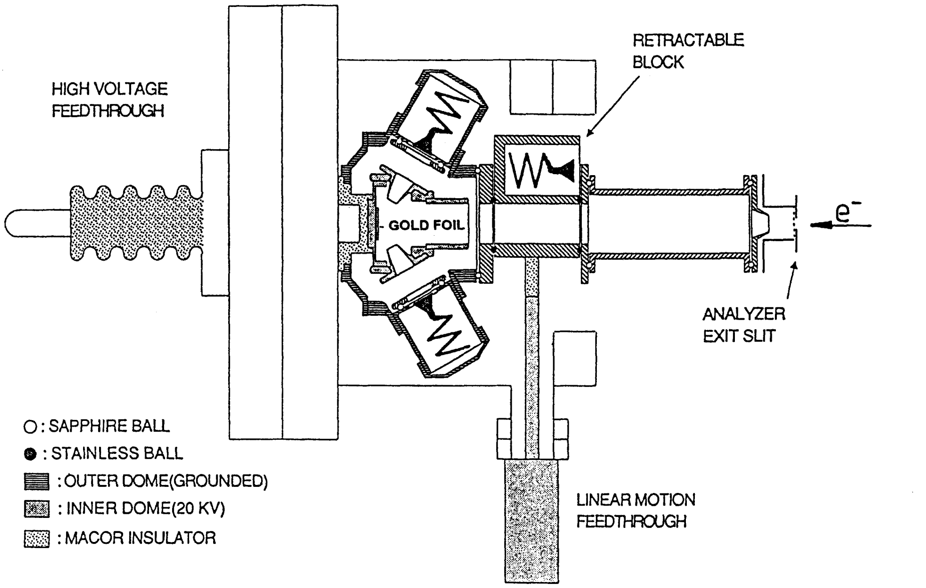

FIG. 26. Cross-sectional view of a micro-Mott spin polarimeter (Huang *et al.*, 1993, by courtesy of American Institute of Physics).

convert the electrons from the channel plate into photons detected by a (one- or two-dimensional) photodiode array or by a sensitive video camera, with digitally controlled readout and image processing. The maximum count rate is limited by the phosphor and the readout time, while the lateral resolution is affected by the broadening from the electron–photon converting and optical elements as well as by the size of the photodiodes. A third possibility is single-particle counting using a resistive anode and a respective anode encoder. In this case the charge of a pulse from the channel plates arriving at the resistive anode is divided according to the resistance ratios between its point of impact and given border points of the resistor. The position of the impact of the particle can be derived from the respective charge (voltage) pulse-height ratios and time differences. Lower count rates are expected with this solution on account of the single-particle counting character and the finite speed of the charge transport.

Detection of *spin-polarized electrons* requires different methods. The most widely used spin analyzer is the Mott polarimeter, based on the asymmetry of the angular distribution of high-energy (10–300 keV), spin-polarized electrons following scattering at large angles from a nucleus of high atomic number. This asymmetry is due to the spin-orbit interaction in the scattering process. The cross section of a micro-Mott polarimeter (Huang *et al.*, 1993) is shown in Fig. 26. It incorporates four channeltrons that detect asymmetric scattering in two orthogonal planes and a fifth retractable one, for cases with no requirement for spin analysis. Incoming electrons from the direction of the analyzer exit slit are accelerated to a gold foil at the end of the detector and biased to +20-kV potential and decelerated by the same field after scattering in front of the channeltrons. In conventional mode, the lens system focuses the electrons into the (fifth) channeltron, while in the spin-analyzing mode, it provides a well-focused beam onto the Au foil. Avoiding the application of high voltage, an alternative option is using electron spin detectors based on the principle of a low-energy (E = 150 eV) diffuse scattering method (Klebanoff *et al.*, 1993).

24.1
Introduction

γ-Rays are the highest-energy photons in the electromagnetic spectrum. Their energies range from tens of kilo electronvolts (10^3 eV, or keV) to multigiga electronvolts (10^9 eV, or GeV) and beyond. Section 24.2 provides an overview of the processes by which γ-rays interact with matter. Below a few mega electronvolts (10^6 eV, or MeV), their detection relies on photoelectric absorption, while at higher energies their interaction results in the creation of electron–positron pairs, which in turn interact with matter by initiating a cascade shower. The detection techniques in these two regimes are distinctly different. The solid-state devices used at low-to-medium energies are discussed in Section 24.3, together with their characteristics and the compromises adopted in modern large segmented detector arrays. In Section 24.4 we discuss the high-energy regime with the physical processes occurring within a cascade shower and the principal shower characteristics. Measurements on the shower allow determination of the γ-ray properties of total energy, arrival position, and arrival time. The various types of calorimeters used for such measurements, along with their characteristics, are discussed in Sections 24.5, 24.6, and 24.7.

24.2
Energy Deposition of γ-Rays in Materials

γ-Rays propagate freely in vacuum at the speed of light leaving no detectable phenomena. It is only through their interaction with matter, and, specifically the generation of charged particles, that they can be detected and studied. Figure 24.1 illustrates the contributions made by the three main interaction processes in the experimentally important sodium iodide scintillation crystal. The figure shows the components of the attenuation coefficient $a(E_\gamma)$, the parameter describing the exponential attenuation of the number N of incident γ-rays as they travel through a crystal to a depth x, as a function of the γ-ray energy E_γ:

$$N = N_0 e^{-xa(E_r)} \tag{1}$$

The dominant process at low energy (≤ 0.2 MeV) is photoelectric absorption of the γ-ray. This results in the emission of a previously bound atomic electron with all the energy of the γ-ray minus the binding energy of the struck electron. As the incident energy is raised, the next phenomenon that becomes important is Compton scattering. In this case, an atomic electron is again struck, but the γ-ray is not absorbed. Instead, the γ-ray scatters off the electron and imparts a fraction of

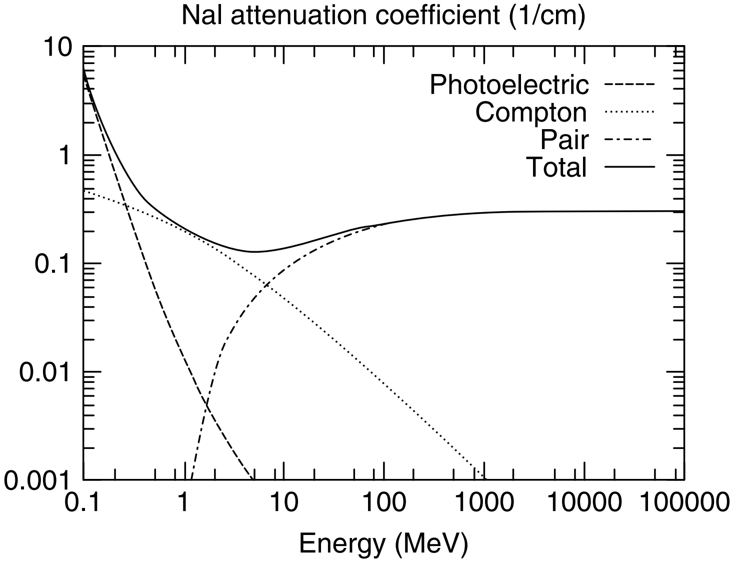

Fig. 24.1 The linear attenuation coefficient of sodium iodide and its decomposition into the contributions from the three interaction processes as a function of γ-ray energy. The results come from the EGS4 Monte Carlo computer program for electron–γ cascade shower modeling (Nelson, Hirayama and Rogers, 1985).

its energy to the struck particle, depending on the angle of scattering. This process is principally important in the transition region of energy before the onset of the third interaction phenomenon.

Pair production is the dominant process by which γ-rays interact with matter in the energy regime above the threshold energy for creating electron–positron pairs ($\geq$1.02 MeV). The γ-ray is transformed into a pair of charged particles, an electron and its antiparticle, a positron. The process requires a virtual photon from the electromagnetic field around a nucleus or electron in order to conserve both energy and momentum. However, essentially, all the γ-ray energy is split between the electron and the positron. The pair emerges nearly symmetrically arranged along the original γ-ray direction with a small average angle between the electron and the γ of $\theta_e \sim m_e c^2/E_\gamma$, where $m_e c^2$ is the rest-mass energy of the electron, 0.511 MeV.

24.3
Solid-State Detectors for Low- and Intermediate-Energy Radiation

Prior to about 1970, γ-rays in the kilo electronvolt to few mega electronvolt range were commonly detected in scintillating materials, which converted the energy deposited into visible light, one of the most common being sodium iodide – see Sections 24.4 and 24.5. A revolution took place with the advent of solid-state devices, particularly germanium counters. These detectors have evolved from tiny crystals with an active volume of a few grams to detector systems containing hundreds of kilograms of active material.

Compared to scintillators, these detectors have remarkable resolution, approaching 1 part in 1000, and are the standard choice for this energy regime.

24.3.1
Solid-State Semiconductors for γ-Ray Detection

The key advantage of using semiconductor materials for detecting electromagnetic radiation lies in the efficient conversion of the photon energy into a large number of charge carriers. The initial photon interaction produces electrons through photoelectric absorption, Compton scattering, and, for energies above 1 MeV, pair production (Section 24.2). The primary electrons thermalize in the semiconductor material, exciting many other electrons from valence states into the conduction band, thus releasing them from lattice sites and allowing them to be swept to the edge of the detector and collected as a charge pulse. In practice, with this process, there are technical issues that must be addressed. First, the material needs be very pure, to keep the number of ambient charge carriers low, and the leakage current small. Second, an electric field needs to be established throughout the detector, to efficiently collect all the charge in the conduction band, before the electrons fall back to valence states through recombination. Third, a rectifying junction needs to be established, to avoid the growth of large leakage currents as the electric field is applied. Reverse biasing this diode junction can allow strong fields to be maintained, more than kilo electronvolts per centimeter, which leads to fast and efficient charge collection. All these issues have been solved and large semiconductor counters are now commonplace for detecting photons with energies below a few mega electronvolts, where a reasonably high fraction of the γ-ray interactions can be contained within the detector material. A comprehensive review of the operating principles of such devices has been made by Knoll (1999).

There are trade-offs to be made in selecting the detector material. In principle, a material with very high density and very small band gap between valence and conduction bands would be ideal: the first to maximize the photon interaction cross section and the second to maximize the number of charge carriers generated. The high-Z aspect of the material is especially important as the γ-ray energy increases, since the probability of interaction changes dramatically both with photon energy and with the detector material (see Section 24.4). In practice, despite many years of effort, silicon and germanium semiconductors still dominate this regime of γ-spectroscopy, though new materials with higher atomic numbers and bigger band gaps, like CdZnTe and HgI_2, and others, are making significant impact in photon imaging and other fields. The band-gap issue is application specific: a small band gap results in more charge carriers, and hence better resolution, but necessitates that the detector be operated at low temperatures, which is usually about 100 K for germanium. A bigger band-gap semiconductor, like in CdZnTe, allows near room-temperature operation, but with loss of resolution. Table 24.1 summarizes the characteristics of common solid-state detector materials.

Large-volume ($>500\,\mathrm{cm}^3$ or $>2.5\,\mathrm{kg}$) germanium detectors, although expensive and requiring cooling, are the counters of choice for research in γ-ray spectroscopy, and usually for isotope identification. They can have good efficiency, excellent energy resolution, and reasonable timing characteristics. For uniform performance,

Tab. 24.1 Characteristics of materials commonly used in semiconductor γ-ray detectors.

Material	Average *Z*	Density (g cm^{-3})	Band gap (eV)	Operating temperature
Si	14	2.33	1.10	$<0\,^\circ$C

detectors are cut from a "boule," a large single crystal of germanium, grown from a molten bath of the material. The first detectors were small and required lithium drifting to keep the leakage currents low, but with improved crystal purification and growing techniques leading to larger volume and purity of material, large intrinsic detectors are now common (up to 10 cm in diameter, and 14 cm in length). These intrinsic materials still retain some impurities. These can be of *p-type*, which can have the largest physical size and highest energy resolution, or *n-type*, which are more radiation hard and can be thermally annealed to remove damage from neutron fluxes encountered in the vicinity of nuclear reactions.

There are limitations on the optimum size of a detector. As the crystals get bigger, more voltage is often needed to deplete the material and allow high internal fields. The physical drift distance for charge also grows, which leads to longer charge collection times and more chance of charge loss in trapping centers. As a result, there has been a move toward mounting multiple crystals in a single cryostat, thus increasing the overall volume of active germanium without pushing the boundaries of crystal growth or operation. The combination of many germanium counters into large arrays has increased the efficiency and sensitivity of experiments by many orders of magnitude.

24.3.2
Requirements of Large Solid-State Detector Arrays

The low and intermediate regimes of γ-rays span the range of energies normally emitted from nuclear bound states. Such emissions arise when the nucleons rearrange themselves to find their most bound configuration. The rearrangements can arise from individual protons or neutrons changing quantum orbits, analogous to atomic X-ray emission, or owing to the more collective bulk motion of nuclei. The resulting radiation has energies from tens of kilo electronvolts to a few mega electronvolts. The study of discrete γ-emissions between nuclear states as the nucleons "fall" from a highly excited configuration to their lowest and most stable arrangement, emitting a burst of γ-rays, has been the most effective tool for investigating nuclear structure. The study of such bursts, which can contain more than 40 γ-rays, requires a range of detector characteristics, sometimes conflicting.

The development of arrays of photon detectors has been progressing for more than 30 years, and is moving into a new generation, the era of γ-ray tracking. Many excellent review articles have been written about this progress, especially for arrays of large germanium counters (Beausang and Simpson, 1996; Lee, Deleplanque, and Vetter, 2003; Gelletly and Eberth, 2006; Eberth and Simpson, 2008).

To develop a spectrometer for investigating modest energy γ-rays, several issues must be considered and optimized. These include the efficiency for detecting photons, the energy resolution, angle resolution, count rate, the number of γ-rays emitted at one time (multiplicity), the time intervals between γ-emissions, and the overall spectral quality (see below). The choice of the detection material and the geometric configuration are largely governed by these issues. All these factors must also be weighed against cost, which can run from thousands to tens of millions of dollars.

24.3.2.1 **Efficiency**

γ-Rays are absorbed in material exponentially, so no detector is ever thick enough to stop all photons. At low-to-medium energies, a compromise thickness corresponding to 80% absorption of the highest-energy photons of interest is often used. The radiation from reactions is emitted in all directions, so a perfect 4π shell of detectors is a goal. In some special applications, for example in decay heat measurements of reactor fuel rods, the total calorimetric sum of γ-energy is more important that individual photons. Maximizing the absolute efficiency, by making a hermetic detector, is very important in such measurements.

24.3.2.2 **Energy Resolution**

Occasionally, just the presence of a γ-ray is important, but most often, high-energy resolution (accurately determining the exact energy of the photon) is critical. At best, with small solid-state detector arrays, energy resolutions of 1 part in 1000 can be approached across this energy regime.

24.3.2.3 **Angle Resolution**

The angle of emission of a γ-ray from a nuclear reaction contains information about the quantum numbers of the parent and daughter states of the decay. For moving nuclei, the Doppler shift of the radiation can be used to infer the lifetime of states. Practically, there is a trade-off between angle resolution and the number of detectors in the system, and how far from the source they are placed.

24.3.2.4 **Count Rate**

The operating mechanism of the detectors determines their count-rate limitation. While for fast scintillators individual counters can detect photons at megahertz rates, large semiconductors are limited to only tens of kilohertz. This has to balance against the number of detectors in the system and their distance from the source to provide a viable operating regime.

24.3.2.5 **Multiplicity**

Some nuclear reactions produce in excess of 40 γ-rays in the cooling process. To retain a good chance of catching individual photons, without any one crystal registering multiple hits, demands high segmentation.

24.3.2.6 **Time Intervals**

The cooling cascade of radiation is usually fast, and is often complete in less than 500 picoseconds (5×10^{-10} seconds). However, occasionally, nuclear states cannot easily decay, and the ‘‘hesitation’’ can be directly measured electronically, especially if the detectors have good time characteristics. Good timing is usually directly associated with high count-rate capability, but it is usually anticorrelated with good energy resolution.

24.3.2.7 **Spectral Quality**

In a perfect detector, a monoenergetic photon would always lead to a monoenergetic signal output. In practice, this never happens, either owing to the primary process (for example, loss of a Compton scattered photon from the counter), or because of detector imperfection (for example, loss of produced light or charge). The spectrum quality is usually defined as the ratio of "full energy," or "photopeak" events, to the total number of interactions. As such, it is essentially the fraction of γ-rays for which a measurement of their total energy is obtained. For low energy radiation (~0.2 MeV) this can be high, >80%, but it falls with energy as secondary photons leak out of the detector.

24.3.3
Modern Detector Arrays

To evaluate the competing criteria, a variety of *figures of merit* have been discussed, which allow arrays to be optimized for specific applications (Beausang and Simpson, 1996; Lee, Deleplanque and Vetter, 2003; Gelletly and Eberth, 2006; Eberth and Simpson, 2008). The most challenging conditions generally involve fusion-evaporation reactions, which produce nuclei at high angular momentum from which large numbers of γ-rays are emitted in the de-excitation process. In such regimes, an effective *resolving power* is frequently used, which reflects the ability to observe the individual γ-ray transitions as the nuclei de-excite. In Figure 24.2, increases in resolving power have accompanied each generation of detector systems. Detector technology is fast approaching a

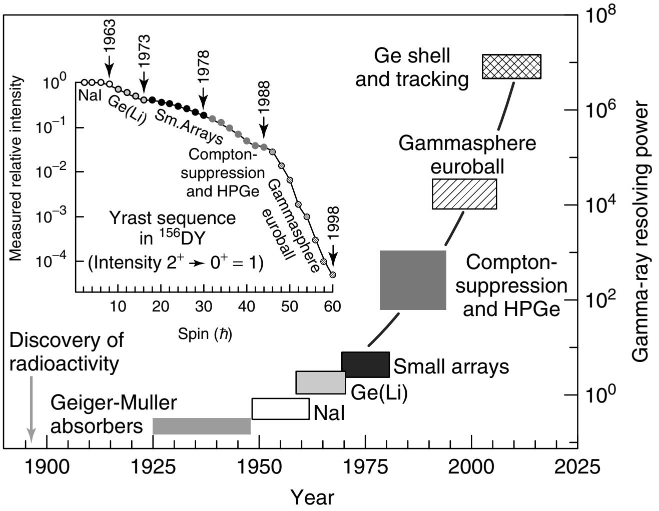

Fig. 24.2 The evolution of γ-ray detection technology from the discovery of radioactivity to the present. The *resolving power* plotted here reflects the ability to observe transitions between rare and exotic nuclear states (LRP, 2002). The insert shows a typical relative intensity for the production of the lowest energy states of a given angular momentum. Excited nuclear states decay by sequentially emitting γ-rays along this *Yrast* sequence. There is a strong inverse relationship between *resolving power* and the experimental limit for the observation of highly excited nuclear states with large angular momentum.

factor of a million in improvement since γ-rays were first observed.

The current state-of-the art detector is the *Gammasphere* array, which was built by a collaboration of US National Laboratories and Universities and has been in operation since 1996 as an international facility for nuclear physics research (Gammasphere, 2008). This is a hybrid system, consisting of 110 separate modules, each with a germanium detector mounted in a bismuth germinate (BGO) shield (Table 24.2) to suppress events in which a Compton scattered photon leaks out, thereby improving the *spectral quality*. The detector can be operated in many modes: as a calorimeter, as a multiplicity filter, or as 110 individual counters. In the high-resolution germanium operation, it has ~10% absolute efficiency for 1.33 MeV γ-rays.

New technologies to progress beyond the Gammasphere generation are currently under study as a project called the *Gamma-Ray Energy Tracking Array* (GRETA, Beausang, 2003). This will involve building a hermetic pure germanium shell. Each detector will have highly segmented electrodes that allow location of the charge deposition. This information allows

"tracking" the reconstruction of events. Tracking has many advantages, including recovering interactions where photons scatter out of the shell. The first phase of this array, a 1/4 prototype GRETINA (Lee *et al.*, 2004), is expected to be operational in 2012. For applications involving the observation of multiple γ-rays, GRETA will surpass Gammasphere by a factor of 1000.

Whenever knowledge of the precise energy has been important, solid-state detectors have revolutionized the scientific study of moderate energy γ-rays. Nonetheless, in some investigations, such as in β-decay, the total integrated flux of γ-rays is of paramount importance, as it can reveal the "strength function" distribution of the decay. This has both spectroscopic interests, for example in investigating the distribution of Gammow–Teller decay strength, and practical interest, as it is a factor in determining "decay heat" in a reactor. For these applications, hermiticity is the key factor, and large-volume scintillators still remain the best solution. For low- to medium-energy γ-rays, these are comparatively simple and inexpensive to operate. As the energy grows above the $e^{\pm}$ pair threshold, and a cascade shower begins to develop, hermiticity becomes a complex issue and the detection systems become elaborate. We discuss this in the next section.

24.4
Shower Development

There are two main processes by which energetic electrons (and positrons) are brought to rest:

1. collisions with atomic electrons, resulting in either ionization energy loss for soft collisions or division of the energy between the incident particle and the atomic electron for harder collisions; and
2. emission of a γ-ray in the electromagnetic field of a nucleus or electron, termed *bremsstrahlung*.

(For positrons, there is the additional process of annihilation, but this mainly occurs at rest and produces two γ-rays each with half the pair-creation threshold energy.) Collisional energy losses dominate at low energy, but bremsstrahlung dominates at high energy. The crossover point is at a material-dependent critical energy (Bethe and Ashkin, 1953),

$$E_c \simeq \frac{1600 m_e c^2}{Z_{\text{eff}}} \tag{2}$$

where $m_e c^2$ is the rest-mass energy of the electron, 0.511 MeV, and Z_{eff} is an appropriately weighted average of the nuclear charge of the material constituents. It is interesting to note that the dominant high-energy electron interaction, bremsstrahlung, is related by crossing symmetry to the dominant high-energy photon interaction, pair production. Thus, it is not surprising that the length of material in which a high-energy electron loses $1/e$ of its energy to radiation, the radiation length X_0 (Tsai, 1974, 1977),

$$\frac{1}{X_0} \simeq 4Z\,(Z+1)\,n\alpha r_e^2 \ln\left(183 Z^{-1/3}\right) \tag{3}$$

is approximately the same as the mean distance for a high-energy γ to travel before producing an $e^{\pm}$ λ_{pair}, where

$$\frac{1}{\lambda_{\text{pair}}} \simeq (7/9)4\text{Z}(\text{Z}+1)n\alpha r_e^2 \ln\left(183 Z^{-1/3}\right) \tag{4}$$

where Z is the charge of the nucleus, $n = \rho N_a/A$ is the atomic number density,

ρ is the mass density of the absorber, N_a is Avogadro's number, A is the atomic weight of the nucleus, α is the fine-structure constant 1/137, and r_e is the classical radius of the electron, 2.8×10^{-13} cm. Similarly, the emission angle between the bremsstrahlung γ and the initial electron is characterized by the same angle, $\theta_\gamma \sim m_e c^2/E_e$, as the pair emission.

24.4.1
Longitudinal Development

The effect of combining these two processes, bremsstrahlung and pair production, is the creation of an electron–γ cascade shower, as shown schematically in Figure 24.3. An incident γ-ray produces an electron–positron pair, which then loses energy by radiating lower-energy γ's, which, in turn, generate more pairs, and so on, until the electrons and positrons are below E_c and no longer lose significant energy by radiation. The strong forward peaking of the pair and bremsstrahlung emission means that the shower tends to progress in a straight line along the initial direction. A vastly oversimplified approximation to the showering process would be that the average energy per particle is halved in each radiation length and the number of particles doubles until the average energy is reduced to the critical energy, at which point the shower terminates. Then the linear extent of the shower is $\sim X_0 \ln(E_\gamma/E_c)/\ln 2$, and the maximum number of particles is just $\sim E_\gamma/E_c$, with approximately equal numbers of γ-rays, electrons, and positrons at each step. Finally, the integral track length of the charged particles in this simplified model is $\sim(2/3\ln 2)(E_\gamma/E_c)X_0$. More detailed calculations support the following qualitative features: that the shower depth is logarithmic in incident energy, and the number of shower particles as well as the integral track length are both proportional to the incident energy.

24.4.2
Transverse Development

After the first few radiation lengths, the transverse extent of the shower is determined by the multiple scattering of the electrons and positrons. According to the Molière theory of multiple scattering (Scott, 1963), the lateral displacement of an electron with energy equal to the critical energy traveling a distance of one radiation length defines the so-called Molière radius,

$$R_M = \sqrt{\frac{4\pi}{\alpha}} m_e c^2 \frac{X_0}{E_c} \tag{5}$$

which characterizes the shower distribution perpendicular to the shower axis. Experimentally, it is found that a

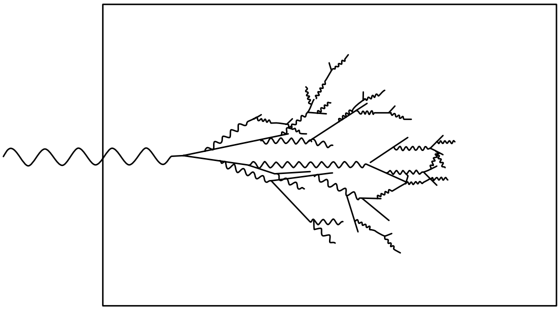

Fig. 24.3 Schematic representation of how an electron–γ cascade shower develops. A high-energy γ-ray enters from the left and produces a pair, which, in turn, emits bremsstrahlung to make more γ-rays, and so on.

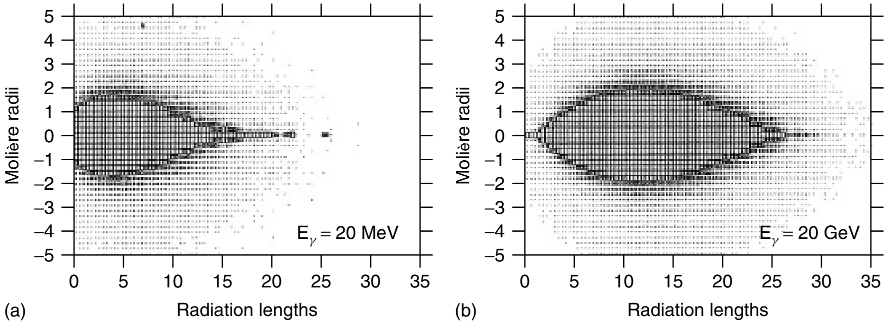

Fig. 24.4 Average relative energy deposition from an electron–γ cascade shower. The size of the box represents the amount of energy deposited in 1-cm cubes of NaI in that position, averaged over many showers. Maximum box size occurs at a level such that the saturated boxes contain 90% of the γ-ray energy. A 20-MeV γ-ray enters from the left in the plot (a) and a 20-GeV one in (b). The radiation length of NaI is 2.6 cm, and the Molière radius is 4.5 cm (see Table 24.2).

cylinder of radius $1R_M$ contains ∼90% of the shower energy deposition; $2R_M$, ∼97%; and $3R_M$, ∼99% (Kleinknecht, 1982).

Figures 24.4 and 24.5 present the results of detailed simulations of such electron–γ cascade showers in NaI with the GEANT Monte Carlo program (Brun and Carminati, 1993). Figure 24.4 shows contours of the energy deposition along and transverse to the initial direction for γ-rays of 20 MeV and 20 GeV. This is the result of averaging over many such showers. As can be seen, the factor-of-1000 increase in energy between the two showers produces a deeper penetration, by about 10 [$\simeq \log_2(1000)$] radiation lengths ($X_0 = 2.6$ cm in NaI, Table 24.2). Both showers exhibit similar radial extent, approximately equal to the Moliere radius ($R_M = 4.5$ cm in NaI, Table 24.2). Any given shower will produce a much more sparse and random energy deposition. Figure 24.5 attempts to give a feel for this by plotting the average number of 1-cm cubes of NaI in which any shower energy

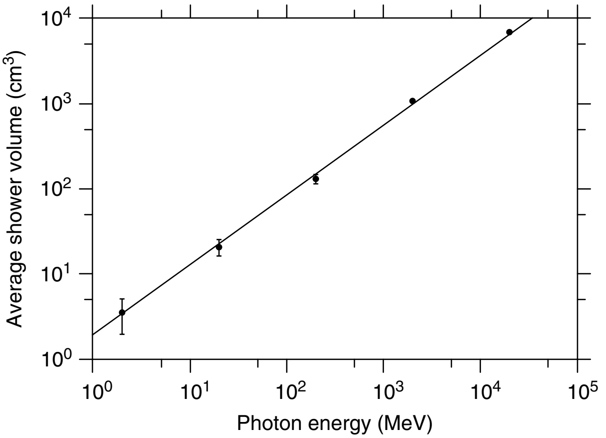

Fig. 24.5 Average number of 1-cm cubes of NaI that receive any energy deposition during an electron–γ-cascade shower as a function of shower energy. The error bars represent the variation in the number of cubes from shower to shower.

deposition has occurred as a function of incident γ-ray energy. For the 20-MeV case, this is only 20 cubes versus the 3400 cm^3 required in Figure 24.4 to contain 90% of the energy. For the 20-GeV case, the comparison is 6820 cubes versus 7000 cm^3.

24.5
Calorimetry Techniques

24.5.1
Calorimeter Types

γ-Ray detection takes place through the fundamental interactions of photons with matter described above. At high energies, the dominant process of pair production leads to electron–positron pairs, which undergo ionization and radiative energy loss in the detector material. The calorimetry technique makes use of the fact that this energy loss is proportional to the total energy deposited in the detector in order to measure the initial photon energy. There are, in general, two classes of calorimeters that are used to measure this energy. The first consists of a *totally active* detector in which all the initial energy is deposited in a material that produces an observable signal. The second is a *sampling* detector in which only a fraction of the initial energy is deposited in an active material, and the rest is deposited in a passive material and is not observed.

Totally active detectors usually consist of a high-density, high-Z material, such as an inorganic crystal or glass, which provides a high conversion efficiency for an incident photon. Table 24.2 lists some of the commonly used inorganic scintillators. The inorganic scintillators have the highest light output and provide the best energy resolution at lower energies. The last (right-most) column of Table 24.2 gives the light output relative to NaI, which yields 38 000 optical photons/MeV of energy deposited (see Table 24.3). The incident photon undergoes an initial interaction on a high-Z atom according to the processes described above, and the resulting electron or positron produces ionization, which leads to the formation of electron–ion pairs. The electrons and ions then transfer their energy to luminescent centers in the material, which can be either intrinsic, such as in a BaF$_2$ crystal, or a dopant or fluor that has been added as an activator, such as thallium (Tl) in the case of NaI or CsI. The excited luminescent centers then radiate their energy in the form of scintillation light, typically in either the visible or the ultraviolet (UV) wavelength range. In this process, each step takes place

Tab. 24.3 Efficiency factors for crystal scintillators.

Scintillator	L (γ's/MeV)	β	S	Q	η
NaI(Tl)	38 000	0.88	0.59	1.00	0.52
CsI(Tl)	65 000	0.97	0.99	1.00	0.96
CsI (pure)	2 000	0.97	0.29	0.10–0.15	0.03

Fast	1 800	<0.82	>0.9	1.00	0.08
Slow	9 950	<0.72	>0.33	1.00	0.24
CeF$_3$	3 200	0.61	0.13	1.00	0.08

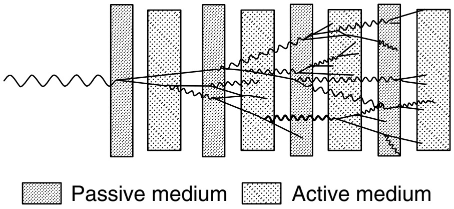

Fig. 24.6 Schematic representation of a sampling calorimeter.

with a certain efficiency that contributes to the overall scintillation efficiency of the material. If we denote the conversion efficiency as β, the efficiency for energy transfer to the luminescent center as S, and the radiative decay efficiency as Q, then the overall scintillation efficiency η is given by $\eta = \beta SQ$. Table 24.3 gives the respective efficiency factors for some commonly used scintillating crystals, taken from Lempicki, Wojtowicz and Berman (1993).

The Cherenkov materials, some of which are also listed in Table 24.2, produce light only by Cherenkov radiation and generally have a much lower light output than inorganic scintillators. Cherenkov radiation is the light emitted by charged particles when their velocity exceeds the phase velocity of light in the medium. It is a very small fraction of the total energy-loss process. These materials are therefore used most often at higher energies where the total amount of energy deposited is much higher. (The columns labeled ''Emission maximum'' and ''Decay time'' in Table 24.2 are not relevant for the Cherenkov materials. The emission is nonresonant and prompt, and so entries have been made with ''Cher.'' to identify these materials.)

A schematic representation of a sampling detector is shown in Figure 24.6. Typically, the passive medium consists of some high-density material, such as lead, which provides the high photon conversion efficiency, while a lower-density material is used as the active medium. Because only a fraction of the total energy is measured, a sampling detector generally has poorer energy resolution than a totally active detector but can be built for a much lower cost on account of the smaller quantity of active detector material required. It is therefore widely used for large-area, high-energy calorimeters.

24.5.2
Energy Measurement

There are several techniques that are used to measure the energy deposited in the active medium in both a totally active and a sampling detector. These are generally based on either the direct detection of the ionization charge or the detection of either scintillation or Cherenkov light produced in the active medium. Direct ionization can be detected in gases, liquids, or solids, and the use of these materials depends largely on the energy range of interest. Because of their low density, gases are rarely used in γ-ray detection, even in sampling calorimeters. Liquids, in particular noble liquids, are often used in sampling detectors because of their relatively high Z and the ability to collect the ionization charge easily using readout electrodes inside the detector. A high voltage is applied across the gap formed by these electrodes, which causes the charge to drift across the gap where it is collected and measured using charge-sensitive detectors. Table 24.4 lists some of the properties of noble liquids that have been used

Tab. 24.4 Properties of noble liquids.

	Liquid Ar	Liquid Kr	Liquid Xe
Density (g cm^{-3})	1.39	2.45	3.06
Radiation length (cm)	14.3	4.76	2.77
Molière radius (cm)	7.3	4.7	4.1
dE/dx (MeV cm^{-1})	2.11	3.45	3.89
Drift velocity (cm μs^{-1})	0.5	0.5	0.3
W-value (eV/ion pair)	23.6	20.5	15.6
Dielectric constant	1.51	1.66	1.95
Triple point (K)	84	116	161

for γ-ray detection. Because of its lower cost, liquid argon has been the preferred choice. All of these liquids operate at cryogenic temperatures and are typically cooled by using liquid nitrogen. Although the implementation of such noble liquid detectors is complex, nonetheless, several have been used in large-area, high-energy physics applications (DØ Collaboration, 1994; SLD Collaboration, 1984).

Plastic scintillators, again because of their low cost, are also widely used in large-area calorimeters. Table 24.5 gives a list of some of the commonly used plastic scintillators along with some of their properties. The light output is given relative to anthracene, an early material now rarely used except as the standard for reporting light output. One aspect of sampling detectors that use scintillating plastic is the need to collect the light produced onto a readout device. This is generally accomplished through the use of light guides, or by allowing the scintillation light to excite another fluorescent material known as a *wavelength shifter* that carries the light to the photodetector. The wavelength-shifting technique has been extensively used because of its ability to provide a wide variety of readout techniques. One such method is illustrated in Figure 24.7 (PHENIX Collaboration, 1993). In this example, the light from scintillation plates, which are interleaved between plates of lead, is used to excite wavelength-shifting fibers that pass longitudinally through the detector. The fibers are then bundled together at the back and read out with photomultiplier tubes (PMT). This provides a convenient way of placing

Tab. 24.5 Properties of Saint-Gobain (Bicron) plastic scintillators (Hurlbut, 1985).

Scintillator	Light output (% anthracene)	Decay time (ns)	Wavelength of maximum emission (nm)	Attenuation length (cm)	Application
BC 400	65	2.4	423	250	General purpose
BC 404	68	1.8	408	120	Fast counting
BC 408	64	2.1	425	380	Large area
BC 412	60	3.3	434	400	Large area

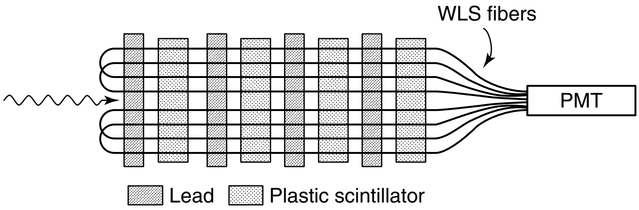

Fig. 24.7 A sampling calorimeter with wavelength-shifting (WLS) fiber-optic readout.

the readout devices at the back of the detector where they will not interfere with any of the incident particles.

Finally, sampling detectors using silicon semiconductor (Table 24.1) as the active medium have also been built and provide good energy resolution because of the large amount of charge produced. However, because of the significant cost of high-purity silicon, these detectors have only been used in rather limited, small-area applications.

24.6
Factors Affecting γ-Ray Calorimeter Response

The overall performance of a γ-ray detector can be characterized by three main categories of resolution that are important experimentally. These are energy resolution, position resolution, and time resolution. There are a number of factors that determine these properties in any calorimeter design.

24.6.1
Energy Resolution

The energy resolution of a calorimeter can be parameterized by the following expression:

$$\left(\frac{\Delta E}{E}\right)^2 = \left(\frac{a}{\sqrt{E_\gamma}}\right)^2 + \left(\frac{b}{E_\gamma}\right)^2 + c^2 \quad (6)$$

The first term is a *statistical* component and contains contributions to the energy resolution due to statistical fluctuations. These can be fluctuations in the amount of primary ionization produced (e.g., the total number of ionizing tracks produced in the electromagnetic shower), or fluctuations in the number of observed particles (either photoelectrons or ion pairs). Usually, for a high-energy shower, the number of ionizing tracks produced is large; hence, the fluctuations are rather small ($\leq 0.5\%/\sqrt{E}$), and the fluctuations in the number of observed particles dominates (Amaldi, 1981). For a sampling detector, this includes a contribution from the so-called *sampling fluctuations,* which are due to the fact that only a fraction of the energy is being detected, and this fraction can vary from one shower to the next. For high-Z inactive radiators of critical energy E_c, radiation length X_0, and total length L_x, the sampling fluctuation contribution to the energy resolution (full width at half maximum of the resulting signal) for γ-rays of energy E_γ can be approximated as (Amaldi, 1981)

$$\frac{\Delta E}{E} = 7.5\% \sqrt{\frac{L_x}{X_0}\,\frac{E_c}{E_\gamma}\,\frac{[\text{MeV}]}{[\text{GeV}]}\,\frac{1}{G(Z, \cos\theta)}} \quad (7)$$

Here, $G(Z, \cos\theta)$ is a complicated function of geometry, the Z of the radiator material, and the angle θ that characterizes the mean angular spread of particles around the shower axis, but it is typically a number between 1.0 and 1.3. In a sampling calorimeter, these fluctuations generally make the largest contribution to the statistical term in the resolution.

The term of Eq. 24.6 with coefficient b contains contributions that are fixed in magnitude relative to the observed signal. This *noise term* contains contributions from various sources of noise. These include any electronic noise in the readout devices or their associated electronics, as well as any constant background noise. Since this term goes as $1/E$, it is most important at lower energies and is often negligible at higher energies.

The term with coefficient c reflects complex functions of the detector that are rather slowly varying with energy and are often approximated by a constant. The two most important are the degree of shower containment and the uniformity of response throughout the active volume. As the fraction of the shower energy escaping a detector volume increases with increasing γ-ray energy, the fluctuations in this signal loss grow until a roughly constant plateau in resolution is reached (Dowell *et al.*, 1987). This contribution can be made small with sufficiently large detector volumes, although the associated costs increase sharply with energy.

Even for large totally active detectors, such as NaI(Tl), inhomogeneities in the crystal can be a fundamental limitation to the ultimate energy resolution one can achieve. The inhomogeneities limit the performance through the variation in light generation and collection for the same amount of energy deposited in different regions of the active volume. This is a significant limitation at moderate energies – for example, the 20-MeV shower shown in Figure 24.4 – where the variations in the shower distributions are large. The effect is much smaller at high energies where each shower fills a large detector volume (see Figure 24.5). Variations are governed by crystal impurities and defects, by deviations in the local concentrations of dopant, by the reflective properties of crystal surfaces, by solid-angle effects and the placement of the light-collection devices, and by nonuniformities in efficiency across the surfaces of the light collectors (Dowell *et al.*, 1990). Controlling, or even predicting, any one of these components is quite difficult. However, their combined effect can be studied with muons and unfolded with the techniques of computer-aided tomography (CAT, or μCAT here) (Dowell *et al.*, 1990).

High-energy muons produce only narrow, well-defined ionization tracks that can completely penetrate even large detectors. Being weakly interacting, they do not undergo nuclear reactions and can be used to deposit a known amount of energy in every element of detector volume along their path. The response to many muons traversing well-defined paths can be combined with Fourier reconstruction algorithms to produce three-dimensional images of the nonuniformities in light generation and collection. As an example, a section of such a μCAT map – a two-dimensional slice through a 24-cm-diameter × 36-cm-long NaI(Tl) crystal viewed at one end by seven 7-cm photomultiplier tubes – is shown in Figure 24.8. The gray-scale image shows the shift in the net collected signal for a nominal muon energy deposition of 5 MeV per cm of track length in each cell. (It is interesting to note that a visual inspection of the interior of this crystal failed to reveal any trace of the complex patterns evident in this μCAT map.) These nonuniformity images can be combined with Monte Carlo simulations of energy deposition in electromagnetic showers to predict

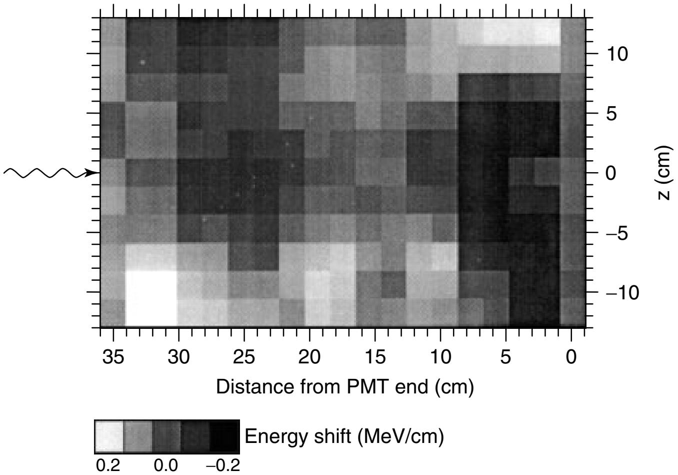

Fig. 24.8 A μCAT scan of an NaI detector, in which cosmic-ray muons deposit the same amount of energy in each cell.

accurately the resolution for γ-rays of any energy (Dowell *et al.*, 1990). On the basis of the μCAT scan in Figure 24.8, the predicted resolution for that detector is shown as the solid line in Figure 24.9, together with measured results. (For comparison, the dashed curve gives the expected behavior of a perfectly uniform detector.) Although the nonuniformities are complex and highly varying, the volume sampled by the γ-ray showers is large (see Figure 24.4) and the net effect is to produce a nearly constant resolution at high energies.

24.6.2
Position Resolution

The spatial resolution of the calorimeter is determined primarily by the density of the detector materials as well as its spatial segmentation. As mentioned earlier, the containment of a shower in the transverse direction is determined by the Molière radius. Therefore, the natural unit for transverse segmentation of a calorimeter is in cells of approximately one Molière radius square. However, the position resolution of the calorimeter will be significantly better than this, since the shower position can be determined from a fit using information from many cells that contain energy from the shower. This can be done as a simple energy-weighted average given by

$$x_{\text{measured}} = \frac{\sum \omega_i x_i}{\sum \omega_i} \tag{8}$$

where ω_i is the energy measured in the ith calorimeter cell and x is the position of that cell for the coordinate being measured. However, more sophisticated techniques are often used where the weighting parameters depend logarithmically on the energy to better account for large transverse energy fluctuations (Awes *et al.*, 1992).

24.6.3
Time Resolution

There are two main aspects of the time resolution of a γ-ray calorimeter. The first is the variation in the measured arrival

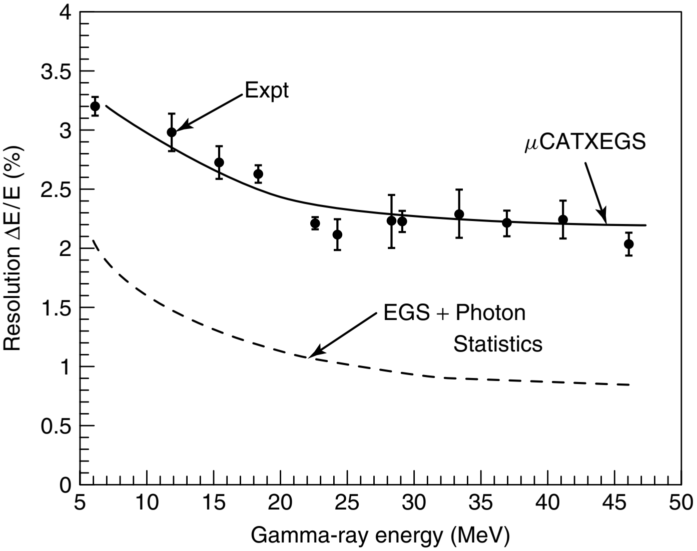

Fig. 24.9 Measured resolution of an NaI detector at several energies, the μCAT predicted resolution (solid line), and the resolution of a perfectly uniform detector (dashed curve).

time of the signal produced by an incident particle, and the second is the ability of the calorimeter to resolve two particles that are close together in time. The first aspect, called the *leading-edge* time resolution, is most important in time-of-flight applications, where the calorimeter is used to measure the transit time of particles arriving from some external source. The principle factors contributing to this resolution are

1. the variation in time in the generation of the detectable signal, which can be either optical photons from a scintillator, Cherenkov photons, or ionization charge;
2. the time variation in the propagation of that signal to the readout device;
3. the variation in time due to changes in the amplitude or shape of the electronic pulse from the readout system, including contributions from electronic noise.

In most cases, the time variation in the production of the primary signal is small compared to the other effects, since the timescale involved for producing either optical photons or ion pairs is rather short ($\leq$1 nanoseconds). The second effect, which is mainly due to light or charge collection, can be significant, especially in a large calorimeter. It is affected by the propagation time in the detection medium (see Table 24.2 for indices of refraction in optical materials and Table 24.4 for drift velocities in noble liquids), as well as the size of the detector. The third effect includes the time variation in the detector response and readout system due to differences in energy deposition. Since the observed energy is subject to statistical fluctuations, this effect can be dominant, particularly at low energies. In general, the larger the prompt signal from the detector and the faster the response time of the readout system, the better will be the time resolution. For optical detectors producing large signals and using fast readout devices, it is possible to achieve time resolutions in the range from a few tenths down to a few hundredths of a nanosecond. For charge-collection devices, depending on the size of the signal, it is possible to obtain time resolutions on the order of a few nanoseconds.

The second aspect of a calorimeter's time resolution is its so-called *pulse-pair* resolution, or resolving time. This is the ability of the calorimeter to resolve two particles closely spaced in time. The main factor determining this resolution is the width in time of the electronic readout pulse. This depends on the response time of the active material (e.g., scintillation decay times, as in Tables 24.2 and 24.5), the propagation time in the detector (e.g., drift velocities in noble liquids, as in Table 24.4), and the response time of the readout system. For a fast device, this can be on the order of a few nanoseconds. For slower detectors, it is possible to resolve two particles close in time by analyzing the pulse shape of the measured signal and comparing it with the known response for a single particle. This technique can provide improved time separation, but may give poorer energy resolution for particles whose arrival times are within the duration of the output pulse.

24.7
Readout Devices

24.7.1
Optical Detectors

γ-ray detectors that produce secondary scintillation photons need a light-sensitive readout device, and a variety of options are available. Which device is used depends strongly on the type of detector (either totally absorbing or sampling), as well as on the type of detector material used. For scintillating materials, the most commonly used readout device is the photomultiplier tube. This device, shown schematically in Figure 24.10, consists of a photocathode that converts either UV or visible photons into electrons (or, more appropriately, photoelectrons), which are then amplified by a series of electron multipliers called *dynodes*. The photoelectrons are produced with an efficiency, known as the *quantum efficiency*, that is typically around 15–25%. The photoelectrons are then accelerated in an applied electric field and they impinge on the dynode, producing several outgoing electrons for each incident electron. This process is repeated many times in subsequent stages of the photomultiplier tube until the desired gain has been achieved and the resulting charge is collected on the anode electrode. Gains of 10^6–10^8 can be readily obtained with modern photomultiplier tubes, providing the possibility of detecting even single photoelectrons and, hence, single incident photons. Photomultiplier tubes are therefore one of the most sensitive types of readout devices used for detecting scintillation light. In addition, they can be designed to have a fast response time (typically a few nanoseconds) and can therefore be used in fast timing applications. Recently, photomultiplier tubes having segmented photocathodes with separate readouts have been developed. These provide an efficient, compact way of processing signals from segmented detector arrays. The disadvantages of photomultiplier tubes are that they require rather high voltages to operate (typically 1–2 kV) and that they do not work well inside a magnetic field.

Another type of optical detector is a light-sensitive photodiode. These can be

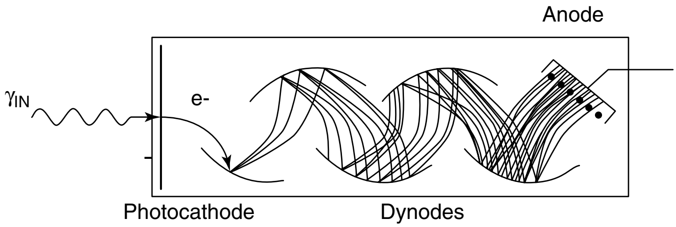

Fig. 24.10 Schematic representation of a photomultiplier tube.

either a silicon photodiode, such as those used in photocell detectors, or a vacuum photodiode, which has a construction similar to that of a photomultiplier tube having only a photocathode and anode electrode. An inherent property of these devices is that they have no intrinsic gain and therefore rely on the incident radiation to produce a sufficiently large signal to be measured directly. However, some devices, such as avalanche photodiodes, can achieve modest gains (10–100) by an amplification process within the silicon detector itself, which greatly improves their sensitivity to low light levels. The active areas of avalanche photodiodes have increased significantly in the last decade (e.g., 25 cm^2 position-sensitive units are currently available), and this has increased their use in many applications. Other types of vacuum devices, such as phototriodes or phototetrodes, are essentially low-gain photomultiplier tubes that can have large photocathode areas and can be used in other applications where modest gain is required.

24.7.2
Readout Electronics

Readout devices that have either no gain or low intrinsic gain usually require the use of a low-noise, charge-sensitive amplifier to detect the signal. The same is true for the detection of the direct ionization charge produced in noble liquids, such as those used in sampling calorimeters. In these cases, the primary signal can be on the order of only a few thousand electrons, and it is generally required to amplify this signal to the level of 10^7 electrons or more in order for it to be used for digitization and readout. This can be achieved with modern electronics through the use of low-noise amplifiers and signal-shaping techniques (Radeka, 1988). These amplifiers are used to integrate the primary charge produced in the detector and deliver a signal that has the proper pulse shape and timing characteristics for the readout system. It is also generally required to carry out this signal processing with a minimum amount of noise introduced by the electronics in order to maximize the signal-to-noise ratio. With a careful design, it is possible to achieve noise levels on the order of a few hundred electrons with signal-shaping times on the order of a few microseconds, or a few thousand electrons with shaping times on the order of a few nanoseconds. However, the choice of the appropriate signal-shaping time and noise considerations depend strongly on the specific experimental application.

Acknowledgments

We gratefully acknowledge additional contributors to the first edition of this chapter: Dr M.M. Lowry (Brookhaven

National Laboratory and Thomas Jefferson National Accelerator facility), Dr S. Hoblit (Brookhaven National Laboratory and the University of Virginia) and Dr M. Lucas (Brookhaven National Laboratory and Ohio University). We are indebted to Dr M. Riley of Florida State University for providing a version of Figure 24.2 suitable for inclusion here.

Glossary

Bremsstrahlung: γ-Ray emitted by a high-energy electron interacting with the electric field of a nucleus or atomic electron.

Calorimeter: Device that measures the total energy it absorbs.

Cascade Shower: The sequential energy-loss process in which γ-rays convert to electron–positron pairs, which then bremsstrahlung, emitting new gamma rays, and these, in turn, pair produce, and so on, until all the energy in the initial γ-ray is dissipated.

Cherenkov Radiation: Photons produced by a charged particle when its velocity in the medium exceeds that of the photons in the medium.

Compton Scattering: Elastic scattering of a γ-ray off an atomic electron.

Hermiticity: The degree to which a detector array is sensitive to all γ-rays, regardless of their directions or angles of emission from the source.

Pair Production: Transformation of a γ-ray interacting with the electric field of a nucleus or atomic electron into an electron–positron pair.

Photoelectric Absorption: Absorption of a γ-ray by an atomic electron.

Photomultiplier Tube: Device that generates a current pulse when struck by an optical photon, via a cascade multiplication of the secondary electron.

Spectral Quality: The fraction of γ–rays for which a measurement of their total energy is obtained.

25.1
Introduction

Infrared (IR) spectroscopy is spectroscopy in the wavelength region of 0.78 μm–1 mm; the corresponding wavenumber region is 12 800–10 cm^{-1} (Griffiths and de Haseth, 2007; Christy, Ozaki and Gregoriou, 2001). The IR region lies between visible and microwave regions and is subdivided into three: near-infrared (NIR) (0.78–2.5 μm; 12 800–4000 cm^{-1}), mid-IR (2.5–25 μm; 4000–400 cm^{-1}), and far-IR (25 μm–1 mm; 400–10 cm^{-1}) regions. In this chapter, we are concerned only with mid-IR region.

IR spectroscopy provides detailed information about vibrations of a molecule (Griffiths and de Haseth, 2007; Christy, Ozaki and Gregoriou, 2001). Since molecular vibrations reflect the physical and chemical features of a molecule, such as the arrangement of nuclei and chemical bonds within the molecule, IR spectroscopy is very useful not only for identification of the molecule but also for study of the molecular structure. Furthermore, interaction of a molecule with the surrounding environment also causes a change in molecular vibrations, and hence, IR spectroscopy contributes considerably in studying the interaction, too. IR spectroscopy has many uses from basic research to various applications.

The history of IR spectroscopy stretches back to the nineteenth century (Sheppard, 2002). In the 1880s, IR spectra of many basic compounds were measured, and the first commercial IR spectrometer was put on the market as early as 1913. In the beginning of the twentieth century, the idea of group frequencies of IR absorptions for spectral analysis was established. Thus, it can be said that IR spectroscopy is very old, but it has always remained one of the most useful spectroscopic techniques ever in molecular science and analytical science.

When irradiated with IR radiation, a molecule absorbs it under some conditions. The energy $h\nu$ of the absorbed IR radiation is equal to the difference between two energy levels E_m and E_n of vibration of the molecule. In the form of an equation,

$$h\nu = E_n - E_m \qquad (25.1)$$

In other words, absorption of IR radiation occurs principally on the basis of a transition between energy levels of molecular vibration. This is why an IR absorption spectrum is a vibrational spectrum of a molecule.

Encyclopedia of Applied Spectroscopy. Edited by David L. Andrews.
Copyright © 2009 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim
ISBN: 978-3-527-40773-6

Satisfying Eq. (25.1) is not always the only criterion for IR absorption to occur. There are transitions that are allowed by a selection rule (i.e., allowed transition) and those that are not allowed by the same rule (i.e., forbidden transition). In general, transitions with a change in the vibrational quantum number by ±1 are allowed and others are forbidden. This is known as a *selection rule* with respect to IR absorption. Another selection rule is one that is defined by the symmetry of a molecule. This selection rule is "IR radiation is absorbed when the transition dipole moment of a molecule changes as a whole in accordance with a molecular vibration."

Since most molecules are in the ground vibrational state at room temperature, a transition from the state $v'' = 0$ to the state $v'' = 1$ (first excited state) is possible. Absorption corresponding to this transition is called the *fundamental* band. Although most bands that are observed in IR absorption spectra arise from the fundamental, in some cases, we can find bands that correspond to transitions from the state $v'' = 0$ to the state $v'' = 2,3,4, \cdots\ldots$ (i.e., *overtone* transitions). However, since overtones are forbidden, overtone bands are very weak.

Figure 25.1 shows typical IR spectra in (a) a transmittance unit and (b) an absorbance unit. The abscissa and the ordinate of an IR absorption spectrum must now be explained. Frequency is indicated along the abscissa in units of wavenumber (cm^{-1}) (with higher wavenumbers always on the left-hand side), while *transmittance T* (%) (Figure 25.1a) or an *absorbance E* (Figure 25.1b) is expressed along the ordinate. While IR spectra include reflectance spectra and emission spectra in addition to absorption spectra, reflectance, emission intensity, and so on are expressed along the ordinate in the case of a reflectance spectrum, an emission spectrum, and so on.

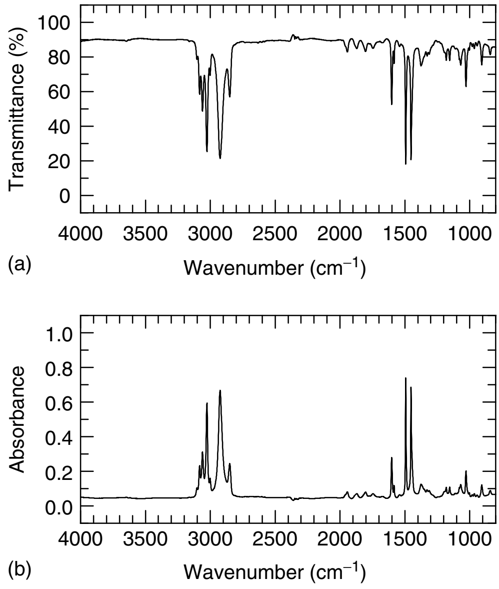

Fig. 25.1 Examples of IR spectra: (a) transmittance spectrum and (b) absorbance spectrum. (Reproduced from Christy, Ozaki and Gregoriou (2001) with permission. Copyright (2001) Elsevier.)

25.2
General Principles of Infrared Spectrometers

IR spectrometers have a long history (Sheppard, 2002). They have made remarkable progress after the Second World War. There were three revolutions in the history of IR spectrometers after the war. The first one, which occurred just after the war because of various technical developments during the war, was concerned with the development of dispersive IR spectrometers using prisms as dispersing elements. During the 1950s, diffraction gratings, detectors, and optical elements developed rapidly, and in 1960s, high-performance dispersive spectrometers with diffraction gratings became widely available commercially. This was the second revolution. The third and the biggest revolution was the advent of Fourier-transform (FT) spectrometers in the 1970s. Indeed, the advances in the field of FT-IR spectroscopy in the past 30 years have been quite remarkable.

In this chapter, we do not describe the detailed history of FT-IR spectrometers, for which many good references are available (Griffiths and de Haseth, 1986, 2007; Ferraro and Basile, 1990; Sheppard, 2002; Kauppinen and Hollberg). However, three important historical events need special mention. In 1952, Fellgett pointed out that, in principle, interferometry also provides a multiplex advantage using broadband sources in that an interferogram records the superimposed signals from all the different wavelengths presented to the detector (Sheppard, 2002). In 1958, Jacquinot emphasized the additional energy throughput advantage of interferometers over dispersive spectrometers on the basis of their circular aperture in comparison with the entrance slits of dispersive spectrometers. Another breakthrough came from the discovery of the *fast Fourier transform* (FFT) by Cooley and Tukey in 1964. The FFT is superior to the discrete FT.

Nowadays, there are two types of spectrometers used to measure IR spectra, namely, dispersive IR spectrometer and FT-IR spectrometer, although the latter is much more popular than the former. Dispersive IR spectrometer is a tool that disperses IR radiation spatially into its constituent wavelengths with a diffraction grating, a prism, or the like. Meanwhile, FT-IR spectrometer utilizes interference of radiation for the purpose of spectral separation of radiation. As each one of the two methods has its own pros and cons, no one can categorically conclude that one is superior to the other. However, FT-IR spectrometer has recently become a principal method for the following reasons:

1. It permits one to measure spectra simultaneously in the entire wavenumber region.
2. Accuracy of the wavenumbers of spectra is extremely high.
3. It secures a constant and high spectral resolution across the whole spectral region.
4. The amount of radiation reaching a detector is high as it utilizes radiation at a very high efficiency.

While FT-IR spectrometer will certainly remain a prominent IR spectroscopic method at least for the time being, dispersive IR spectroscopy could well attract a lot of attention in the future, again if multichannel detectors operable in the IR region advance and improve further. Noting that many researchers today chose FT-IR spectroscopy in almost

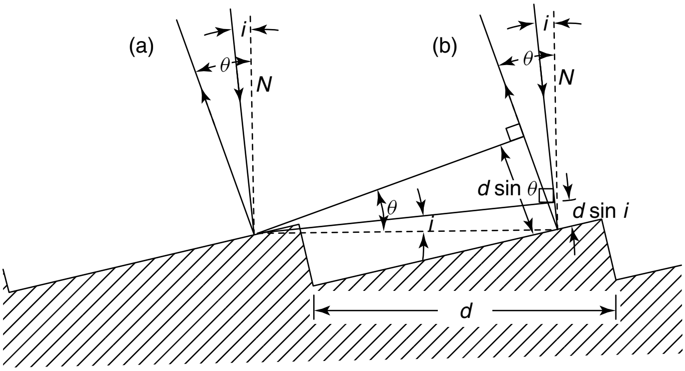

Fig. 25.2 An echelette grating, a typical reflection grating used in a dispersive IR monochromator. (Reproduced from Kauppinen *et al.* (1997) with permission. Copyright (1997) Wiley-VCH.)

all of their research activities that use IR spectroscopy, we discuss FT-IR spectrometer more in detail than dispersive IR spectrometer in this chapter.

25.2.1
Principles of Dispersive IR Spectrometers

A typical IR spectrometer consists of a radiation source, a wavelength selector, a sample compartment, a detection system, and an electronic and computer unit (Kauppinen and Hollberg; Griffiths and de Haseth, 1986, 2007; Christy, Ozaki and Gregoriou, 2001). In dispersive IR spectrometers, prisms and gratings are used as wavelength selectors. They measure a single wavelength at a time, that is, they scan over the wavelength region so that the wavelength through the selector is changed by rotating the prism or grating.

In the following part, we focus on grating spectrometer because prism spectrometer is rarely used in recent years.

25.2.1.1 **Diffraction Grating**

A grating acts like a multislit source when collimated radiation strikes it. Different wavelengths are diffracted and constructively interfaced at different angles. There are two types of diffraction gratings: transmission and reflection gratings. In grating IR monochromators, plane reflection gratings are used because transmission gratings have very poor transmission in the IR region.

Figure 25.2 shows an echelette grating, a typical reflection grating used in a dispersive IR monochromator. It has alternating reflecting and nonreflecting areas called *facets* or *lines*. The constructive interference condition for a reflection diffraction grating with the grating constant d is given by

$$k\lambda = d(\sin i + \sin\theta),$$
$$k = 0, \pm 1, \pm 2, \ldots \qquad (25.2)$$

where i is the angle between the incident radiation and the normal N of the grating (incident angle), θ is the angle between the diffracted radiation and the normal N (diffracted angle), and k is the order of diffraction.

Angular dispersion, D, which represents a variation in the diffracted angle $d\theta$ against a variation in wavelength ($d\lambda$)

is given by

$$D = \frac{d\beta}{d\lambda} = \frac{k}{d\cos\beta} = \frac{\sin i + \sin\beta}{\lambda\cos\beta} \tag{25.3}$$

The resolving power, *R*, is yielded by

$$R = \frac{\nu}{\Delta\nu} = \frac{\lambda}{\Delta\lambda} = \frac{k\pi}{\pi/N} = kN = hD \tag{25.4}$$

where, h is an order of diffraction and N is a total number of facets of a dispersive grating. $\Delta\lambda$ and $\Delta\nu$ are defined by a line width that becomes zero first from the center of a spectral line (Rayleigh's criteria).

In an echelette grating when an incident angle and a diffracted angle satisfy the following relation

$$2\alpha = i + \theta \tag{25.5}$$

where α is an angle between the facet plane and the line plane, called *blaze angle*, the intensity of diffracted radiation becomes strong. For the radiation that illuminates and diffracts with the normal of facet ($i = \theta = \alpha$), one can obtain the following relation:

$$k\lambda = 2d\sin\alpha \tag{25.6}$$

when $k = 1$ and λ_b is called the *blaze wavelength*. This is the wavelength with $k = 1$ where the diffracted radiation becomes the strongest for the grating.

25.2.1.2 **Monochromators**

Figure 25.3 depicts a typical grating monochromator used in an IR spectrometer (Kauppinen and Hollberg). By rotating the grating G or by changing the angle δ, one can scan the wavelength. For a given δ, a certain wavelength is allowed to go through the slit S_2 onto the detector D.

To judge the quality of IR monochromators, optical slit width (ΔV) and mechanical slit width (w) are important. The relation between the two slit widths is given by

$$(\Delta V)^2 = (\Delta V_1)^2 + (\Delta V_0)^2 \tag{25.7}$$

$$\Delta V_1 = \frac{V^2 wd}{kf}\cos i, \quad \Delta V_0 = \frac{V}{Nk}$$

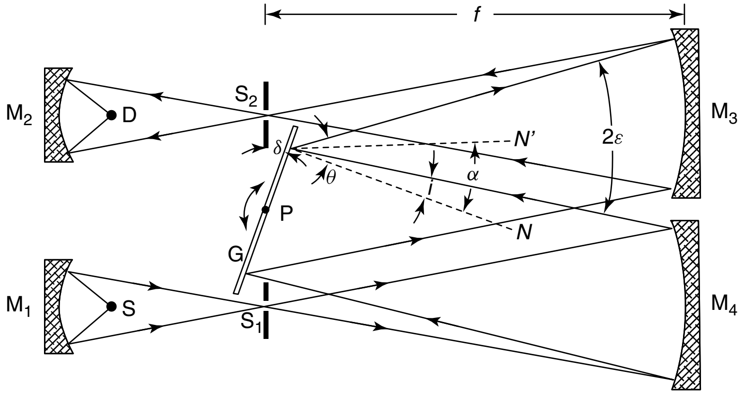

Fig. 25.3 A typical grating monochromator used in an IR spectrometer. (Reproduced from Kauppinen and Hollberg (1997) with permission. Copyright (1997) Wiley-VCH.)

where ΔV_1 and ΔV_0 are determined by a finite slit width and an infinite slit width, respectively, and f is a focal length of a collimator lens.

25.2.2
Principles of FT-IR Spectrometers

The design of many interferometers used for IR spectrometers today is based on that of the two-beam interferometers originally designed by Michelson in 1891 (Griffiths and de Haseth, 1986, 2007). Let us take a look at the principles of FT-IR spectrometers with reference to a Michelson interferometer. It comprises of a half mirror (beamsplitter) and two mutually perpendicular plane mirrors, as shown in Figure 25.4. The beamsplitter is an optical element that separates the incident ray into transmitted ray and reflected ray. Of the two plane mirrors, one is fixed (fixed mirror) and the other is movable parallel to an optical axis (movable mirror). A collimator lens shapes the rays from a light source into parallel rays, which will then impinge upon the beamsplitter. The beamsplitter separates the rays into those heading for the fixed mirror and those heading for the movable mirror (Figure 25.4). As the two rays return to the beamsplitter after being reflected, respectively, by the fixed mirror and the movable mirror, the two rays interfere with each other at the beamsplitter. The intensity of the interference wave is dependent upon how different the distance between the beamsplitter and the fixed mirror is from the distance between the beamsplitter and the movable mirror.

Let us now consider the case when monochromatic radiation is incident upon the beamsplitter. Where the fixed mirror and the movable mirror are equidistant from the beamsplitter, the optical path difference between the two rays is zero, and therefore, the two rays intensify each other. Assuming now that the movable mirror has moved by $\lambda/4$ from its position when the optical path difference is zero, the optical path difference between the two rays becomes $\lambda/2$ and the two rays weaken each other. As the movable mirror further moves by $\lambda/4$, the optical path difference becomes λ, whereby the two rays intensify each other again. The way the two rays

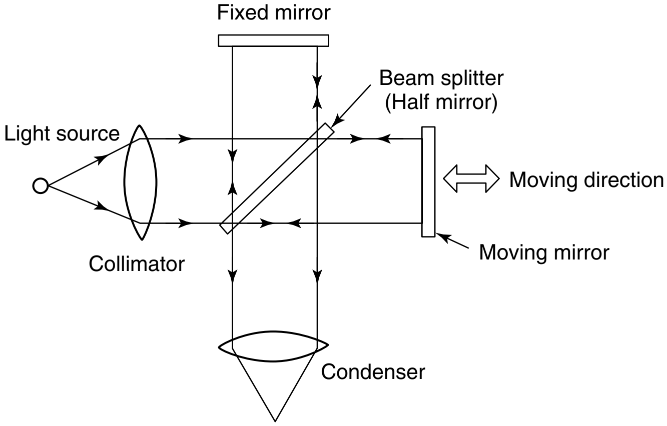

Fig. 25.4 Optical layout of a Michelson interferometer.

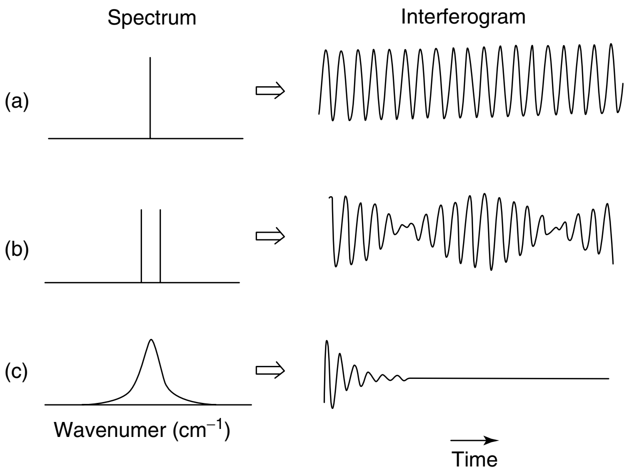

Fig. 25.5 Simple light source spectra and the corresponding interferograms from an interferometer: (a) single infinitesimally narrow line; (b) two infinitesimally narrow lines of equal intensity; (c) continuous light source.

interfere with each other thus changes as the movable mirror moves. In general, two rays intensify each other when their optical path difference is $n\lambda$ (where n is an integer) but weaken each other when their optical path difference is $(n + 1/2)\lambda$. The intensity I of radiation that we observe is expressed as a function of the optical path difference x:

$$I(x) = 0.5P(\lambda)\left(1 + \cos\frac{2\pi x}{\lambda}\right) \quad (25.8)$$

where the $P(\lambda)$ indicates the intensity of the light source. Assuming that the speed of the movable mirror is v and the time is t, x can be expressed as

$$x = 2vt \quad (25.9)$$

Substituting formula (25.9) in formula (25.8) and replacing the wavelength λ with the wavenumber $\tilde{\nu}$, we obtain

$$I(t) = 0.5P(\tilde{\nu})(1 + \cos 4\pi v\tilde{\nu}t) \quad (25.10)$$

Formula (25.10) indicates that the intensity I of radiation consists of a direct current component $0.5P(\tilde{\nu})$ and an alternating current component $0.5P(\tilde{\nu})\cos 4\pi v\tilde{\nu}t$. The alternating current component indicates that radiation of the wavenumber $\tilde{\nu}$ has been amplitude-modulated to a frequency $2v\tilde{\nu}$. If translated into a drawing, the second term in formula (25.10) is as shown in the right-hand side section in Figure 25.5(a).

The component $0.5P(\tilde{\nu})$ in formula (25.10) is what we could obtain if our interferometer is ideal. In reality, it is $0.5P(\tilde{\nu})$ times $H(\tilde{\nu})$, which is the efficiency of the beamsplitter. Let us therefore decide that $0.5P(\tilde{\nu})H(\tilde{\nu}) \equiv B(\tilde{\nu})$.

Let us now consider what happens when two rays of monochromatic radiation that have the wavenumbers $\tilde{\nu}_1$ and $\tilde{\nu}_2$ impinge upon an interferometer at the same time. In this instance, the respective rays are modulated to frequencies $2v\tilde{\nu}_1$ and $2v\tilde{\nu}_2$ and a signal indicative of the sum of them is obtained as an output (Figure 25.5b).

Where continuous ray is incident, the intensity of outgoing ray can be expressed as a function of an optical path difference.

$$I(x) = \int_0^{\infty} B(\tilde{\nu})\ (1 + \cos 2\pi\tilde{\nu}x)\ d\tilde{\nu} \tag{25.11}$$

The second term in this formula, namely, $F(x) = \int_0^{\infty} B(\tilde{\nu}) \cos 2\pi\tilde{\nu}x d\tilde{\nu}$ is an *interferogram*. As an output corresponding to each wavenumber is expressed as a cosine function as shown in Figure 25.5(a), the sum of these outputs $F(x)$ takes a maximum value at the position of $x = 0$. When x shifts from $x = 0$, the outputs corresponding to the respective wavenumbers interfere with each other in various phases, whereby $F(x)$ rapidly becomes weak while winding. Further, an interferogram has a symmetrical profile as $F(x)$ is an even function (i.e., $F(x)$ does not change even when x is replaced with $-x$).

Introducing functions $Be(\tilde{\nu}) = B(\tilde{\nu})/2$ ($\tilde{\nu} \geq 0$) and $Be(-\tilde{\nu}) = Be(\tilde{\nu})$, we obtain

$$F(x) = \int_{-\infty}^{\infty} Be(\tilde{\nu}) \cos 2\pi\tilde{\nu}x d\tilde{\nu} \tag{25.12}$$

Hence,

$$Be(\tilde{\nu}) = \int_{-\infty}^{\infty} F(x) \cos 2\pi\tilde{\nu}x dx \tag{25.13}$$

Formulae (25.12) and (25.13) form a famous FT pair. In short, the interferogram $F(x)$ is obtained through Fourier transformation of $Be(\tilde{\nu})$ and the spectrum $Be(\tilde{\nu})$ is obtained through Fourier transformation of the interferogram $F(x)$.

While FT-IR thus requires measuring an interferogram first and Fourier transformation of the interferogram on a computer thereafter for rendering of a spectrum, an actual spectroscopic system is inclusive of a few more complex processes. First, although integration in formula (25.13) is from $-\infty$ to $+\infty$ of an optical path difference x, this is not realistic. An *apodizing function* is therefore introduced for integration within a finite range after measurement of $I(x)$ while moving the movable mirror within a finite range.

Figure 25.6 shows typical examples of apodizing functions. We introduce an apodizing function $A(x)$ whose profile is shaped as a rectangular wave,

$$A(x) = \begin{cases} 1 & (|x| \leq L) \\ 0 & (|x| > L) \end{cases} \tag{25.14}$$

and we obtain the following definite integration to replace formula (25.13):

$$Be'(\tilde{\nu}) = \int_{-\infty}^{\infty} A(x)F(x) \cos 2\pi\tilde{\nu}x dx \tag{25.15}$$

Since $A(x)$ has a finite value only within the range of $|x| \leq L$, $A(x)$ limits the range of integration. $Be'(\tilde{\nu}) = \widetilde{A(x)F(x)}$ (where the symbol $\sim$ is used to denote Fourier transformation) is a convolution of $\widetilde{A(x)}$ and $\widetilde{F(x)}$ ($= Be'(\tilde{\nu})$) according to the theorem of convolution.

$$Be'(\tilde{\nu}) = \widetilde{A(x)} * \widetilde{F(x)} = \widetilde{A(x)} * Be(\tilde{\nu}) \tag{25.16}$$

Formula (25.16) indicates that the resultant spectrum is multiplication of spectrum $Be'(\tilde{\nu})$ with an instrument function $\widetilde{A(x)}$. It is therefore very important to know the profile of the instrument function $\widetilde{A(x)}$. Calculating $\widetilde{A(x)}$, we obtain

$$\widetilde{A(x)} = \frac{\sin(2\pi L\tilde{\nu})}{\pi\tilde{\nu}} \tag{25.17}$$

This function is similar to the function shown in Figure 25.6(a). The half width

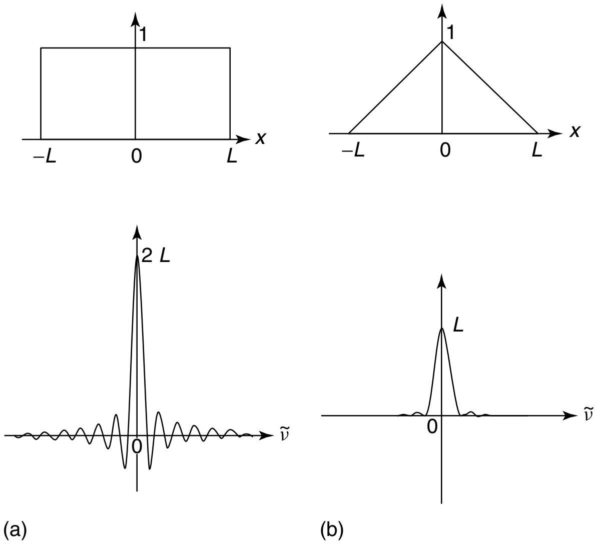

Fig. 25.6 Apodization functions and their corresponding instrument lineshape functions: (a) boxcar truncation and (b) triangular apodization.

of this function has a value $0.6/L$. As a half width determines the spectral resolution, the longer the distance L through which the movable mirror moves, the better the spectral resolution becomes. An instrument function, as that shown in Figure 25.6(a), has a major disadvantage that it includes associated ripples at which it yields positive and negative values. Using the following function $A'(x)$ (Figure 25.6b), we have

$$A'(x) = \begin{cases} 1 - |x/L| & (|x| \le L) \\ 0 & (|x| > L) \end{cases} \tag{25.18}$$

as an apodizing function instead of the function shown in Figure 25.6(a); the instrument function becomes as shown in Figure 25.6(b). In the case of this instrument function, although the half width is $0.88/L$ and the spectral resolution is slightly inferior to what it is in Figure 25.6(a), problems of an associated ripple, a rebound toward the negative side, and the like are suppressed better. Several apodizing functions are implemented in FT-IR spectrometers that are available in the market. One needs to choose a suitable apodizing function in accordance with their purpose.

The second issue on an actual spectrometer is that an interferogram is not an even function but is asymmetric in reality for various reasons. A process called *phase correction* is necessary to solve this.

The flow of an FT-IR signal is described here. Figure 25.7 shows the structure of a spectroscopic unit of an FT-IR spectrometer and the behaviors of the signal within components that form the spectrometer. Radiation from a light source (denoted in [1] in Figure 25.7) impinges upon an interferometer via an incident hole. At the interferometer, the radiation is modulated into frequencies that are

proportional to the respective wavenumbers (denoted in [2] in Figure 25.7).

Leaving the interferometer, the radiation impinges upon a measurement sample that absorbs radiation whose wavenumbers are unique to the sample. Section [3] in Figure 25.7 illustrates absorption of radiation having the characteristic wavenumbers by the sample (Section [3] in Figure 25.7 shows the signal as a spectrum for the simplicity of illustration although an actual signal has the shape of an interferogram). A detector converts the radiation from the sample into an electric signal (the section [4] in Figure 25.7). After being amplified by an amplifier, the electric signal is converted into a digital signal by an A/D converter via a sample hold circuit (which samples the signal) (Section [5] in Figure 25.7). The AD-converted interferogram is fed a set number of times to a computer and accumulated (Section [6] in Figure 25.7). Thus, the accumulated interferogram has the shape of a Fourier-transformed spectrum as shown in Figure 25.8(a).

Fourier spectroscopy is bright because it requires simultaneous capturing of incident radiation and simultaneous measurement of the spectrum in the entire wavenumber region. As the spectrum thus measured is inclusive of the emission spectral characteristic of a light source, the spectroscopic characteristics of an interferometer and a detector and the like, without any processing, it is necessary to measure a background spectrum (Figure 25.8b) and divide the observed spectrum by the background spectrum (Figure 25.8c). The resultant spectrum is a transmission spectrum $T(\tilde{\nu})$. We can calculate an absorbance spectrum $E(\tilde{\nu})$ (Figure 25.8d) using the following formula:

$$E(\tilde{\nu}) = -\log_{10} T(\tilde{\nu}) \tag{25.19}$$

25.2.3
Advantages of FT-IR Spectrometers

It is worth summarizing the three major advantages of FT-IR spectrometers.

25.2.3.1 Fellgett Advantage (Multiplex Advantage)

The biggest advantage of FT-IR spectrometer is the simultaneous detection of the whole spectrum at once. Even though a factor of 2 in signal strength is lost because half the beam is reflected back to the source, the multichannel advantage is nevertheless 10^4 or higher. That is, theoretically, an interferometer can achieve a signal-to-noise (S/N) ratio comparable to that of a dispersive monochrometer 10^4 times faster.

25.2.3.2 Jacquinot Advantage (Throughput Advantages)

Total radiation power on a detector is much higher in a Michelson interferometer than in a grating instrument because at the optimum resolution the area of a circular aperture (the Jacquinot stop) in an FT-IR spectrometer is about 200 times larger than a slit in a grating spectrometer.

25.2.3.3 Connes Advantage

Connes advantage arises from the ability of interferometry using a monochromatic source to accurately and precisely index the retardation, resulting in a superior determination of the retardation sampling position.

25.2.4
Phase Correction

An interferogram measured in the real world, however, has an asymmetric shape because of various reasons although it is supposed to be symmetric with respect to a position of zero optical path difference, and it is therefore impossible to obtain an expected spectrum through mere Fourier cosine transformation of the interferogram (Griffiths and de Haseth, 1986, 2007; Christy, Ozaki and Gregoriou, 2001). The causes of the asymmetric shape include those attributable to a thickness difference between a half mirror and a compensator plate of a beamsplitter, those attributable to the frequency characteristics of an electric circuit system, those attributable to a deviation of the optical path of the main interferometer and that of the associated (laser) interferometer, and so on. Thus, we need what is called *phase correction*. Phase correction is the correction of an asymmetric interferogram into a symmetric interferogram. Equation (25.20) shows the modified relation for the intensity of the interferogram.

$$I(x) = \int_{-\infty}^{\infty} B(\tilde{\nu})\,[1 + \cos(2\pi\tilde{\nu}x + \Phi_{\mathrm{BS}}(\tilde{\nu}))]\,d\tilde{\nu} \qquad (25.20)$$

where $\Phi_{\mathrm{BS}}(\tilde{\nu})$ is the wavelength-dependent phase shift introduced by the beamsplitter.

Phase correction is the mathematical procedure to remove the sine components from the interferogram. There are two popular phase correction algorithms used in single-sided interferograms: the Mertz algorithm and the *Forman* algorithm. In the former, the largest data point in the interferogram is assigned as the zero retardation point and the amplitude spectrum is calculated with respect to this point. A short double-sided interferogram is measured and its corresponding phase array is used to phase correct the entire single-sided spectrum. The *Forman* correction is essentially equivalent to the Mertz routine but it is performed in the retardation space. Besides phase effects, one must consider the effects of beam divergence, of mirror misalignment, and poor mirror drive for the performance of FT spectrometers (Griffiths and de Haseth, 2007).

25.3
Components of FT-IR Spectrometers

The basic components of dispersive spectrometers and FT spectrometers are the same with the exception of the interferometer (Kauppinen and Hollberg; Chalmers and Griffiths, 2002; Griffiths and de Haseth, 2007; Christy, Ozaki and Gregoriou, 2001). Any differences are within the elements and are the result of the different ways in which the source radiation is detected. For example, sensitive thermocouple detectors are commonplace in dispersive instruments, whereas they are not appropriate for rapid-scanning instruments.

25.3.1
Light Sources

Requirements for an IR light source are that the spectrum distribution of the light source is close to that of black body radiation, the light source offers stable emission for long periods of time, the lifetime of the light source is long, and so on. A globar lamp, Nernst heat generator, a nichrome heat generator, and the like have often been used; however, nowadays, ceramic sources have become more popular.

25.3.2
Interferometers

As shown in Figure 25.9, an interferometer of an FT-IR spectrometer is formed by a main interferometer and an associated

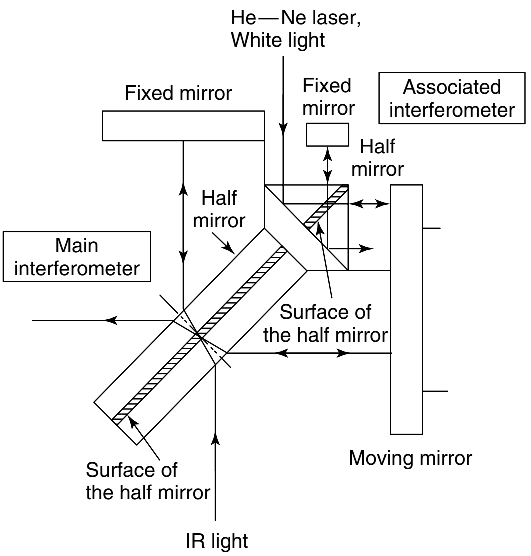

Fig. 25.9 Main and attached interferometers.

interferometer. The associated interferometer is attached for monitoring of an optical path difference x of the main interferometer. Like the main interferometer, the associated interferometer is formed by a half mirror, a fixed mirror, and a movable mirror (which is shared by the main interferometer). The associated interferometer accepts both white light and He–Ne laser radiation and outputs interferometer output signals corresponding to the two types of radiations. The interferometer output signal resulting from the white light is used to denote when to start sampling the interferogram that the main interferometer yields. Meanwhile, the interferometer output signal resulting from the laser radiation is used to monitor the location of the movable mirror and instruct sampling of the interferogram, which is obtained by the main interferometer.

Spectra measured by FT-IR spectrometers have extremely high (on the order of 7 or more digits) wavenumber accuracy. This is because a Michelson interferometer directly reads the frequency of incident radiation while referring to an optical path difference determined by the emission wavelength of the He–Ne laser whose accuracy is on the order of 7 or more digits.

25.3.3
Sample Compartments

Sample compartments of commercial FT-IR spectrometers are quite different from each other depending upon models. We must pay extra attention to the shape of a ray, to where the ray converges, and to a method for measuring the ray. Cross section of the ray is usually circular and converges in the central part of the sample compartment (when the sample compartment is of the center-focus type) or on a wall surface of the sample compartment (when the sample compartment is of the side-focus type) or remains as a parallel beam without converging. We need to adequately utilize the size and the shape of a ray to enjoy the full capability of an FT-IR spectrometer. When setting a cell or accessory to a sample compartment, therefore, we must make sure that the cell or accessory will not block the ray as much as possible.

FT-IR measurement methods include those of a single-beam type and those of a double-beam type. The former is a method for measuring spectra with a measurement sample and a reference sample set alternatively on the same optical path, and is superior in terms of ordinate accuracy because of the use of the same optical path. When we use a single-beam method, we must be careful about any change in measurement environment with time. This is because any change in measurement environment with time will deteriorate the reproducibility of an ordinate. When choosing a double-beam method, we set a measurement sample and a reference sample on different optical paths at the same time and measure the samples alternately for a designated number of integration times. While the measurement environments are considered to be approximately the same, a difference with respect to the optical capabilities between the two optical paths, if any, will give rise to a problem with ordinate accuracy. The two methods thus each have their own pros and cons. This has led to the development of what is known as a *sample switching double-beam method* that enjoys the advantages of the two methods. Where the sample switching double-beam method is used, measurements are taken principally by a single-beam method while a measurement sample and a reference sample are set simultaneously on separate optical paths. After measurements are taken up to a designated number of integration times, an automatic switch mechanism switches the measurement sample and the reference sample and measurements are taken again. Resultant spectra are extremely reliable as the measurement sample and the reference sample are measured on the same optical path in the same environment. The air-tightness of the environment against external air is always critical to any measurement. IR absorption by carbon dioxide, vapor, and the like contained in the atmosphere is strong, and therefore, no matter how strong the spectral correction using a reference sample may be, the influence of the IR absorption will remain persistently. It is important to close the sample compartment airtight, fill the sample compartment with nitrogen gas, dry air, or the like and take the measurement with vapor and carbon dioxide sufficiently removed.

25.3.4
Detectors

Requirements for an FT-IR detector include, among others, that (i) the sensitivity of the detector be high; (ii) the detector remain sensitive in a wide wavenumber region; (iii) a radiation-receiving surface of the detector be large to a certain extent (so as to leverage on the "an optical system is bright" is a characteristic of FT-IR); (iv) the detector be sensitive to a wide frequency region; and (v) the detector exhibit a linear response to the intensity of incident radiation. IR detectors can be divided into two types: thermal detectors and quantum detectors. The former detectors sense the variation in temperature of a detector material due to absorption of the IR radiation. In quantum detectors, incident IR photons result in the production of free charge carriers in the responsive element. No serious temperature change in the element takes place during this process. TGS (tryglycine sulfate) detectors and MCT ($Hg_{1-x}Cd_xTe$; $x \sim 0.2$) detectors are often used in FT-IR spectrometers. The former detectors, utilizing the pyroelectric effect, are characterized by their relative inexpensiveness and sensitivity to a wide IR region. The latter detectors are semiconductor detectors that utilize the photovoltaic power caused by optical absorption by semiconductors or the photoconductivity effect, and are more sensitive than TGS detectors.

25.3.5
Beamsplitters and Mirrors

A typical beamsplitter IR instrument is of the germanium (Ge)-on-potassium bromide (KBr) substrate type. Recently, semiconductor film beamsplitters, which are formed from self-supporting semiconductors, including carbon films, have been described. Preferably, the beamsplitters are formed from silicon, germanium, or diamond films.

25.3.6
Amplifiers and AD Convertors

An interferogram converted into an electric signal by a detector is fed to a computer via a preamplifier, a main amplifier, an electric filter, a sample-hold circuit, and an analog-to-digital (A/D) convertor.

The amplifiers amplify the interferogram up to the input level of the A/D convertor without distortion. The electric filter removes unwanted signals belonging to a high-frequency region and noises that arise from sampling. These electric systems are designed so that their noises are smaller than those caused by the detector, permitting the detector to exhibit its capability adequately.

The A/D convertor is one of the factors that restrict the S/N ratio of FT-IR. Where a high-sensitivity detector such as an MCT is used for measurement, the S/N ratio of an incoming interferogram to the A/D convertor may be significantly high and exceed the dynamic range (the solution power to convert a signal) of the A/D convertor in some instances.

25.4
Various Types of FT-IR Interferometers

25.4.1
Continuous-Scanning Interferometers

Most commercially available FT-IR spectrometers use the continuous-scan mode of operation, where the movable mirror scans at constant velocity. This type of scanning works very well for routine measurements. Also, the fact that continuous-scanning interferometers can measure an interferogram in a time of 1 second or less makes them excellent tools to follow time-dependent processes. In the continuous-scan mode of interferometry, the laser fringe counter is used to sense the accuracy of the scanning velocity. If a deviation is sensed, correction signals are generated that assure proper operation (constant velocity). The consequence of this mode of operation is that each IR wavelength (λ) is modulated at its own particular Fourier frequency, given by Eq. (25.21):

$$f(\lambda) = \frac{2v}{\lambda} \tag{25.21}$$

where v is the mirror velocity.

25.4.2
Step-Scan Interferometers

Step-scan interferometers are powerful for time-resolved FT-IR measurements (Griffiths and de Haseth, 2007; Christy, Ozaki and Gregoriou, 2001). By using a step-scan FT-IR spectrometer, one can monitor much faster reactions if a reaction or sample perturbation is repeatable. In the step-scan interferometer, the optical path difference is held constant over the course of the reaction or perturbation. The optical path difference is then changed, typically by one wavelength of the He–Ne laser, and the process is repeated. This procedure is reiterated at constant intervals of retardation until the optical path difference is sufficiently high that the desired spectroscopic resolution has been reached.

In step-scan FT-IR data are collected while the retardation is held constant or is oscillated about a fixed value. Therefore, to apply the technique to mid-IR and shorter wavelength measurements, a method for controlling the retardation and implementing a special sampling rate comparable to that achieved in modern continuous-scan instruments is required. In recent years, different control methods have been reported. However, all of these basically rely on the use of the He–Ne laser fringe pattern to generate the control signal and to determine the stop size. The biggest advantage of the

Copyright (1992) Society for Applied Spectroscopy.)

step-scan mode is the separation of the time of the experiment from the time of the data collection.

25.4.3
Asynchronous Time-Resolved FT-IR Spectrometer

In 1992, Masutani *et al.* (1992) proposed a time-resolving method for a conventional FT-IR spectrophotometer, which does not require synchronization between the timing for time resolving and that for the sampling of the AD converter. The system was named as an *asynchronous time-resolving system*. This method has the following advantages: (i) the signal-proceeding assembly for time-resolving measurements can be attached to any kinds of commercial FT-IR spectrometers and (ii) in principle, there is no shortest limit in time for transient phenomena to be measured.

Figure 25.10 shows a typical set up for the asynchronous time-resolved

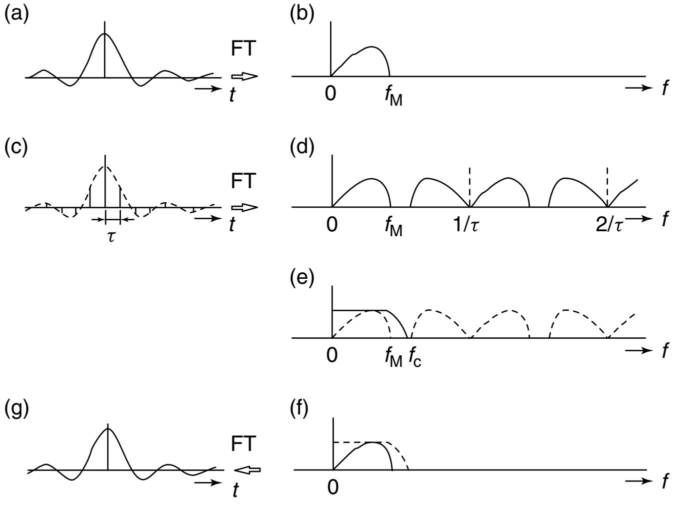

Fig. 25.12 Role of the low-pass filter. (a) An analog interferogram; (b) the spectrum corresponding to the analog interferogram in A with a maximum modulation frequency f_M; (c) a discrete interferogram (full line) with a sampling time interval t and its envelope (broken curve) corresponding to the analog interferogram in (a); (d) the spectrum obtained by inversely Fourier-transforming the discrete interferogram in (c); (e) frequency response of the low-pass filter with a cutoff frequency f_c (full curve) and the same spectrum as in (d) (broken curve); (f) output spectrum from the low-pass filter (full curve) and the same frequency response as in (e) (broken curve); (g) output analog interferogram from the low-pass filter (to be obtained by Fourier-transforming the spectrum in (f)). (Reproduced from Masutani *et al.* with permission. Copyright (1992) Society for Applied Spectroscopy.)

measurement (Masutani, 2002). Figure 25.11 depicts shapes of the signals in processes A–H in Figure 25.10 in alphabetical order: The main feature of this method is the use of a low-pass filter placed between the gate circuit and the A/D converter. The role of the low-pass filter is explained in more detail in Figure 25.3.

Figure 25.12 (a) and (b) shows an analog interferogram for radiation from the light source and a corresponding spectrum obtained by inversely Fourier-transforming the interferogram. When a discrete interferogram (c) obtained by sampling this analog interferogram by the gate circuit is inversely Fourier transformed, the spectrum obtained (d) consists of the original component and others that appear at the position determined by multiplying the sampling frequency $1/t$ by integers. Therefore, when this discrete interferogram is passed through a low-pass filter with an appropriate cutoff frequency f_c (e), the high-frequency components

are eliminated (f). The output spectrum (f) is identical to the spectrum (b) for the analog interferogram before sampling. Consequently, the analog interferogram (g) is obtained from the low-pass filter. Although the above Fourier transformations are not actually done by the low-pass filter, it has the function, in effect, as described above.

Figure 25.13 shows a typical setup of the multichannel asynchronous time-resolving system. The time-resolving module of the system has 32 time-resolving units, each of which consists of a gate circuit, a low-pass filter, and an A/D converter. In this system, time resolving is performed by setting each gate circuit at a different time delay. The sample is excited by repetitive stimuli at constant intervals, which do not depend upon the sampling timing of the FT-IR spectrometer. The sample excitations result in transient transmission differences, and thus the analog interferogram is modulated at very high frequency because of the repetitive excitation of the sample. The low-pass filters eliminate high-frequency components from the discrete time-resolved signals generated by the gate circuit and convert them to analog signals. The analog signals thus obtained are processed by the A/D converter at the sampling rate of the FT-IR spectrophotometer itself, as shown by the trigger signal for the sampling in Figure 25.13, which has no relation to the gate timing for time resolution.

INTRODUCTION

Mass spectrometry is both a method of physical and chemical analysis and a tool for studying chemical and physical processes (e.g., processes at the solid–vacuum interface, gas-phase ion chemistry, amino-acid sequences in proteins, etc.). It embraces a collection of topics united by common instrumentation. It is simultaneously

1. a form of spectroscopy,
2. a means of carrying out chemical reactions, and
3. a means of separating mixtures of ions on the basis of mass-to-charge ratios.

The principal area of application of mass spectrometry is chemical analysis—molecular analysis, isotopic analysis, isomer analysis, trace analysis, elemental analysis, and surface analysis. Its extremely wide applicability, high sensitivity, and isotopic specificity give mass spectrometry unique applications across the sciences (White, 1986). These applications include investigations of trace contaminants of gases, liquids, or solids as well as the study of the relative abundances of isotopes, and also unimolecular and bimolecular kinetics on time-varying systems including chemical reactors, flames, and the atmosphere. Thermochemical measurements, including measurements of enthalpies, excited-state energies, and bond energies, often rely on mass spectrometry. In

addition to these application areas, mass spectrometry is essential to the subject of ion chemistry, which includes ion structures, reaction mechanisms, and reaction dynamics associated with unimolecular and ion/molecule processes in a variety of environments.

In combination with chromatographic separation, principally in the form of the combined gas chromatography/mass spectrometry (GC/MS) instrument, mass spectrometry is the principal method used for organic analysis in environmental science. This application, like many others, is based on its high detection efficiency and specificity of molecular recognition. The combination of mass spectrometry with liquid chromatography (LC/MS) is increasingly important in characterization of biologically derived compounds, and recently much progress has been made in extending the applications of mass spectrometry to include both molecular-weight (MW) determinations and sequence analysis of biopolymers, including proteins, oligonucleotides, and glycopeptides. Often this type of measurement is performed using tandem mass spectrometry (MS/MS), an experiment in which mass analysis is performed twice, once to separate particular (ionized) compounds from a mixture, and then a second time to characterize the fragments generated from the selected ion. Drug metabolite studies in a biological matrix and protein sequencing often depend upon this method, both applications requiring the high sensitivity and chemical specificity of the mass spectrometer. The same characteristics have made mass spectrometry a major method of trace elemental analysis. This latter application is carried out by atomizing and ionizing the sample using a glow discharge or inductively coupled plasma, and the result is a sensitive, precise, and universal method of trace elemental analysis.

Mass spectrometry is also the principal tool in the analysis and separation of stable and of short-lived isotopes. Precise isotopic abundance measurements are possible even when one isotope of an element is many orders of magnitude less abundant than another. One specific method for achieving this uses the accelerator mass spectrometer (AMS). These high-energy (MeV range) instruments, usually based on Van de Graaff accelerators, often employ sputter ionization of solid samples and provide data of value in geology, biology, and other areas of science. For example, age determinations are made in geological as well as in anthropological time.

Mass spectrometry is also used for material modification through ion implantation and in microscale machining. It is an invaluable source of thermochemical information as well as a unique way of preparing and studying elusive neutral molecules and free radicals. It allows interstellar and atmospheric ion chemistry to be studied in the laboratory. It is the principal experimental tool in cluster science and is important in materials science. Finally, it provides unique insights into chemical reaction mechanisms by allowing their study under solvent-free or controlled-solvent conditions.

Mass spectrometry developed from 19th-century physics, starting with the study of electrical discharges in evacuated tubes. J. J. Thomson measured the charge-to-mass ratios of cathode rays, while W. Wien discovered the existence of positively charged ions in 1898 using a velocity filter consisting of crossed magnetic and electric fields (Fig. 1). Thomson built the first mass spectrometer, an instrument to measure the *m/z* values (i.e., mass *m* divided by the positive charge *z*) of the "corpuscules" that make up "positive rays," and this led to his 1912 demonstration of the existence of isotopes. Later in-

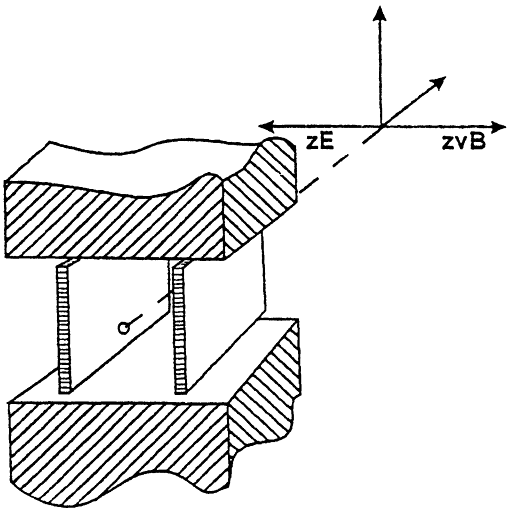

FIG. 1. Crossed magnetic and electric fields as used by Wien as a velocity filter.

struments allowed the determination of the natural abundances of isotopes and their mass defects, which helped unveil the shell structure of protons and neutrons in the atomic nucleus. Early applications in chemistry included bond energies and molecular ionization energies. Around 1940, chemical analysis by mass spectrometry began with the use of mass spectra to characterize petroleum distillates.

The principles of mass spectrometry can be illustrated by describing Thomson's positive-ray apparatus, which used a horizontal magnetic deflection and a vertical electrostatic deflection of ions (Fig. 2). From the patterns recorded on photographic plates, mass-to-charge ratios of the ions and their kinetic energies were determined (Fig. 3). Ions with a fixed mass-to-charge ratio but different kinetic energies appear as a parabola since the magnetic deflection is proportional to z/mv and the electrostatic deflection to z/mv^2. Later, Thomson scanned the magnetic field and used electrical detection to record the first mass spectrum; a 1912 spectrum is shown in Fig. 4.

In these early studies, molecular ions, isotopic ions, multiply charged ions, and negatively charged ions were all observed, as were products of charge exchange and other high-energy collision processes. The first observations of ion–molecule reactions (e.g., the production of H_3^+ from reactions of ion-

ized molecular hydrogen) were also made. Incipient in Thomson's work was organic analysis, thermochemistry, and mixture analysis. In 1913 Thomson urged "... especially chemists, to try this method of analysis. I feel sure that there are many problems in Chemistry which could be tackled with far greater ease by this than any other method. The method is surprisingly sensitive—more so than that of Spectrum Analysis, requires infinitesimal amounts of material, and does not require this to be specially purified: the technique is not difficult. ..."

Different physical principles can be used to separate and measure the masses of ions, and this results in a plethora of mass spectrometers of different types. The criteria of greatest importance in a mass spectrometer vary with the type of application. Precise abundance measurements are important in isotope-ratio mass spectrometry, access to ions of very high mass in applications to biopolymers, maximum resolution in identification of new synthetic organic compounds, and maximum sensitivity in trace analysis of environmental toxins. Various types of mass spectrometers best satisfy these different criteria, and this accounts for the variety of mass spectrometers one encounters. For example, widely used instruments are based on physical dispersion of ion beams as in Thomson's magnetic deflection instrument, on measuring the flight time of accelerated ions (time-of-flight mass spectrometers), and on measuring frequencies of motion of trapped ions (ion cyclotron resonance mass spectrometers). If one adds to this variety of mass analyzers the variety of methods of producing ions and detecting them, one understands why there is an enormous diversity of modern instruments.

1. IONIZATION METHODS

An ideal ion source for mass-spectrometric analysis should provide a high ionization efficiency, and high stability with minimum kinetic energy distribution and minimum angular dispersion of the ions produced so as to optimize the performance of the attached mass analyzer. In addition, when molecular analysis is of interest, the ion source should produce intact molecular ions for MW information, fragment ions for structural information, and control over the internal energy transferred to the molecule for control over the degree of fragmentation, and it should be possible to couple it with various types of chromatographs. The various ionization methods suitable for molecular analysis include electron-impact (EI) ionization, chemical ionization (CI), desorption ionization (DI), and spray ionization (SI). Techniques suitable for production of elemental ions include the DI technique of secondary-ion mass spectrometry (SIMS), glow-discharge (GD) ionization, inductively coupled plasma (ICP) ionization, as well as thermal ionization and other less frequently used methods (field ionization, electrohydrodynamic ionization, and spark-source mass spectrometry). A knowledge of the sample type (gas, liquid, solid, single component, complex mixture) and the desired specific application (elemental analysis, MW determination of a biopolymer, isotope ratio measurement, etc.) as well as information on how most compound types behave under different ionization conditions will dictate the most appropriate method. Table 1 summarizes some characteristics of different ionization methods.

1.1 Electron-Impact Ionization

Molecules of vaporized samples are ionized by collisions with energetic electrons (typically of about 70 eV) produced from a heated filament. Figure 5 shows a schematic diagram of a typical EI ion source. Electrons emitted from the filament (typically 100 μA) are accelerated into the ionization region where a small fraction of them collide with the sample molecules. The resulting molecular ions, together with fragment ions produced by their dissociation in the ion source, are then injected into the mass analyzer by the repeller electrode, which is held at a positive voltage relative to the ion-source block.

The mass of the molecular ion yields the nominal MW of the compound (nearest atomic mass unit), while the masses and abundances of the fragment ions can be interpreted to give structural information. Electron-impact sources require volatile, thermally stable samples and generate mainly positive ions.

Because of the physical processes involved in ionization and the limitation of fragmen-

Table 1. Summary of main ionization methods.

Ionization method		Ionization agent	Pressure	Characteristic	Application
EI	Molecular	Electrons (~70 eV)	$\sim 10^{-5}$ Torr	Reproducible spectra, extensive fragmentation	Volatile compounds; structural elucidation
CI	Molecular	Gaseous ions	~1 Torr	Molecular ions and controllable fragmentation	Volatile compounds; MW determination
DI	Molecular	Energetic particles, photons	10^{-6}–10^{-5} Torr	Intact molecular ions from high-mass compounds	Condensed phase, high-mass compounds; MW and structure determination
SI	Molecular	Electrical, thermal, and pneumatic energy	1–760 Torr	Intact molecular ions from high-mass compounds	Solutions of high-MW compounds; used with LC/MS to determine MW's and structures
GD	Elemental	Plasma	0.1–10 Torr	Very stable, reproducible spectra	Elemental analysis of solids
ICP	Elemental	Plasma	Atmospheric pressure	High ionization efficiency	Elemental analysis of solutions

tation to unimolecular processes, EI produces highly reproducible mass spectra. Hence, library searching of EI mass spectra is possible. Algorithms are available that search more than 100 000 mass spectra and record matches with the spectrum of an unknown compound within a few seconds. In order to interpret EI mass spectra and gain structural information, it is necessary to understand the series of competing and consecutive unimolecular fragmentations originating from the molecular ion. Generally, the rate constant for each step can be calculated by applying an appropriate form of reaction-rate theory, and in this way, the mass spectra of simple compounds can be calculated.

Figure 6 shows an EI mass spectrum of acetophenone. The small peak at $m/z = 120$ corresponds to the intact molecular ion. The major fragment ion is at $m/z = 105$ and is due to the loss of a methyl radical, a feature of the structure of the compound. The loss of carbon monoxide (28 atomic mass units) from this fragment ion leads to the fragment ion at $m/z = 77$, and further fragmentation (loss of acetylene, 26 atomic mass units) gives rise to the fragment ion at $m/z = 51$. The peak at $m/z = 43$ is a result of fission of

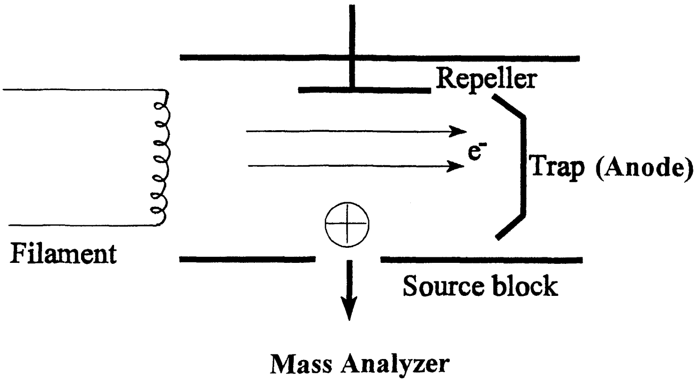

FIG. 5. Electron-impact ionization source.

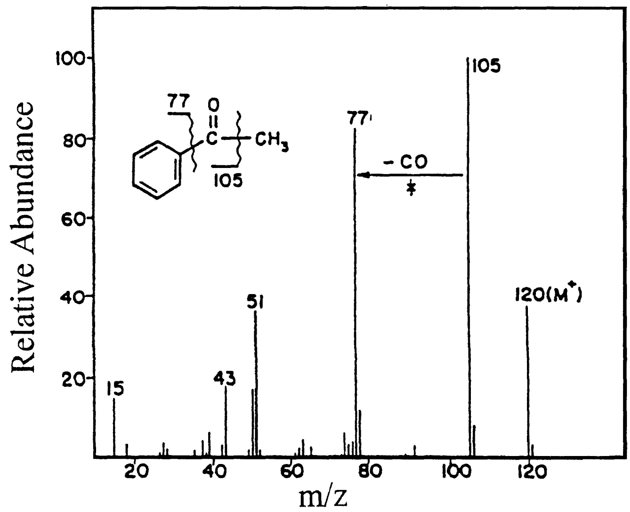

FIG. 6. El mass spectrum of acetophenone (Budzikiewicz *et al.*, 1967).

the phenyl-carbonyl bond with retention of charge on the carbonyl fragment. It can be seen from this example that EI produces structurally characteristic fragmentations. Information of this type can, in turn, be used to facilitate identification of unknown compounds.

1.2 Chemical Ionization

Many molecules do not give recognizable molecular ions in EI because of extensive fragmentation. However, this difficulty can be overcome by using CI. A reagent gas (e.g., CH_4) is ionized in an ion source at a pressure of about 1 Torr, and a characteristic set of product ions is generated in the lightly ionized plasma by ion–molecule and electron–molecule interactions. These reagent ions, in turn, undergo ion–molecule reactions with the analyte, which is present at low partial pressures to avoid its direct EI.

The reaction sequence is as follows:

1. Reagent gas molecules (e.g., CH_4, NH_3, NF_3, N_2O) are ionized by EI,
2. ion–molecule reactions produce reagent ions (e.g., correspondingly, CH_5^+, NH_4^+, F^-, O^-),
3. these reagent ions react with sample molecules (M) to form quasimolecular ions [MH^+, $(M - H)^-$, $(M + O)^-$], and finally
4. unimolecular fragmentation or collisional cooling of these ions produces the ions observed in the mass spectrum.

For example, the reaction sequence in the case of ammonia as the reagent gas is

1. $NH_3 + e^-(70\ eV) \rightarrow NH_3^{+\cdot} + 2e^-$,
2. $NH_3^{+\cdot} + NH_3 \rightarrow NH_4^{+*} + NH_2^{\cdot}$, $NH_4^{+*} + NH_3 \rightarrow NH_4^+ + NH_3^*$,
3. $NH_4^+ + M \rightarrow NH_3 + MH^{+*}$,
4. $MH^{+*} \rightarrow$ fragment ions and neutral fragments, $MH^{+*} + NH_3 \rightarrow MH^+ + NH_3^*$,

where the asterisk indicates internal molecular excitation. Fragmentation patterns for EI and CI give complementary information; often both ion sources are available on the same instrument.

The CI method is versatile because it depends on chemical reactions that yield particular products, and it deposits a controlled amount of energy into them. This leads to selective ionization of particular compounds present in a mixture. The energy deposited into the quasimolecular ion, and hence the extent of its fragmentation, can be changed by choosing a different reagent ion. For a proton-transfer reaction $M + GH^+ \rightarrow MH^+ + G$, the enthalpy change for the reaction is given by the proton affinity difference between the sample (M) and reagent gas (G). The proton affinity (PA) is defined as $PA(M) = \Delta H_{reaction}\ (MH^+ \rightarrow M + H^+) = \Delta H_f(H^+) + \Delta H_f(M) - \Delta H_f(MH^+)$. The maximum internal energy in the protonated molecule produced in CI is therefore given by ΔPA, the difference in proton affinities of M and G, and this energy controls the degree of its fragmentation. For instance, protonated methane (PA = 536 kJ/mol) reacts with acetophenone (PA = 859 kJ/mol), transferring large amounts of energy (ΔPA = 323 kJ/mol) to protonated acetophenone. This ion therefore fragments extensively. Ammonia, by contrast, is a relatively gentle reagent (PA = 857 kJ/mol) in the proton-transfer reaction with acetophenone. The spectrum therefore shows an abundant protonated molecular ion due to the low internal energy deposited in the protonated molecule (ΔPA = 2 kJ/mol). Any compound in the sample with a proton affinity less than that of the reagent gas molecule will not undergo proton transfer, and hence the experiment is transparent to such compounds, which will not interfere with the observation of other compounds in the sample.

1.3 Desorption Ionization

A major limitation of both EI and CI is the requirement that the sample be volatile, and this means that both methods are limited to thermally stable compounds of low molecular weight. Desorption ionization provides one means to ionize nonvolatile samples with high molecular weight. In this family of ionization methods, energy is provided to a condensed-phase sample that is deposited on a surface. The energy can take the form of high-energy particles, or a photon beam. Particle bombardment can be achieved using atoms (e.g., Ar) or ions (e.g., Cs^+) with 5–10-keV energies, as well as multiply charged atomic ions with energies up to 100 MeV, generated in accelerators or from nuclear fission. Laser beams used for DI often have short pulse lengths (10 ns) and photon energies in the UV spectral region. High electrical fields are used in field desorption (FD), where ionization occurs by ion–molecule reactions at a heated surface with transport of ions into the gas phase as a result of a high electrical field. Sample molecules are deposited from solution on fine dendritic needles, which yield field strengths of ca 10^{10} V/m when kilovolt potentials are applied. Table 2 summarizes some of the procedures used in the DI family of ionization methods.

The key feature in DI is the formation of intact quasimolecular ions. When the sample surface is energized, the energy is not transferred directly to the sample molecules. Rather, the transfer of energy is mediated by absorption, excitation, and relaxation processes in the matrix (Fig. 7). This liberates intact molecules of analyte, which are observable by mass spectrometry after ionization, which often occurs in the course of ion/molecule reactions in the energized interface.

Desorption ionization has wide applications both in elemental surface analysis and for the characterization of organic, inorganic, and biological molecules. For example, static secondary-ion mass spectrometry (SIMS) uses a low flux of primary ions and allows the determination of elemental composition, including the spatial distribution of

Table 2. Procedures used in desorption ionization.[a]

Agent	Method	Flux	Matrix	Mass analyzer	Comments
keV ions	Static secondary-ion MS (SIMS)	10^{-10} A cm^{-2} (Ar^+, Cs^+, etc.)	None, solid	Any	Surface sensitive, nondestructive, low signal
keV ions	Dynamic SIMS	10^{-6} A cm^{-2} (Cs^+, etc.)	Liquid	Any	Higher, longer-lasting signal
keV atoms	Fast-atom bombardment (FAB)	10^{13} atoms cm^{-2} s^{-1} (Ar atoms)	Liquid	Any	High long-lasting signal, high background
MeV ions	Plasma desorption (PD)	10^3 particles cm^{-2} s^{-1}	None	Time-of-flight	Best ionization efficiency, low signals
Photons	Laser desorption (LD) and matrix-assisted laser desorption (MALDI)	$\geq 10^6$ W cm^{-2}	Solid matrix absorbs radiation in MALDI	Often time-of-flight	CW lasers can give thermal degradation

elements in the outermost atomic layers of a material surface. Dynamic SIMS uses a high flux of primary ions, which allows depth profiling by removal of material, layer by layer, via sputtering. Imaging is achieved by rastering a finely focused ion beam across the surface (ion microprobe) or through the use of a direct-imaging instrument (ion microscope). The SIMS process involves a series of binary atomic collisions (a collision cascade) within the near-surface layers of the sample, which serve to transfer momentum and release atoms and ions into vacuum. SIMS has been utilized in material science, metallurgy, catalysis, and polymer science, and it is extremely sensitive. However, a problem associated with SIMS is the difficulty of quantification, since the ionization probability depends strongly on the surface composition. External standards with similar compositions to the sample are essential for quantitation. Traditionally, quadrupole mass filters and sector magnets have been used as SIMS analyzers; more recently, time-of-flight analyzers have been used in such experiments.

An increasingly popular alternative technique for the ionization of nonvolatile compounds, matrix-assisted laser desorption ionization (MALDI), employs a UV-absorbing matrix such as nicotinic acid, present in large excess, to absorb the photon energy. As the energized matrix evaporates, it carries the sample into the gas phase without extensive fragmentation. MALDI mass spectra are dominated by singly charged molecular ions with molecular weights as high as 500 000 atomic mass units. Figure 8 shows a MALDI mass spectrum of the protein glucose isomerase. The highly abundant molecular ion at m/z = 172 450 is evident, as is the relatively low mass resolution.

1.4 Spray Ionization

The DI techniques constitute one means to ionize nonvolatile biological compounds; SI constitutes another group of methods for handling such samples. In the latter case, aqueous solutions are examined directly. In the SI methods, thermal, electrical, or pneu-

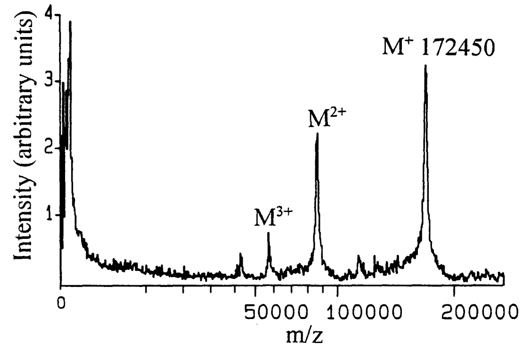

FIG. 8. MALDI mass spectrum of glucose isomerase recorded using nicotinic acid matrix (Karas *et al.*, 1991).

Table 3. Characteristics of the spray-ionization techniques.[a]

Ionization method	Energy source	Operating condition	Ion formation	Comments
Thermospray (TS)	Thermal energy	1–10 Torr, elevated temperature	Gas-phase ion–molecule reactions	Temperature-dependent spectra, interface for LC/MS
Electrospray (ES)	Electric field	Reduced pressure, ambient temperature	Ion–molecule reactions in solution, droplets	Multiply charged ions for high-MW determination; interface for LC/MS and capillary-zone electrophoresis (CZE)/MS
Atmospheric-pressure chemical ionization (APCI)	Corona discharge	Atmospheric pressure, elevated temperature	Gas- and solution-phase ion–molecule reactions	Multiply charged ions; interface for LC/MS and GC/MS

[a] There is considerable overlap in techniques and phenomena between these methods.

matic energy, or a combination of these, is used to accomplish both vaporization and ionization. Small, charged droplets are formed when an aqueous sample solution is sprayed from an electrically charged needle. Evaporation is facilitated by a heated gas, and droplet subdivision occurs by a Coulomb explosion process until, eventually, individual ions remain. These typically have multiple charges, due to attached protons or adventitious alkali metal ions in the case of positive ions. Mass/charge analysis of these ions reveals that the number of charges is not fixed, and so molecular weights can be measured from *m/z* values with some redundancy (see below). Some characteristics associated with different SI methods are summarized in Table 3.

A variant on CI, which is also closely related to electrospray ionization, is atmospheric-pressure chemical ionization (APCI). Figure 9 illustrates a typical APCI source. In APCI, ion–molecule reactions or electron–molecule reactions occur at atmospheric pressure where long residence times in a field-free drift region govern the reaction dynamics. These long residence times, typically 2–5 s, allow sufficient collisions with reagent molecules or electrons to completely ionize trace organic compounds introduced into the source. This method provides high sensitivity (subpicogram detection limits) and is there-

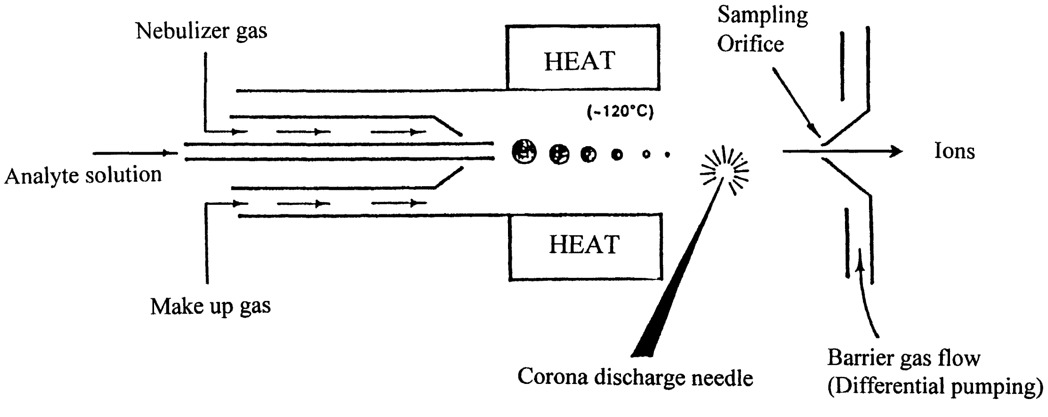

FIG. 9. Typical atmospheric-pressure chemical-ionization (APCI) source (Chapman, 1993).

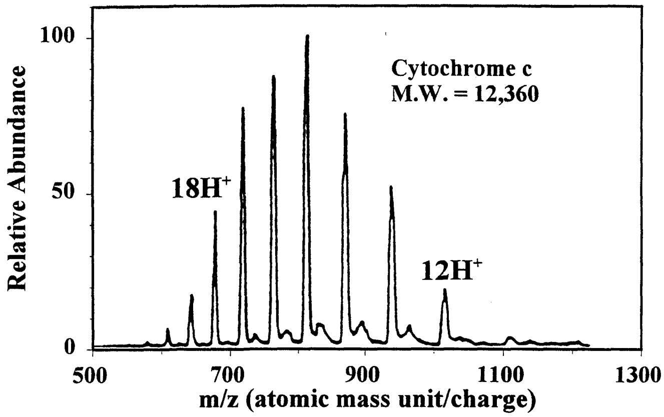
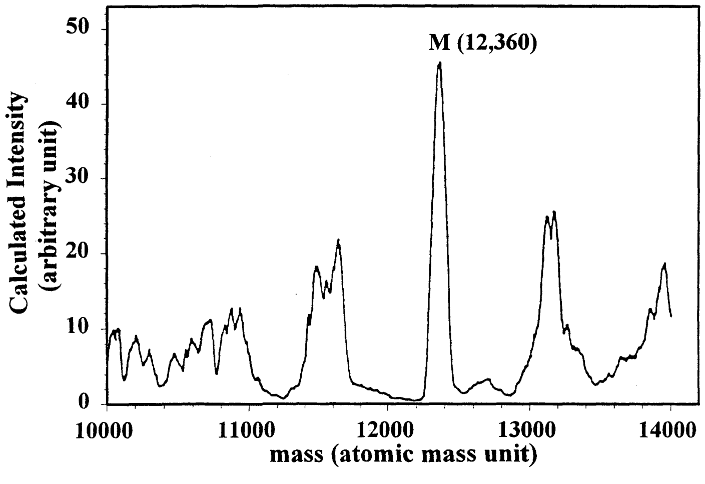
fore very useful in environmental monitoring and biological-molecule characterization.

A valuable feature of APCI and electrospray (ES) ionization itself is the formation of multiply (as opposed to singly) charged ions from high-MW species. For example, on the order of 100 protons can be attached to a bovine albumin dimer with a MW of about 133 000 atomic mass units to give ions with *m/z* values of only 1330 atomic mass units/charge. These values are easily accessible with conventional instruments. Charge accumulation on the liquid surface and subsequent disruption of the droplet by the applied high electrical field yield, after complete solvent vaporization, intact molecules bearing multiple charges and allow accurate determinations of the molecular weights of large biomolecules. Because multiple charging reduces the *m/z* ratio of an ion, this ionization method has greatly extended the applicability of mass spectrometry to high-MW compounds. For example, simple quadrupole mass analyzers can be used to measure molecular weights of up to 100 000 atomic mass units with a mass accuracy of ±0.01%. Figure 10(a) shows an ES mass spectrum of cytochrome *c*, a compound with a MW of 12 360 atomic mass units. Charge states from 10 up to 19 are observed, i.e., $(M + 10H)^{10+}$ through $(M + 19H)^{19+}$, providing redundancy in establish-



(a)



(b)

FIG. 10. (a) Electrospray-ionization mass spectrum of cytochrome *c* plotted conventionally in terms of mass-to-charge ratio. (b) Deconvoluted spectrum from (a), plotted as ion mass vs. abundance. Charge states are shown next to individual peaks in (a). (Mann *et al.*, 1989.)

ing the MW. Figure 10(b) illustrates a deconvoluted spectrum that displays ion abundance vs. mass (not mass–charge ratio). It shows that the major component of the spectrum has a MW of 12 360 atomic mass units. The fact that this ion can acquire a variable number of charges accounts for the appearance of the mass spectrum in Fig. 10(a). The ionization efficiency in ES is extremely high, and this leads to very low detection limits—in exceptional cases down to the attomole range. Electrospray also provides sequence information, for example, for peptides and proteins through the use of tandem mass spectrometry (see Sec. 3.4).

1.5 Glow-Discharge Ionization

Glow discharge is an ionization method that is most often employed in trace elemental analysis of samples in the solid state. A GD results from the passage of electric current (typically in the microampere range) through a gaseous medium (0.1–10 Torr), traditionally using a dc voltage of several hundred volts. Inherent in the operation of the GD source is the cathodic sputtering process that produces a population of atoms directly from the solid cathode. In the steady state, accelerated positive ions of the gaseous species (e.g., Ar^+), present in the discharge, strike the sample surface with sufficient energy to create a collision cascade and to dislodge one or more surface atoms per incoming ion. These sputtered gas-phase atoms are then excited and ionized through collisions in the plasma. Sampling of the plasma with a mass spectrometer produces a mass spectrum from which elemental identities and abundances are determined.

The GD ion source is popular in the elemental analysis of solids on account of its stability, sensitivity, and simplicity of operation. It suffers from minimal matrix effects because atomization and ionization occur as separate steps. This results in a range of relative elemental sensitivities of less than one order of magnitude across the periodic table. Quantification is performed with certified standards. The detection limit for most elements is in the parts-per-billion (ppb) range. The method has been widely applied to the analysis of metals, alloys, high-purity materials, thin films, and coatings, and also for surface studies and in material science applications. Figure 11 shows the results of a thin-film analysis, which includes the detection of two 10-nm-thick iron films separated by EuO layers. The sputter removal rate of material was about 0.035 nm/s.

An older alternative to GDMS, spark-source mass spectrometry, is still used for the direct elemental analysis of solid samples. In this source a pulsed MHz-frequency radio-frequency (rf) voltage of several tens of kilovolts is applied across a small gap between two electrodes, creating a spark plasma. Usually, samples are incorporated directly into the electrodes. The ion beam produced may be erratic and has a wide kinetic energy spread (2–3 keV), which has often resulted in a double-focusing mass spectrometer being employed for analysis (see Sec. 2.2.1). The reproducibility is poor, and long integration times are required because of the instability of the ion signal. However, this method has the advantage of simultaneously monitoring all elements (except hy-

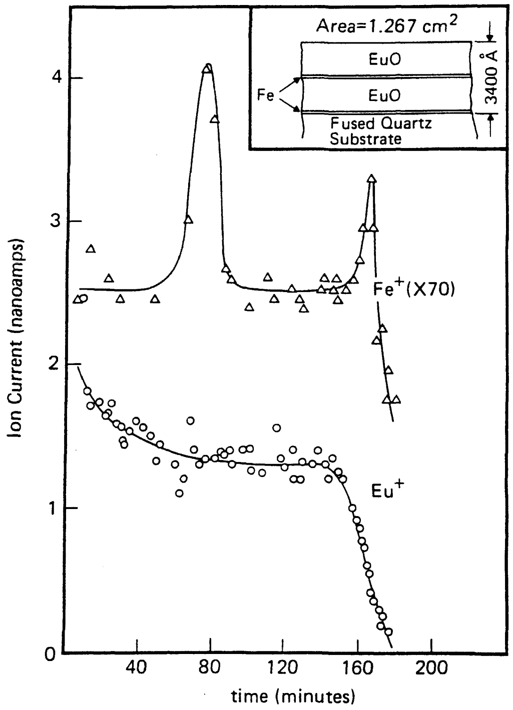


FIG. 11. Glow-discharge mass-spectrometric analysis of a 3400-Å EuO film containing two thin layers of iron, during rf discharge (13.56 MHz) in argon. Iron was detected as m/z = 56 and europium as m/z = 151 and 153. (Coburn and Kay, 1971.)

drogen) with detection limits down to 10 ppb, and it has been used for microsamples and surface contamination studies.

1.6 Inductively Coupled Plasma Ionization

The inductively coupled plasma ion source is used for elemental analysis of aqueous solutions. Figure 12 shows a schematic diagram of the ICP source and its ion-extraction optics. The main body of the ICP torch consists of a quartz tube surrounded by an induction coil that is connected to a rf generator. The sample solution is aspirated into the tube via an argon gas stream. The temperature in the ICP can reach 5 000–10 000 K, resulting in a high ionization efficiency for most elements. The ions leave the ICP together with neutral gas atoms through an extraction aperture in a sampling cone, and they are then analyzed by a mass analyzer, typically of the quadrupole type.

Inductively coupled plasma MS is often used in geological, environmental, clinical, and food analysis. The method has very low detection limits (few pg/mL range), excellent quantification, and a wide linear dynamic range (ca six orders of magnitude). The attainable precision in quantitation in ICP-MS is on the order of 0.1–0.5% relative standard deviation, by using internal standards or isotope dilution techniques. Isobaric interferences and sample matrix interferences cause difficulties in the analysis of a few elements.

In addition to chemical studies, ICP and GD, as well as spark-plasma mass spectrometry, find applications in plasma physics, microelectronics, fusion research, and combustion engineering among other fields. For example, mass-spectrometric studies on phenomena associated with electrical arcs and the thermodynamic and electrical properties of vapors have contributed greatly to the development of electrical discharge lamps. Mass-spectral data relating to chemical intermediates in flames provide valuable diagnostic information in combustion engineering.

1.7 Thermal Ionization

This ionization method produces atomic or molecular ions at the hot surface of a metal filament, the temperature of which can reach 2000 K. High yields of positive and negative ions can be obtained for atoms or molecules with low ionization energy (e.g., metals, such as K with ionization energy $I_P = 4.3$ eV) and with high electron affinity (e.g., nonmetals, such as Cl with electron affinity $E_A = 3.6$ eV). The ion yield β, the ratio of the number of ions to the total number of ions and neutral atoms, is usually represented by the following equations for positive and negative ion formation:

$$\beta^+ = N^+/(N^0 + N^+) = \{1 + (g_0/g_+) \exp[(I_P - W)/kT]\}^{-1},$$

$$\beta^- = N^-/(N^0 + N^-) = \{1 + (g_0/g_-) \exp[(W - E_A)/kT]\}^{-1},$$

where N is the number of ions or atoms; g is a statistical factor; I_P is the first ionization energy of the analyte; k is the Boltzmann constant; T is the temperature of the filament in kelvins; W is the work function of

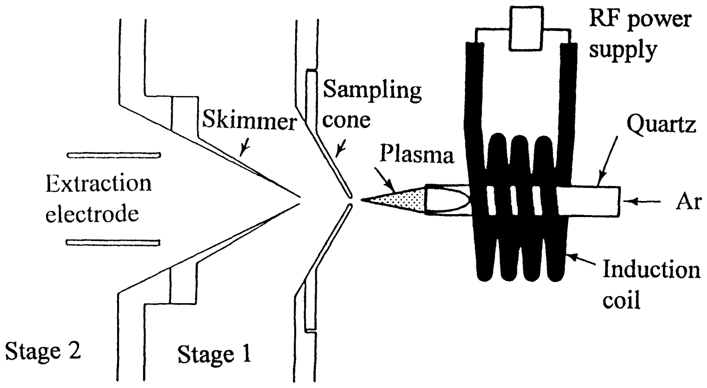

FIG. 12. Schematic diagram of ICP source and its ion-extraction interface. Typical operating pressure: stage 1, 1–3 Torr; stage 2, 10^{-3}–10^{-4} Torr. (Adams *et al.*, 1988; Ingle and Crouch, 1988.)

the filament material; E_A is the electron affinity of the analyte; and the indices 0, +, and − indicate a neutral atom, a positive ion, and a negative ion, respectively. It can be seen that a high work function of the filament material is advantageous in increasing the positive ion yield, whereas for the production of negative ions a material with a low work function should be used.

Thermal ionization generates ions with a very narrow kinetic-energy spread. It is primarily used in conjunction with isotope-dilution (ID) techniques in the nuclear and earth sciences. The detection limits are generally in the order of μg/g, viz., parts per million.

2. INSTRUMENTATION

2.1 Ion Optics

To understand how different mass spectrometers function, it is necessary to understand how ions move in magnetic and electric fields. An ion of mass m, bearing electronic charge z, i.e., of mass-to-charge ratio m/z, is accelerated by a potential V to the kinetic energy $K = mv^2/2 = zV$ and thus to a velocity $v = (2K/m)^{1/2}$. Numerically, this velocity is given in mm/μs, or equivalently in km/s, as

$$v \approx 13.89\sqrt{K/m}, \qquad (1)$$

with K in electron volts (eV) and m in atomic mass units (i.e., 1/12 of the mass of a ^{12}C atom). Assume now that ions of mass-to-charge ratio m/z are formed in processes that leave them moving in all directions with energies $K_i \leq K_{i0}$ or, in other words, velocities $v_i \leq v_{i0}$, where K_{i0} and v_{i0} are the initial energy and velocity of the ions formed in the source. Upon accelerating these ions perpendicularly (in the z direction) at potential V_0 to an energy $K_0 + K_i$, the velocity component v_z is increased while the perpendicular velocity components v_x and v_y are unchanged. Thus one finds

$$v_x \leq 14\sqrt{K_{i0}/m}, \quad v_y \leq 14\sqrt{K_{i0}/m},$$
$$v_z \leq 14\sqrt{(K_{i0} + K_0)/m} \approx 14\sqrt{K_0/m}.$$

One notes also that the ion trajectories are all inclined relative to the ion optic z axis at angles α and β, where

$$\tan \alpha \approx v_x/v_z \leq \sqrt{K_{i0}/K_0},$$
$$\tan \beta \approx v_y/v_z \leq \sqrt{K_{i0}/K_0}.$$

Diverging ions starting from one point can be focused back to a point—for instance, by rotationally symmetric lenses. Such a lens—as indicated in Fig. 13—always has a region in which the ions are forced toward the optic axis (focusing forces) and two regions in which the ions are forced away from the optic axis (defocusing forces). These forces, however, do not cancel and leave the ion trajectories undeflected; rather, over all, the ions are focused toward the optic axis since they move through the focusing regions with a reduced forward velocity component as compared to the defocusing regions. This finding holds true whether the center electrode in the rotationally symmetric lens is at a potential that reduces or one that increases the ion velocity. Note that Fig. 13 shows the case of a reduced intermediate ion velocity. Note also that the second half of the lens in Fig. 13 represents an ion acceleration system, which clearly has an overall focusing action as well.

Alternative focusing devices are quadrupole lenses (Fig. 14) in which the potential increases quadratically with x, so that ions are forced back to the optic axis (in x direction) or away from it (in y direction) with both forces increasing linearly with x or y, respectively. Since quadrupole lenses use their main field components for focusing, they are much stronger than rotationally symmetric lenses whose focusing strength depends on differential effects in their fringing fields. However, quadrupole lenses can only be used in doublets, triplets, quartets, . . . with alternating field configurations, since they always focus the beam in one direction and defocus it in the perpendicular direction and thus achieve overall focusing by appropriate combinations of lenses.

The considerations presented so far assume that all ions start from a pointlike ion source. In reality such a source always has a certain width—for instance, x_0 (Fig. 15)—from each point of which ions leave with divergence angles less than $\pm\alpha_0/2$. These ions then are focused to form an image of width x_1, i.e., each point of the image is reached by

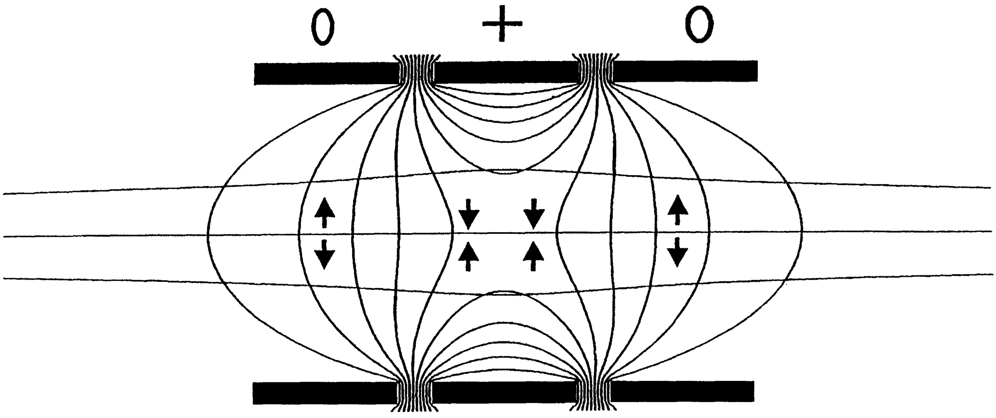

FIG. 13. An electrostatic lens that consists of three coaxially arranged metallic tubes. The two outer tubes are at ground potential, while the middle one is at a potential such that the incoming charged particles are decelerated between the first and second electrode and accelerated again between the second and third electrode with all forces acting perpendicularly to the equipotential lines shown. In the first half of the lens the charged particles are decelerated, and these particles thus are first pushed away from the optic axis (defocusing) and then pushed toward the optic axis (focusing). In the second half of the lens, these forces are reversed so that the charged particles are first pushed away from the optic axis (defocusing) and then toward the optic axis (focusing). Since in the center region the forward component of the particle velocity is reduced, the focusing forces are always larger than the defocusing forces in the initial and final regions.

ions with angles in the range $\pm\alpha_1/2$. If an object–image relationship exists between the ion source and the image, i.e., if ions that leave one point of the source all reach a corresponding point of the image, one finds for ions of given velocity that

$$x_0\alpha_0 = x_1\alpha_1,$$

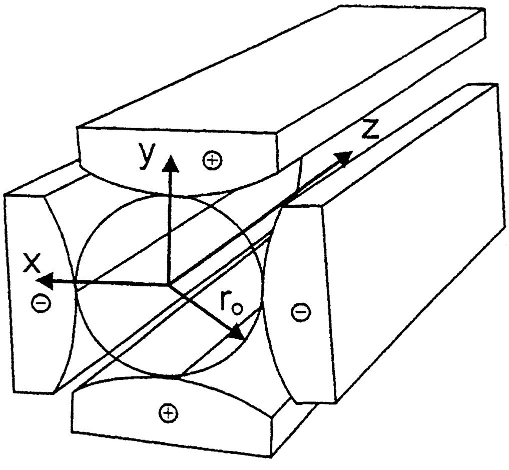

FIG. 14. Quadrupole electrode system that focuses in one direction and defocuses in the perpendicular direction. The inscribed radius is r_0.

which is a consequence of Liouville's theorem derived from thermodynamics. From this relationship it follows that a small image ($x_1 < x_0$) is always accompanied by large angles of divergence ($\alpha_1 > \alpha_0$) of the ion trajectories and a large image by more nearly parallel trajectories.

2.2 Mass Analyzers

The function of a mass analyzer is to measure the mass-to-charge ratios of ions, thus providing a means to identify them. Although there are different types of mass analyzers, their operating principles all depend on the interactions of charged particles with electric or magnetic fields. Five types of mass analyzers in common use are sector magnets, quadrupole mass filters, ion traps, time-of-flight (TOF) instruments, and Fourier-transform ion-cyclotron-resonance (FT-ICR) mass spectrometers. Table 4 summarizes some of their performance characteristics.

2.2.1 Sector Magnets An ion that passes perpendicularly through a magnetic field B moves along a circle of radius r_B along which the centrifugal force mv^2/r_B is balanced by the magnetic force Bzv so that

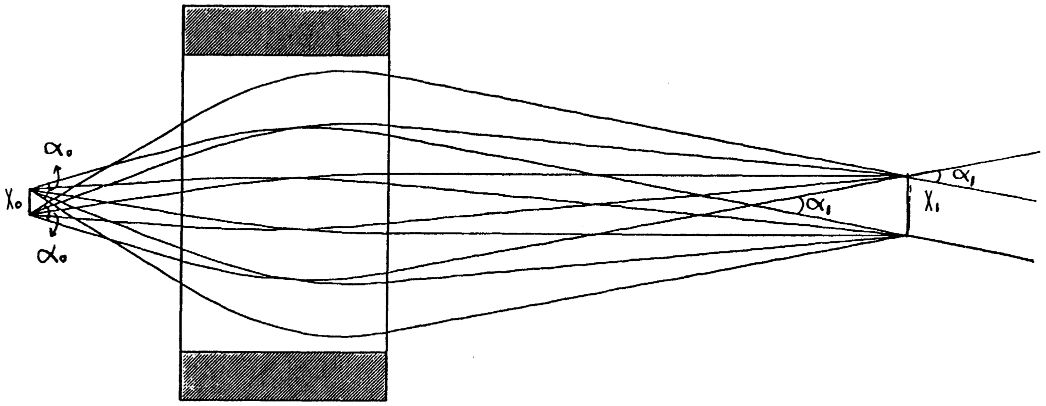

FIG. 15. An ion source of width x_0 from which ions leave with divergence angles $\pm\alpha_0/2$. The corresponding image parameters are x_1 and α_1.

$Br_B = mv/z$. Thus the magnetic field B directs ions along radii r_B that are proportional to their mv/z ratio. Numerically, this value, the magnetic rigidity, is obtained in tesla-millimeters as

$$Br_B \approx 0.144\sqrt{Km/z^2} \qquad (2)$$

where B is in teslas (V m/s^2) and r_B is in millimeters if the mass m is in atomic mass units and the energy K in eV. For ions accelerated through the same potential V one obtains the mass analysis equation $m/z = 48.9B^2r_B^2/V$.

When an ion passes through a cylindrical electrostatic sector field (also called an electrostatic sector analyzer, ESA), it moves along a curve of momentary radius r_E along which the centrifugal force mv^2/r_E is balanced by the electrostatic force zE so that $Er_E = mv^2/z$, where E is the component of the electrostatic field that is perpendicular to the ion trajectory. Thus an ESA directs ions on radii r_E proportional to their translational energy-to-charge (K/z) ratios. Numerically, this so-called electrostatic rigidity is obtained in volts as

$$Er_E = 2K/z = 2V, \qquad (3)$$

where E is in V/mm and r_E in mm.

Equation (2) is the basic equation for magnetic mass analyzers. The geometry of a more realistic system is indicated in Fig. 16, where ions that diverge from a point source are focused to a point on the focal plane (confining attention to the plane of ion deflection). In this type of mass analyzer, a mass-to-charge spectrum can be obtained after accelerating all ions through the same potential (V) and placing an imaging detector along the image plane. While this method collects all ions in the spectrum, one can alternatively collect only those ions that pass through a narrow exit slit placed in the focal plane, while V or, alternatively, B is

Table 4. Performance characteristics of mass analyzers.[a]

Mass analyzer	Quantity directly measured	Ion energy (eV)	Upper mass limit (m/z)	Resolution at m/z = 1000	Dynamic range
Sector magnet	Momentum per charge	10^4	$>10^4$	$>10^5$	$>10^6$

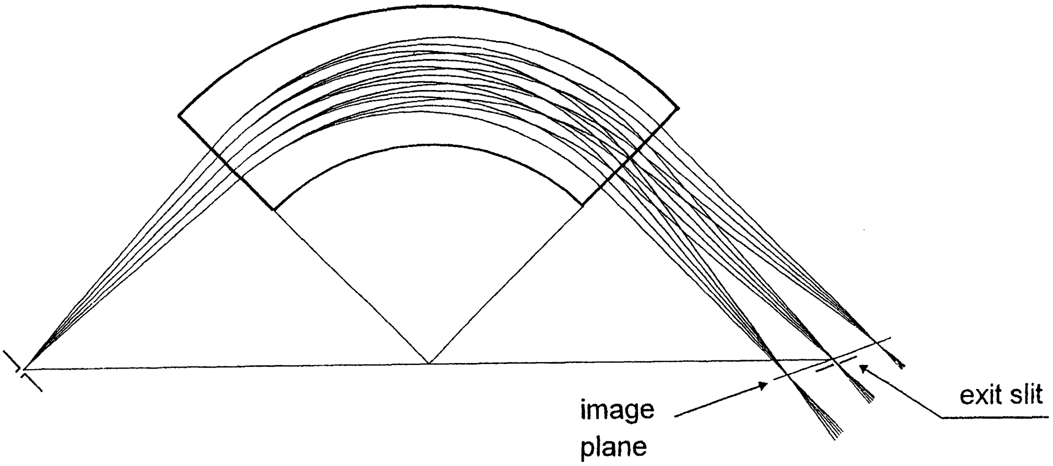

FIG. 16. Monoenergetic ions of three mass-to-charge values that leave a source divergently from a point are focussed by a sector magnet to three points on the image plane.

scanned. This allows ions of different m/z values to successively reach an ion collector placed behind the exit slit.

In a real mass analyzer, as shown in Fig. 16, ions of equal mass-to-charge ratios are perfectly focused only if they all have the same energy and leave the source from a single point. Since a real ion source produces ions with a certain energy distribution, $\Delta K = zV(1 \pm \delta_K)$, the available mass resolving power is always limited. However, a magnetic sector field can be combined with an electrostatic field to produce the high-resolution system shown in Fig. 17. Note that the trajectories for ions of two energies $zV(1 \pm \delta_K)$ and three masses, m_0 and $m_0(1 \pm \delta_m)$ are indicated. Further note that both sector fields are angle focusing and that the energy-to-charge dispersion of the electrostatic sector field is chosen such that it compensates for the energy-to-charge dispersion of the magnetic sector. Such a system is termed double focussing. It produces pure mass-to-charge dispersion independent of the ion energies and gives a mass resolving power $R_s = m/\Delta m$ independent of mass.

2.2.2 Quadrupole Mass Filters If a quadrupole is operated not by applying dc but rather by applying ac potentials, an ion that moves along the system axis experiences the same field distributions as would be produced by a large number of dc quadrupole lenses of alternating sign. If one applies an rf potential $\pm V \cos\omega t$ of angular frequency ω as well as a dc potential U to neighboring pairs of rods, i.e., a potential $U + V \cos\omega t$ to one opposing pair of rods and $-U + V \times \cos\omega t$ to the other, the voltage difference between neighboring electrodes is $2(U + V \times \cos\omega t)$. The ion motion under the influence of this two-dimensional field is described by the Mathieu equation:

$$\frac{d^2u}{d(\omega t/2)^2} + [a_u - 2q_u \cos(\omega t)]u = 0. \tag{4}$$

Here u represents either x or y in Cartesian coordinates, while a_u and q_u are parameters: $a_x = -a_y = -4zU/m\omega^2 r_0^2$ and $q_x = -q_y = 2zV/m\omega^2 r_0^2$. Depending on the magnitude of a and q, this equation has stable or unstable solutions, in which cases the ions either move periodically or diverge to infinity in the x and y directions. Figure 18(a) displays the results of solving Eq. 4 in one dimension in the form of a stability diagram that indicates, by shading, values of the parameters a and q in which stable solutions exist. Figure 18(b) illustrates ion trajectories in one dimension corresponding to two points in the stability diagram, one of which displays motion of a stable ion. In practice, ions will be subjected to forces in two dimensions as they drift down the rod assembly; only ions that undergo stable motion in both directions will remain within the device and be

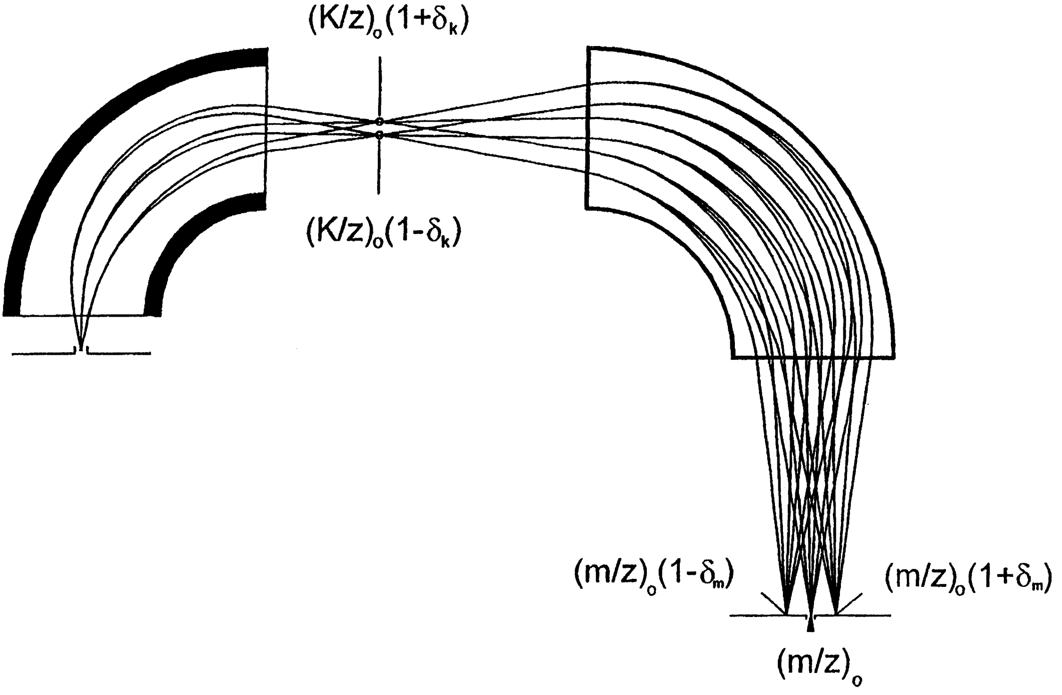

FIG. 17. Schematic diagram of a double-focussing mass spectrometer.

detected by an ion detector as they emerge from the quadrupole. In this experiment, ion motion parallel to the rod assembly is not tightly controlled since the ion separation, made according to mass, occurs only as a result of the field components perpendicular to the rod assembly.

Figure 19 shows an expanded region of part of the stability diagram in which both x and y stability are considered. Points of stability may be satisfied by many combinations of U, V, and m for a constant value of r_0 and ω. However, the shape of the stability region is such that a point near the apex of the diagram is intersected by a line of constant a/q ratio. For a given U-to-V ratio, ions of different mass occur at different points on this line, but only a narrow range of masses (near m_2 in Fig. 19) have stable motion. A mass spectrum may therefore be generated by scanning U and V with this fixed U/V ratio. Thus the mass scan line consists of the locus of values having a constant a/q ratio, and the mass analysis equation for a quadrupole mass filter operated in this way is

$$m/z = 2V/q_z\omega^2r_0^2, \tag{5}$$

showing that V is directly proportional to the m/z ratio of the ejected ions. Differentiating Eq. (5), one finds the mass resolving power R_s to be $m/\Delta m = (m/z)/\Delta V$, showing that for a given precision of V the mass resolving power increases with m/z. An ion transmitted through the array can be detected if its trajectory is characterized by particular values of a and q lying within the stable region, and this condition is established in turn for ions of increasing mass as U and V are scanned together. Typical operating conditions are $U/V = 0.17$, $\omega = 1.0$ MHz, and $r_0 = 1.0$ cm. The devices are typically 10 cm in length, ion energies along the axis are 5–20 eV, and residence times in the quadrupole array are tens of microseconds, corresponding to tens of cycles of ion motion.

Ions heavier than the stable ion, m_2^+, are discriminated against compared with lighter ions because they cannot respond sufficiently fast to the rapidly oscillating field. Ions lower in mass than m_2^+ follow the rapidly changing ac field and leave the device. The combination of high-mass and low-mass filters constitutes a mass analyzer. Resolution depends on the slope of the scan line. If the

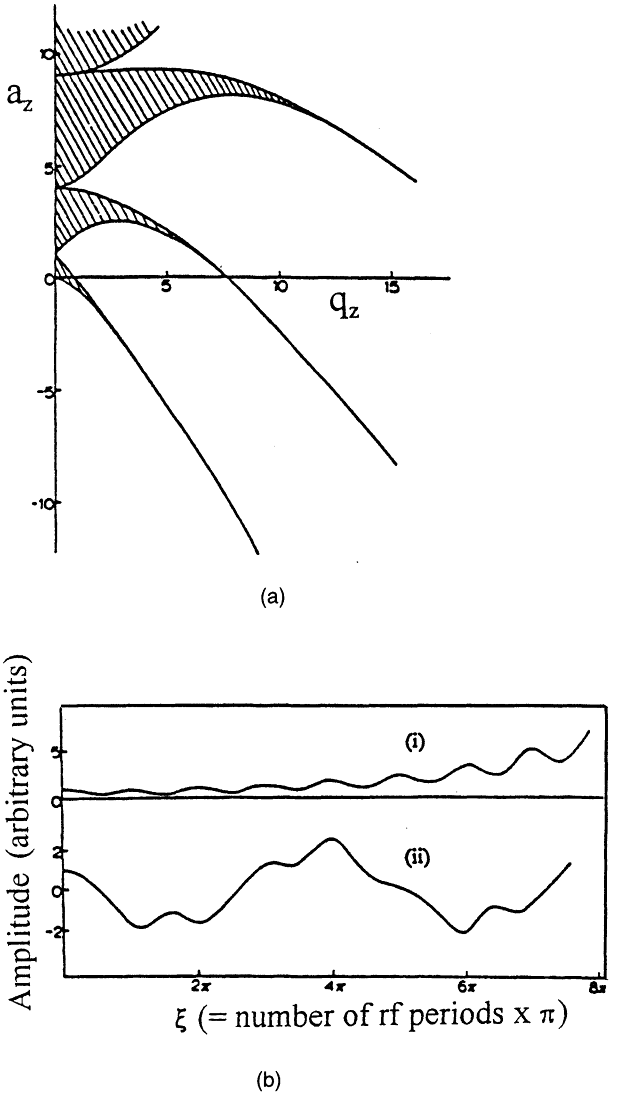

FIG. 18. (a) The *a*-*q* stability diagram displaying stable solutions to the Mathieu equation considering only a single coordinate direction. (b) Ion trajectories for ions with Mathieu parameters (i) $q_z = 0.55$, $a_z = -0.1625$ lying outside the stability region (unbounded motion) and (ii) $q_z = 0.55$, $a_z = 0$ lying within the stability region. (Dawson, 1976.)

scan line intersects the stability diagram very near the apex ($a = 0.23699$, $q = 0.70600$), higher resolution is achieved but at lower sensitivity.

Quadrupole mass spectrometers are small and inexpensive and have found wide application in surface science, leak detection, environmental monitoring, industrial process control, and on-line monitoring. For example, on-line monitoring of fermentations, the trace analysis of chlorinated compounds in drinking water, and the reaction kinetics of the formation of drug metabolites are among many studies reported using quadrupole mass spectrometers.

2.2.3 Quadrupole Ion Traps The quadrupole ion trap is a three-dimensional analog of the quadrupole mass filter. It consists of two end-cap electrodes of hyperbolic cross section that normally are operated at ground potential. Located between the end caps is a ring electrode to which an rf voltage is applied. In such a device a rotationally symmetric electric quadrupole field is generated because of the hyperbolic shape of the electrodes. Because the electric field is rotationally symmetric, it is convenient to consider only radial [$r = (x^2 + y^2)^{1/2}$] and axial (z) displacements. The potential ($\Phi_{r,z}$) at any point in this field is given by

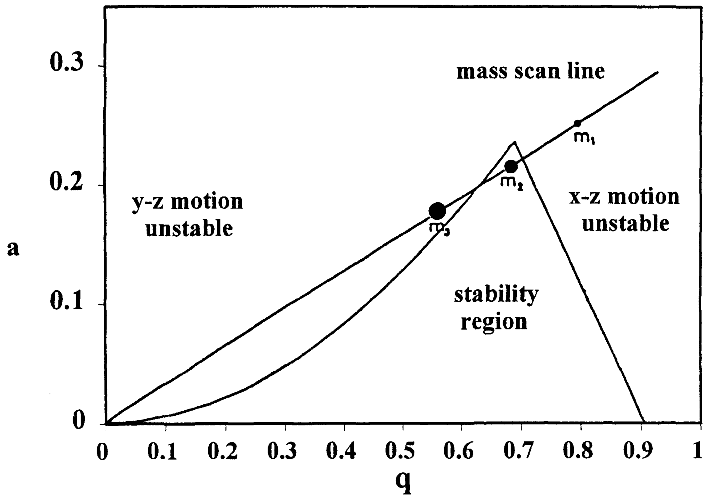

FIG. 19. Part of the Mathieu stability diagram for the linear quadrupole mass filter; m_1, m_2, and m_3 represent three singly charged ions of increasing mass. Only m_2^+ undergoes stable oscillations for the operating voltages represented by the *a* and *q* values shown. (Campana, 1980.)

$$\Phi_{r,z} = (U + V\cos\omega t)\left[\frac{r^2 - 2z^2 + 2z_0^2}{r_0^2 + 2z_0^2}\right], \qquad (6)$$

where r_0 is the internal radius of the ring electrode, z_0 is the closest distance from the center to the end-cap electrode, U is the dc potential and V is the rf potential (zero-to-peak) applied to the ring electrode, ω is its angular frequency, and t is time. In analogy to the two-dimensional quadrupole mass filter, ion motion is governed by the Mathieu equation with the coordinates a_z and q_z defining the operating conditions of the trap [$a_z = -2a_r = -16zU/m(r_0^2 + 2z_0^2)\omega^2$ and $q_z = -2q_r = 8zV/m(r_0^2 + 2z_0^2)\omega^2$]. Depending on the values of a_z and q_z, ions may fall in regions corresponding to simultaneous stability in both the r and z directions, as can be seen in the stability diagram shown in Fig. 20.

Normally, mass spectra are recorded by operating the quadrupole ion trap in a mass-selective instability scan mode in which ions are moved along the q_z axis by raising the rf voltage V until they become unstable at the boundary, where $q_z = 0.908$. They then exit the trap through a hole in the end-cap electrode. Thus ions of increasing m/z are ejected and detected as the rf voltage V is raised. For a quadrupole ion trap operated in this mass-selective instability mode, the mass analysis equation is

$$m/z = 8V/q_z\omega^2(r_0^2 + 2z_0^2), \qquad (7)$$

which is very similar to Eq. (5). Here, too, the mass resolving power increases with m/z. Typical operating conditions are $V_{0-p} = 7500$ V, $r_0 = 1.0$ cm, and $\omega = 1.1$ MHz. The maximum m/z range that can be achieved under these conditions is about 650 atomic mass units/charge. The simplest way to extend the mass range of an ion trap is to cause the trapped ions to become unstable at a lower q_z value by resonant ejection. From Eq. (7) it is clear that means of achieving mass range extension include operation at higher values of the rf voltage V, use of lower angular frequencies (ω), or use of a smaller trap (r_0). A mass/charge range in excess of 10^4 atomic mass units/charge, very high resolution, and very high sensitivity are characteristic features of the ion trap, though one should mention that an ion trap can typically only hold up to about 10^6 ions before Coulombic effects greatly reduce the achievable mass resolving power.

Trapped ions have characteristic frequencies of oscillation, known as secular frequencies. The principal component of these secular frequencies is $(\omega/2)\beta$ radian per second, where β is a parameter that varies with the coordinates a and q. At low values of a and q, β_z is approximately given by $(a_z + q_z^2/2)^{1/2}$. The presence of a helium buffer gas inside the ion trap removes kinetic energy from the ions by collisions, causing them to occupy the central region of the trap. Optimum conditions are found at a helium pressure of about 1 mTorr. Figure 21(a) shows a simu-

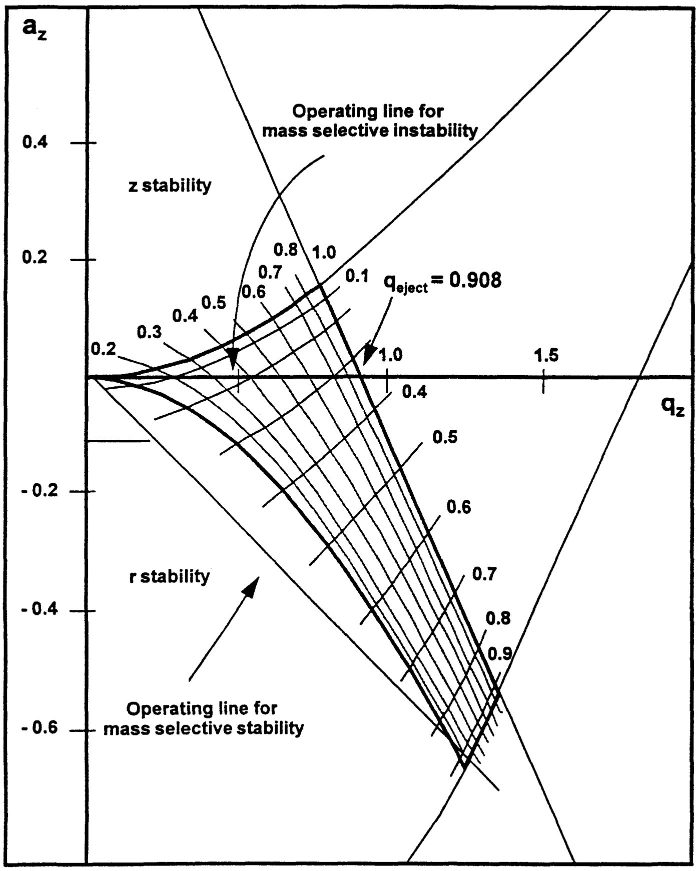

FIG. 20. The Mathieu stability diagram for the quadrupole ion trap. The common operation mode is the mass-selective instability scan in which the rf potential is raised to increase the value of q_z, while $a_z = 0$.

lation of the trajectory of an ion of $m/z = 100$ in an ion trap operated at an rf voltage of 500 V and a frequency of 1.1 MHz. It can be seen that the center of the trap is not occupied by the ion; instead, a "donut" of space is accessed. When a supplementary ac potential, in resonance with the frequency of ion motion in the z direction, is applied across the end-cap electrodes, ions are resonantly ejected from the trap. Figure 21(b) shows the simulation of the ion trajectory in the presence of this ac potential. It can be seen that there is no effect on ion motion in the r direction. However, the excursion in the z direction increases, and the ion is ejected and reaches the end-cap electrode after just a few cycles of application of the ac potential. This method of resonance ejection is used in order to extend the mass-to-charge ratio of the ion trap.

Quadrupole ion traps are small, inexpensive, and highly sensitive instruments. Like quadrupole mass filters, ion traps have found wide applications in environmental, industrial, and on-line monitoring. Their low cost and high sensitivity lead to their wide use as detectors for liquid and gas chromatography, and their small size makes ion traps suitable for field analysis (March, 1989).

2.2.4 Fourier-Transform Ion-Cyclotron-Resonance Mass Spectrometers The operating principle of FT-ICR is that an ion in a strong magnetic field undergoes cyclic motion with an angular frequency ω_c in a plane perpendicular to the direction of the field. This frequency is calculated from the fact that the magnetic force Bzv is balanced by the centrifugal force mv^2/r_B so that

$$\omega_c = \frac{v}{r_B} \approx \frac{13.89\sqrt{K/m}}{(0.144/B)\sqrt{Km/z^2}} \approx \frac{96.485Bz}{m}, \qquad (8)$$

where ω_c is the ion-cyclotron frequency in

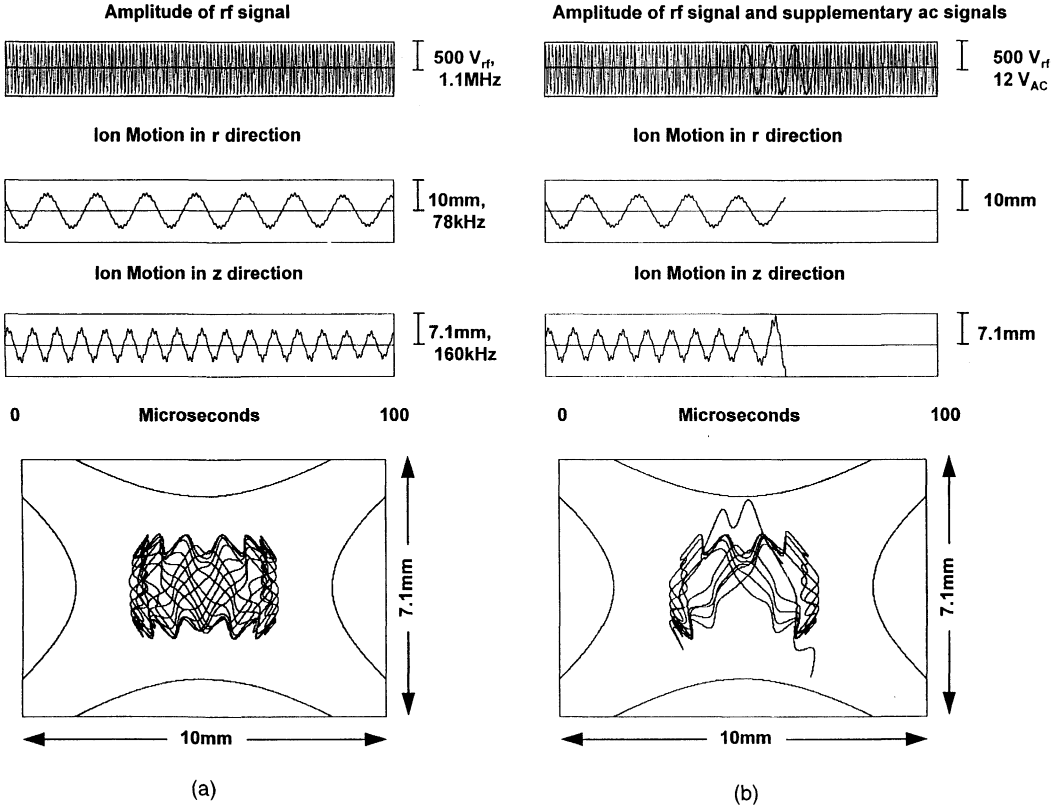

FIG. 21. (a) A simulation of the trajectory of an ion of *m/z* 100 in an ion trap operated at a rf voltage of 500 V and a frequency of 1.1 MHz. (b) The same simulation in which a supplementary ac voltage is used to resonantly excite ion motion. (Cooks *et al.*, 1991.)

MHz, B is in teslas, and m is in atomic mass units with v and r_B taken from Eqs. (1) and (2). The remarkable result is that all ions rotate with frequencies that depend on their mass-to-charge ratios (m/z) but are independent of their energies K, and this feature was put to use in the construction of the cyclotron accelerator by E. O. Lawrence. If the magnetic field strength B is known, measurement of the ion-cyclotron frequency ω_c suffices, in principle, to determine the m/z ratio. Since frequencies can be measured with high precision, mass-to-charge ratios of ions can be determined very accurately from Eq. (8). Besides cyclotron motion of an ion in the ICR cell, the ion also undergoes magnetron motion as a result of a small electric field applied to the two end plates T (Fig. 22). This magnetron motion is a slow—typically a few hundred hertz—circular drift of an ion along a path of constant electrostatic potential. In typical FT-ICR mass spectrometry ex-

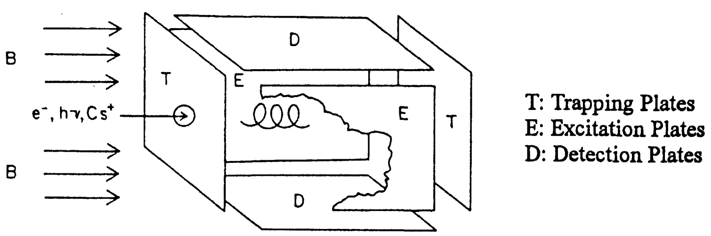

FIG. 22. Schematic diagram of a cubic ICR cell. The method of ionization is indicated by e^-, $h\nu$, Cs^+. (Marshall, 1985.)

periments, the magnetron frequency is much smaller than the cyclotron frequency, and it is often neglected.

Figure 22 shows a schematic of an ion cyclotron cell in which ions are trapped. The magnetic field, *B*, constrains the ions from escaping anywhere in a plane perpendicular to the magnetic field, and a small static trapping voltage (+1.0 V) applied to the two end plates, *T*, prevents the ions from escaping in a direction parallel to the magnetic field. In order to detect the ions, it is necessary to set them in phase-coherent motion by applying to the excitation plates *E* an rf voltage having the cyclotron frequency of the ions. Even after termination of the applied rf voltage, the coherent circular motion of the resonant ions creates in the electrodes an alternating image current, the amplitude of which decreases exponentially with time. The decay of the image current is a result of momentum loss of the ions through collisions with residual gas atoms or molecules. The image current provides a time-domain signal (Fig. 23). If the excitation is performed using a signal containing many frequencies that excite many ions at their respective cyclotron frequencies, the time-domain signal will contain multiple cyclotron frequencies. This signal can be Fourier transformed (FT) into the frequency-domain signal in which each frequency is related to a particular value of *m*/*z* by Eq. (8). Figure 23 displays the time-domain and frequency-domain ion-cyclotron signals for CO^+ and N_2^+. One advantage of simultaneous detection is a significant increase in signal-to-noise ratio.

Differentiating Eq. (8), one finds the mass resolving power R_s of an ICR mass spectrometer to be

$$R_s = \frac{m}{\Delta m} = \frac{96.485Bz}{m\Delta\omega}; \tag{9}$$

$\Delta\omega$ is usually defined as the full spectral peak width at half-maximum peak height. Hence, the mass resolving power decreases with *m*/*z* but increases with *B*, so that commercially available superconducting magnets of field strength of 3–7 T are advantageous. High mass resolving power requires ultrahigh vacuum (below 10^{-8} Torr); otherwise collisions with residual gas atoms and molecules too rapidly degrade the coherent motion of the ions. However, some ionization methods such as electrospray and thermospray require a relatively high pressure. This problem is solved by injecting ions from an external ion source into a differentially pumped ICR cell. Recent methods of injecting ions from external ion sources have led to the coupling of ICR instruments with a variety of chromatographs. In all cases, only a limited number of ions, typically 10^6, can be present in the trapping cell without Coulombic repulsion between the individual ions seriously affecting ion motion and degrading the resolving power and mass measurement accuracy.

The resolving power of FT-ICR is sufficiently high at low mass to allow one to distinguish (Fig. 24) between a positively and a negatively charged ion that differ only by the mass of two electrons. The available high resolving power is particularly valuable in conjunction with electrospray ionization in

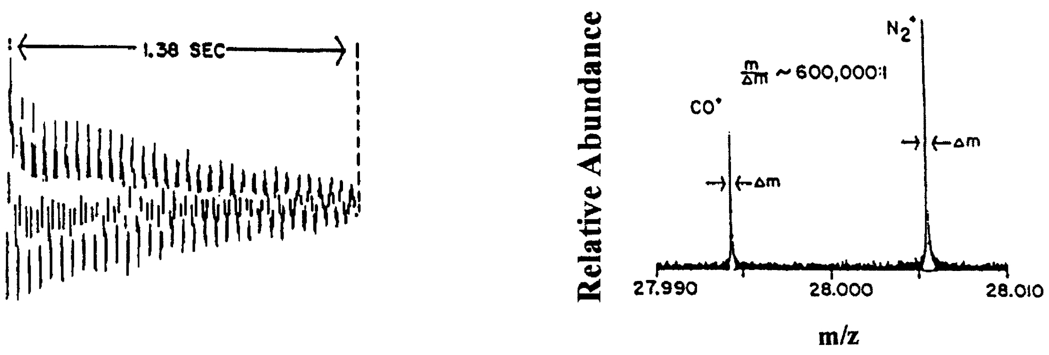

FIG. 23. Time-domain (left) and frequency-domain (right) ion-cyclotron signals for ions of two *m*/*z* ratios (Marshall, 1985.)

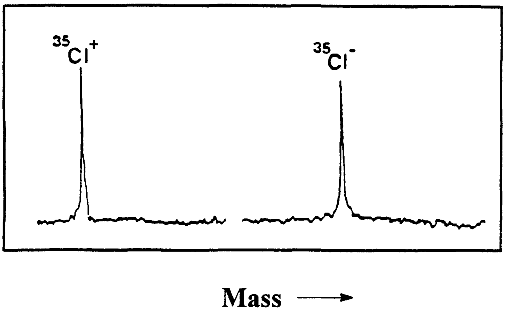

FIG. 24. Mass spectrum of $^{35}Cl^+$ and $^{35}Cl^-$ at a pressure of 10^{-8} Torr and a mass resolution of ~1.5 × 10^6. The Cl^+ and Cl^- ion signals were alternately acquired, stored, and transformed and are presented on a single mass scale. (Allemann *et al.*, 1982.)

which the carbon-isotope peaks in biomolecules are resolved; i.e., mass peaks are separated due to molecules that contain one or several ^{13}C instead of ^{12}C atoms. From the spacing between adjacent isotopic peaks in large molecules, the charge state of multiply charged ions can be determined. Figure 25 shows part of an electrospray ionization spectrum of a mixture of cytochrome c and myoglobin (note that the portion of the spectrum shown occupies a single *m*/*z* unit). The average spacing reveals that the observed ions are due to the 13+ and 18+ charge states of cytochrome c and myoglobin, respectively. That is, they represent intact molecules to which 13 and 18 protons have been added, respectively. The statistical variations in ^{13}C content of large molecules account for the relative abundances of ions with various *m*/*z* values. Multiplying the observed *m*/*z* by the charge state and correcting for the number of added protons yields the molecular weight.

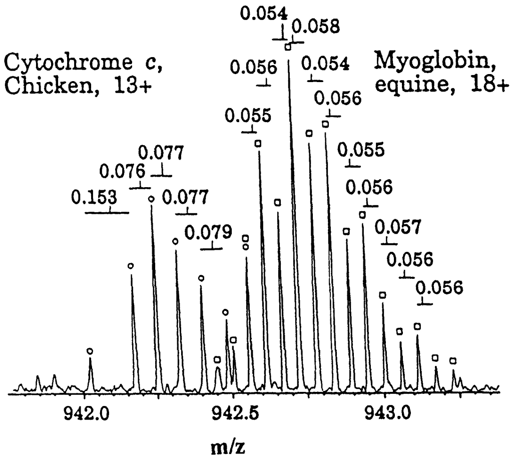

FIG. 25. Single-scan ESI spectrum of the 13+ charge state of cytochrome *c* (circles) and the 18+ charge state of myoglobin (squares). Measured mass-to-charge ratio differences of the isotopic peaks are indicated by values on the bars. (Beu *et al.*, 1993.)

In an FT/ICR, no slits or lenses are required, so that the loss of ions is minimized. Sensitivity is further enhanced by the fact that ion detection is nondestructive and by the fact that a wide range of *m*/*z* values can be measured simultaneously. Because detection does not destroy the ion population of the trap, re-excitation and remeasurement are possible. This step can be repeated hundreds of times with very high efficiency. An ICR cell can trap ions for many seconds, which makes it useful for the study of ion–molecule reactions. The high mass resolving power, R_s, facilitates accurate mass measurement.

2.2.5 Time-of-Flight Instruments In a TOF mass spectrometer, one determines the ion flight time t in μs as it passes through a distance d in mm, where

$$t = \frac{d}{v} = \sqrt{\frac{m}{2zV}}\,d = \frac{d}{13.89}\sqrt{\frac{m}{K}} \tag{10}$$

and v is taken from Eq. (1). This relationship gives the mass-to-charge ratio (m/z) in atomic mass units as

$$m/z = 193t^2V/d^2, \tag{11}$$

where $V = K/z$ is the ion acceleration voltage in volts. Differentiating Eq. (11), one finds the mass resolving power of a TOF mass spectrometer to be

$$R_s = m/\Delta m = t/2\Delta t. \tag{12}$$

The mass resolving power is independent of ion mass but, for a given uncertainty in time Δt, the mass resolving power increases with $(m/z)^{1/2}$. Mass resolving power can be improved by increasing the flight time t, which can be achieved by using lower accelerating voltages or longer flight distances d.

In spite of the simplicity of the method in principle, in practice high performance requires consideration of the effect on the flight time of differences in initial velocity (i.e., kinetic energy spread), initial direction of motion (i.e., angular spread), and initial position at which ions are formed. A well-known method that compensates for velocity differences is to have the ions undergo reflection in a repeller field. The more energetic ions penetrate more deeply into the field so that their flight paths are elongated. By adjusting this field strength appropriately, the overall ion flight time becomes energy independent (Fig. 26). Instead of a homogeneous repeller field, magnetic or electrostatic sector fields can also be used. Additional angular focusing is often achieved by rotationally symmetric lenses (see Fig. 13) or by grid-free ion reflectors (see Fig. 26). The dispersion in ion arrival time due to differences in initial position of ionization is corrected for by generating the ions in an electric field such that those formed further from the detector are accelerated toward it more strongly. Time-focusing of ions of the same mass occurs at the detector focal plane.

In all TOF work, ions must be produced in bursts. Thus, TOF systems are best coupled with ion sources that naturally produce ions in pulses. These include plasma desorption, pulsed SIMS, pulsed laser desorption, and other desorption ionization techniques. However, one can also produce ions continuously, store them for up to 1 ms, and extract them using a voltage pulse of perhaps 1 μs duration and then bunch them in time to perhaps 10 ns. This bunching can be achieved by using the Wiley–McLaren principle by which the leading ions are accelerated to lower energies than the tailing ions. Alternatively, one can produce a continuous low-energy ion beam and apply an appropriate voltage pulse to accelerate these ions at right angles to their initial flight direction.

The predominant method of data collection in TOF mass spectrometry is the integrating transient recording (ITR) in which the arrivals of ions in short time intervals are stored in consecutive recording channels of a multichannel analyzer. Adding several of these spectra achieves relatively noise-free mass spectra. When signals are much weaker, the flight times of individual ions can be determined from their start and stop signals. This method usually achieves better time resolution but requires that the ion intensities be so low that the individual ion ar-

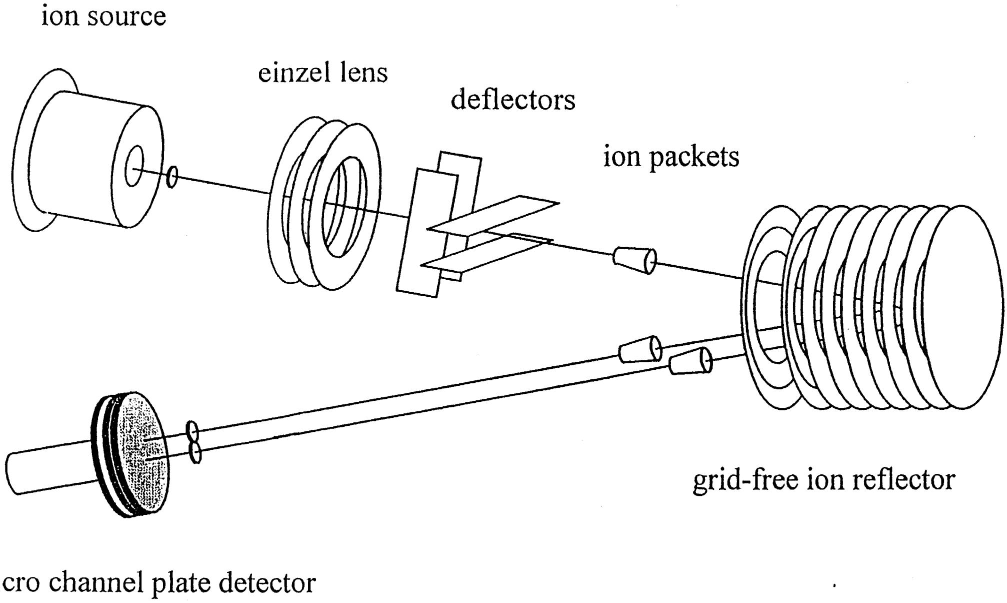

FIG. 26. A reflector is used to compensate for differences in ion kinetic energies and achieve temporal focusing at the detector in TOF mass spectrometry.

rival events not be coincident. In most cases such systems involve a multistop time-to-digital converter (TDC).

The outstanding feature of a TOF/MS is its high mass range ($>10^5$ atomic mass unit/charge). This property has allowed the measurement of molecular weights of proteins in excess of 500 000 atomic mass units using matrix-assisted laser-desorption ionization. However, TOF mass analyzers also have the valuable capability of producing mass spectra of good quality within a short time (a few milliseconds). This makes them ideal for recording mass spectra of time-varying samples as is required in process-control systems and kinetic measurements. Together with their high sensitivity, this feature is also important for their use as mass-sensitive recorders for monitoring the effluent in fast gas chromatography or capillary-zone electrophoresis experiments.

2.3 Ion Detection

When energetic ions impinge on a suitable metal surface, the electron cloud of the ions interacts violently with the electrons of the surface atoms. As a result of this interaction, multiple secondary electrons are released with energies of a few eV. These secondary electrons then can be accelerated and guided from the conversion dynode to an electron-multiplier detector (Fig. 27). In the electron multiplier, N electrons impinge on a surface releasing $\approx 2N$ electrons (the factor 2 being nominal and being chosen only for purposes of illustration). Accelerating these electrons by ≈ 200 V and allowing them to impinge on another surface yields $\approx 4N$ secondary electrons, and by repeating this process $\approx 8N$, $\approx 16N$, etc. Thus the initial number of electrons N is finally multiplied by a large factor. The most common electron multiplier is a continuous-dynode device known as a channeltron across which a potential of several keV is applied. Provided the ion arrival rate is slow ($<10^6$ ions/s), one can record the arrival of each ion on the converter electrode by amplifying the electron multiplier signal. This ion-counting method was introduced by White in the 1950s. In the case of negatively charged ions, a conversion dynode must be used (Fig. 27), but its electrical bias is changed so as to collect positively charged ions generated at its surface by sputtering and other processes. Another detector is the channel plate, which is made up of an array of small (30 μm) individual electron-multiplier elements. The channel plate has a time resolution of about 10^{-10} s, which is much smaller than that of a conventional electron multiplier. Its spatial resolution is an additional advantage, and gains are up to 10^6. The channel plate can be very useful as a beam visualization device when it is operated closely coupled to a phosphor for electron-to-photon conversion. The light from such a phosphor can fall on a vidicon

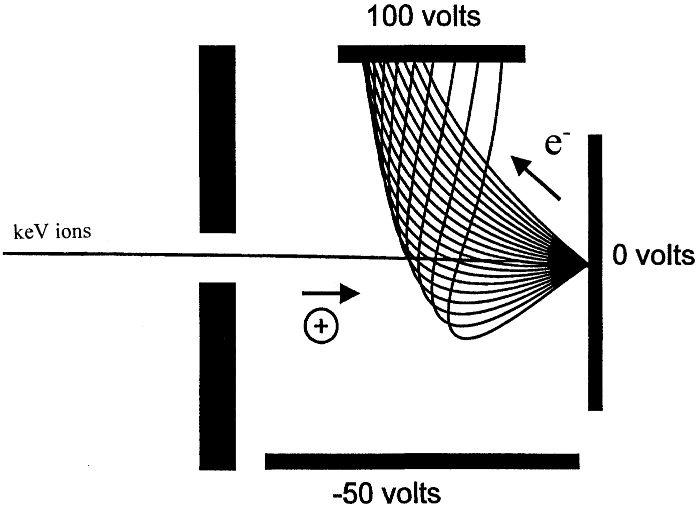

FIG. 27. An ion detector that records incoming ions by the released secondary electrons. The potentials shown give only a rough impression of the required voltages. Analogous procedures are used to record negatively charged ions.

or other photosensitive element to record the ion-beam image. The signal-to-noise ratio for the channel-plate detector is improved over single-channel detectors because of the Felgett advantage.

The release of secondary electrons from a surface is velocity dependent, making it difficult to record very heavy molecular ions. Such ions can be recorded, however, in a two-step process. The ions first impinge on a surface (such as that of the conversion dynode in Fig. 27) where the impact breaks the molecules up into fragments (surface-induced dissociation). The ionic fragments are then accelerated toward a second surface, where these smaller and faster ions form secondary electrons upon impact. In addition to the common electron multipliers, there are several other detectors that are used in mass spectrometry. Photoplates are still occasionally used as imaging detectors. They are sensitive to as few as 50–100 ions. One illustration is shown in Fig. 3. A modern charge-coupled device (CCD) also behaves as an imaging detector. Faraday collectors accept ions quantitatively while preventing loss of any electrons or ions produced. They are used in quantitative work especially in isotopic analysis and can have precisely unit gain.

3. SPECIAL TECHNIQUES AND THEIR APPLICATIONS

3.1 Applications of Electron Capture

The lightly ionized plasma in the CI ion source (Sec. 1.3) contains approximately equal numbers of positive and negative particles, ion–molecule reactions or attachment of thermal energy electrons to molecules yielding negatively charged sample ions. Reagent gases that produce thermal-energy electrons allow electron-attachment chemical ionization to be performed. This method is extremely sensitive (i.e., gives low detection limits) because of the high electron mobility and the large cross section for electron capture by suitable compounds. Often a functional group (e.g., pentafluorophenyl) with high electron affinity is added to a molecule to enhance its sensitivity to electron capture. High selectivity is also obtained since most compounds do not give stable anions upon electron capture. Figure 28 shows a negative chemical ionization mass spectrum of the environmentally important compound 3,3′,4,4′-tetrachlorodiphenyl ether. The most abundant peaks are due to isotopic forms of the intact molecular anion M^- at *m/z* = 306, 308, 310, and 312 containing from zero to three ^{37}Cl atoms. Fragmentation with the loss of an HCl molecule from this anion produces the cluster of peaks centered at *m/z* = 272. The small peak at *m/z* = 161 is due to the product of structurally diagnostic oxygen-phenyl cleavage in the molecular anion. The characteristic isotope ratios of each group of peaks facilitate the identification of the number of chlorine atoms in each fragment (e.g., the natural isotopic abundance ratio for Cl_2 and molecules containing Cl_2 is 9:6:1). The electron-attachment method is used in forensic science, in environmental

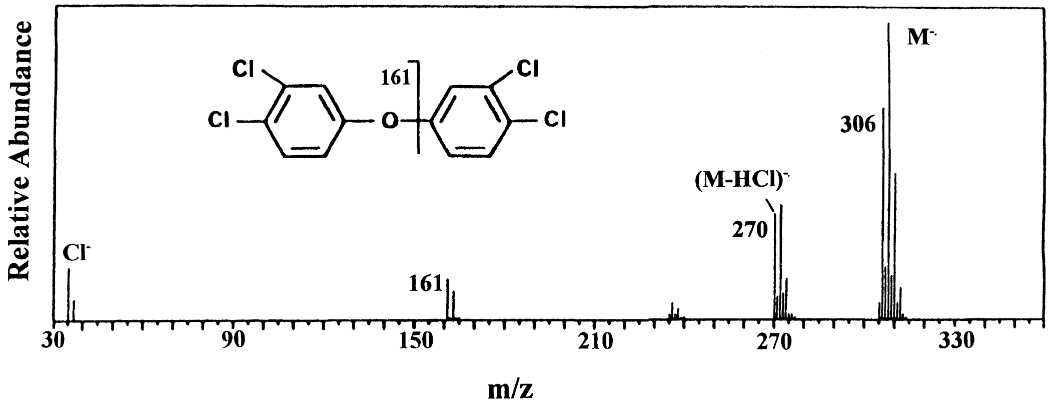

FIG. 28. Electron-attachment chemical-ionization mass spectrum of 3,3′,4,4′-tetrachlorodiphenyl ether using methane to moderate electron energies (ion source temperature = 250°C) (Stemmler and Hites, 1988).

monitoring, and particularly in drug metabolism where selective, ultratrace-level determinations are important and the matrices in which compounds of interest occur are very complex.

3.2 Chromatography/Mass Spectrometry

Chromatography/mass spectrometry is a group of techniques in which the separating power of chromatography is combined with the specificity of mass spectrometry in analyzing particular compounds present in complex mixtures. The chromatography step also serves to preconcentrate analytes and deliver them in a continuous automated fashion for examination by the mass spectrometer. The mass spectrometer can be operated as a universal detector, by recording the total ion abundance in the mass spectrum as each compound elutes from the chromatograph. Alternatively, it can be operated as a selective detector, by providing information on one type of compound through examination of a few characteristic ions, or even just one, in the spectrum.

Selective detection is often performed by recording an ion chromatogram, which displays the abundance of a selected ion(s) as a function of elution time. The total ion chromatogram, on the other hand, is the sum of the individual ion chromatograms (i.e., the total ion current at each point in time) and represents the chromatogram as measured using the total ion abundance, without regard to types of ions. Maximum sensitivity is achieved by limiting the mass-spectrometer scan to one ion, viz., by selected-ion monitoring (SIM), where a single ion of interest is monitored continuously by the mass spectrometer. The signal-to-noise ratio of this experiment is increased greatly compared to an experiment in which much of the analysis time is spent in monitoring ions that provide less or no information on the analyte. SIM trades specificity for sensitivity, and detection limits in SIM can be as low as 100 femtomoles. This is an improvement over full–mass-scan mass spectra by a factor of 100 to 1000, an improvement in sensitivity that is crucial in applications where low levels of specific compounds are to be recognized and quantified.

There are two major types of chromatography/mass-spectrometry instruments: gas chromatography/mass spectrometry (GC/MS) and liquid chromatography/mass spectrometry (LC/MS) instruments. In interfacing a chromatograph to a mass spectrometer, one must maintain chromatographic performance and achieve high transfer efficiency. Three types of GC/MS interfaces are used: direct coupling, splitters, and molecular separators. The interface for the LC/MS combination has similar basic requirements to GC/MS, viz., LC integrity must be maintained without significant loss in efficiency. Table 5 summarizes the main types of LC/MS interfaces.

Both GC/MS and LC/MS play important roles in environment monitoring and life science research. For example, on-line LC/ES/MS is a significant method for the analysis of peptides and other biopolymers. Figure 29 shows the total-ion chromatogram recorded in an LC/ES/MS analysis of a tryptic (enzy-

Table 5. Summary of LC/MS interfaces.

Interface	Ionization mode	Maximum flow rate (μl min^{-1})	Characteristics
Moving belt	EI/CI/FAB	2000	Limited to volatile organic mobile phases, excellent enrichments and efficiency; memory effects
Direct liquid introduction	EI/CI	50	Mechanically simple, no memory effect; inefficienct
MAGIC	EI/CI	500	Limited to relatively volatile compounds; not very sensitive; good for EI
Thermospray	TS	2000	Used for volatile or nonvolatile compounds; is also an independent ionization method in MS
Electrospray	ES	10	Interface for LC/MS and CZE/MS; multiply charged ions; high-MW determination; also independent ionization method

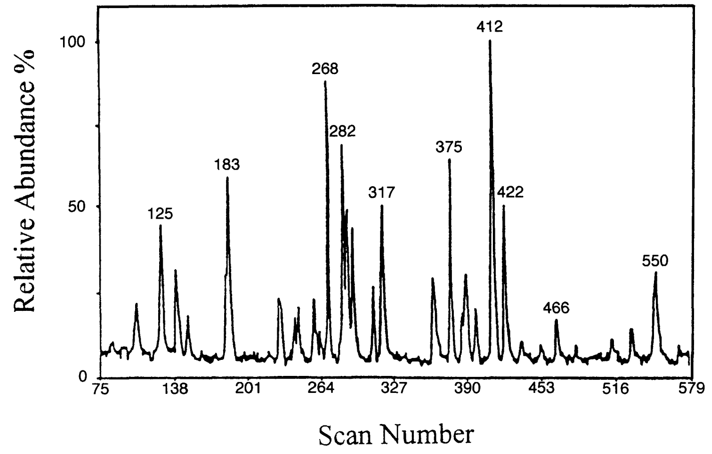

FIG. 29. Total-ion–current chromatogram of an LC/ES/MS analysis of a tryptic digest of reduced and alkylated glycoprotein (Carr *et al.*, 1991).

matic) digest of a glycoprotein. During the acquisition of these data, hundreds of mass spectra were recorded. A representative spectrum is shown in Fig. 30. This type of data is valuable in the recognition of individual glycopeptides; the compound eluting at the time this scan was taken clearly has a molecular weight of 3260 atomic mass units. With the application of tandem mass-spectrometric techniques in conjunction with GC/MS and LC/MS, more structural information on individual compounds can be obtained (see below). For example, sequence information on peptides can be acquired by capillary-zone electrophoresis (CZE) combined with ES/MS/MS.

3.3 Mass Spectrometry/Mass Spectrometry

Mass spectrometry/mass spectrometry (MS/MS), or tandem mass spectrometry, is a procedure for examining individual ions in mixtures of ions. The ions often serve as surrogates for the corresponding neutral molecules, making MS/MS a formidable method of analysis of complex mixtures. The ions of interest are separated by mass and allowed to dissociate upon collision, and the resulting product ions are examined by a second mass measurement. Figure 31 illustrates the concept.

In MS/MS experiments, two mass analyz-

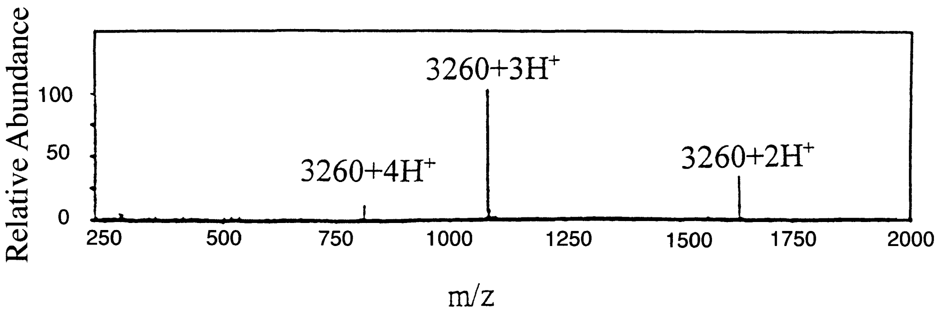

FIG. 30. Representative ES mass spectrum from the LC/ES/MS analysis shown in Fig. 29 (scan 550), showing a compound of molecular weight 3259.7 atomic mass units with two, three, or four charges. The mass assignments are given in parenthesis and are accurate to a single atomic mass unit. (Carr *et al.*, 1991.)

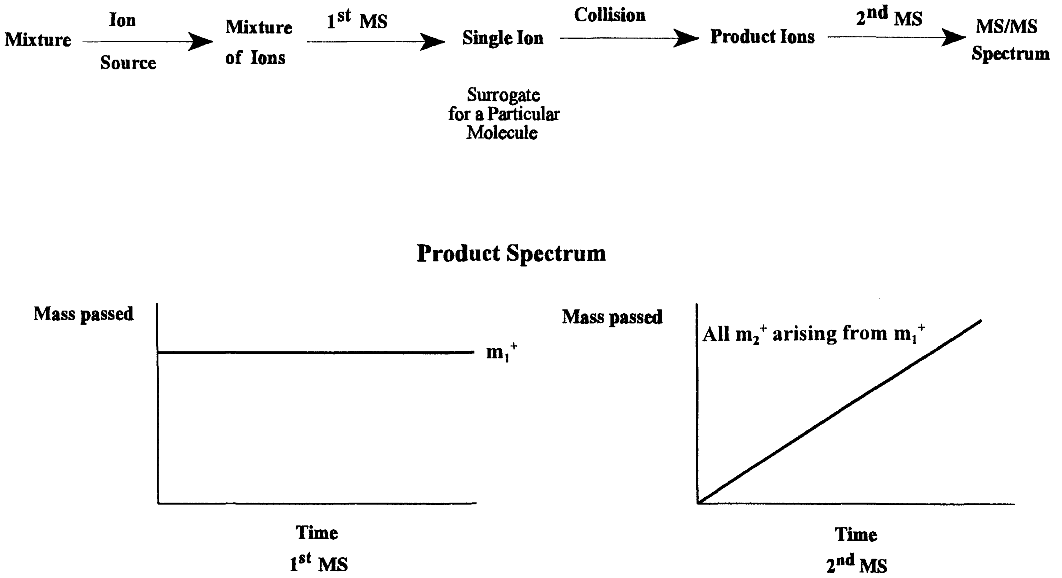

FIG. 31. Concept of tandem mass spectrometry, showing scan (product-ion spectrum) that characterizes particular compounds in mixtures.

ers (or two mass-analysis events) are used to measure the parent and product ions, m_1^+ and m_2^+, explicitly. The first mass analyzer is usually set to pass m_1^+, which then undergoes dissociation to give product ions, m_2^+. Ion dissociation in MS/MS can be achieved by collision with a target gas (collision-induced dissociation, CID), collision with a surface (surface-induced dissociation, SID), or photodissociation (PD), which is a process in which an ion absorbs one or more photons of appropriate wavelength and then dissociates. The cross sections for CID and single-photon photodissociation are about 10–200 and 10^{-2} Å^2, respectively, making collisions with gaseous targets a simple and successful way to excite and dissociate ions. Ion dissociation in MS/MS is represented by the following equation:

$$m_1^+ \to m_2^+ + m_n.$$

Since mass spectrometers naturally can only analyze charged particles, the neutral molecular fragment m_n is not usually detected. But the value of m_n can be inferred from m_1^+ and m_2^+.

Historically, MS/MS arose from the fact that metastable ions, which dissociate in flight in sector instruments prior to mass analysis, give products that appear in a normal mass spectrum at an apparent mass of m^*, where $m^* = m_2^2/m_1$. The positions of the peaks due to these processes provide information on the masses of both the parent ion, m_1^+, and the product ion, m_2^+. For example, benzene shows a metastable peak at an apparent $m/z = 34.7$ due to the following reaction:

$$\begin{array}{lll} C_6H_6^{+\cdot} \to & C_4H_4^{+\cdot} & + C_2H_2 \\ m/z\ 78 & m/z\ 52 & (m^* = 34.7)\,. \end{array}$$

The metastable ion peak usually appears in a sector mass spectrometer as a nonintegral and broad mass peak, and it provides valuable information when interpreting fragmentation patterns.

The product ions formed in MS/MS experiments are usually recorded by scanning the second mass analyzer. This type of scan, a product-ion scan, is very useful in elucidating the structure of the parent ion, which is often an ionized form of the intact analyte molecule. This can be seen for a very simple example in Fig. 32, where a comparison is made between the MS/MS spectrum of an ion of $m/z = 143$, derived from a sample of diesel particulates, and the MS/MS spectrum of authentic protonated 2-methylnaphthalene

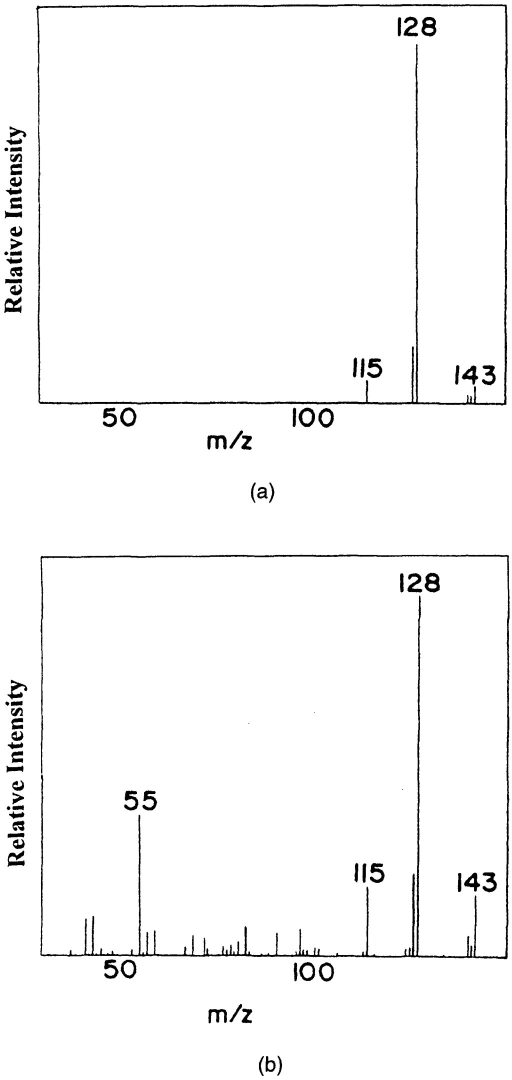

FIG. 32. MS/MS product-ion spectrum of *m/z* = 143 from (a) authentic, protonated 2-methylnaphthalene. (b) A diesel particulate. (Wood *et al.*, 1982.)

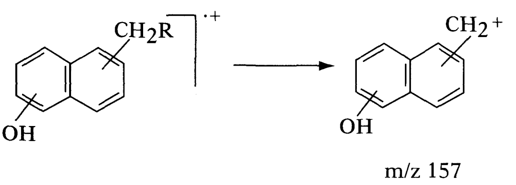
(also *m/z* = 143). The agreement between the high-mass fragment ions confirms the presence of methylnaphthalene isomers as a major constituent at *m/z* = 143 in the diesel particulate sample. The ions present at low *m/z* indicate the presence of at least one other component that also gives an ion at *m/z* = 143.

There are other MS/MS scan types. A parent-ion scan is one in which the product ion is selected and a scan is performed to detect all parent ions that fragment to yield this particular product. This scan can be used to identify members of a class of compounds defined by their characteristic product. For example, all alkylnaphthols in a mixture can be identified by setting the second mass analyzer to a fragment ion (*m/z* = 157) characteristic of this class of compounds and scanning the first analyzer so as to record the molecular weights of all compounds that fragment by the following process:



A neutral-loss scan is one that identifies all parent ions formed from a complex mixture that fragment by loss of a particular neutral molecule. Like the parent-ion scan, it is useful in identifying the presence (and molecular weights) of groups of compounds containing a designated functional group. For example, a neutral-loss scan of 44 atomic mass units in a negative ion MS/MS experiment indicates the presence of carboxylic acids, recognized via their characteristic loss of carbon dioxide (mass 44) from the $[M-H]^-$ ions.

MS/MS experiments can be performed with a wide variety of instruments. Multiple analyzer sector, quadrupole, and TOF instruments are all used. Figure 33 shows a schematic diagram of one such instrument, a triple-quadrupole mass spectrometer. The central quadrupole (*Q*2) is operated in the rf-only mode, which allows all ions to pass through, and is used as the collision region. The scanning procedures used for the acquisition of the various types of MS/MS data are straightforward. A product-ion scan is obtained by simply setting the first quadrupole to pass the desired parent ion and scanning the last quadrupole (*Q*3) in the normal manner. Parent-ion scans are performed by setting the last quadrupole (*Q*3) to pass the desired product ion while the first quadrupole *Q*1 is scanned in the normal manner. Neutral-loss spectra are obtained by scanning the first and last quadrupole mass analyzers in concert at the same rate, the offset in the masses of the ions passed by the

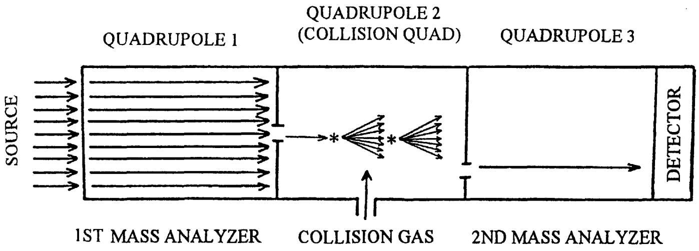


FIG. 33. Operation of the triple-quadrupole mass spectrometer as a MS/MS instrument. The parent scan mode is illustrated.

analyzers corresponding to the desired neutral loss.

Ion-trapping instruments (FT-ICR and quadrupole ion traps) can be used to perform MS/MS experiments, and they require only the use of an additional sequence of operations in the scan function. In the case of the ion trap, the scan function begins with ionization followed by the selection of a parent ion in a step that involves ejecting all other ions from the ion trap. The parent ion is then translationally excited, typically by applying a supplementary rf voltage to the end caps. The product ions resulting from collision-induced dissociation are recorded by scanning the rf voltage to perform a second mass-analysis scan.

The main advantage of MS/MS experiments is their enhanced specificity. This is useful in isomer distinction, biological-molecule sequencing, and the analysis of complex mixtures. For example, a parent ion can be separated from a complex mixture in the first analyzer and then dissociated and its products analyzed by a second analyzer. The MS/MS experiment is often done in conjunction with chromatographic separation.

3.4 Mass Spectrometry for Analysis of Biopolymers

Tandem mass spectrometry can be used to obtain structural information on biopolymers such as proteins and oligonucleotides. Sequence information on peptides is obtained, as shown in Fig. 34. With the development of matrix-assisted laser-desorption ionization (MALDI) and electrospray ionization (see Secs. 1.4 and 1.5), mass spectrometry has begun to make significant contributions to the analysis of higher–molecular-weight biopolymers ($\leq$100 000 atomic mass units). Applications to protein/peptide characterization are well established, and some work on oligonucleotide sequencing has appeared. Conventional methods for DNA sequencing employ sequencing reactions to generate the four nested sets of DNA fragments terminating in dideoxynucleotides A, C, G, or T (where A, C, G, and T represent the four nitrogenous bases adenine, cytosine, guanine, and thymine, respectively) followed by electrophoretic separations in polyacrylamide gel matrices to separate the single-stranded DNA fragments by size and fluorescence detection to characterize the terminal base. In experiments using mass spectrometry, the DNA fragments can be subjected to MALDI or electrospray molecular-weight analysis without intervening electrophoretic separation. These ionization techniques can be coupled with TOF, FT-ICR, or quadrupole mass spectrometers, suggesting that sequences can be read directly from the mass spectra of the mixture. Figures 35(a) and 35(b) show MALDI mass spectra recorded for A, C, G, and T mock-sequence mixtures. The ion signals for each fragment are labeled according to the base length (i.e., the number of synthetic nucleotides). In the A, C, G, and T mixtures, all fragments are terminated with the base A, C, G, and T, respectively. The mass spectrum in Fig. 35(b) was generated by overlaying the four spectra in Fig. 35(a). The order of the peaks corresponds to the sequence, which is GAATTCGAGCTCGGTACCCGGGGA, and each peak differs from its neighbors by one base. DNA sequencing by mass spectrometry potentially has detection limits in the femtomole region.

3.5 Isotope-Dilution Mass Spectrometry

Isotope-dilution mass spectrometry (IDMS) is one of a few methods of quantitation that have high sensitivity, high reproducibility, and excellent accuracy for both elemental and molecular analysis. Provided

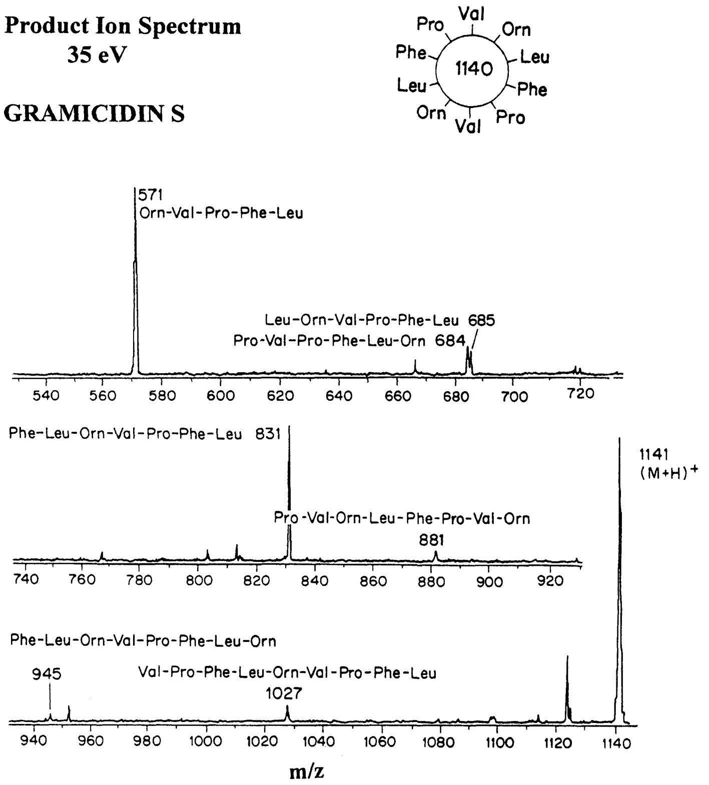

FIG. 34. Use of MS/MS to obtain sequence information on a cyclic peptide (Lambert *et al.*, 1987).

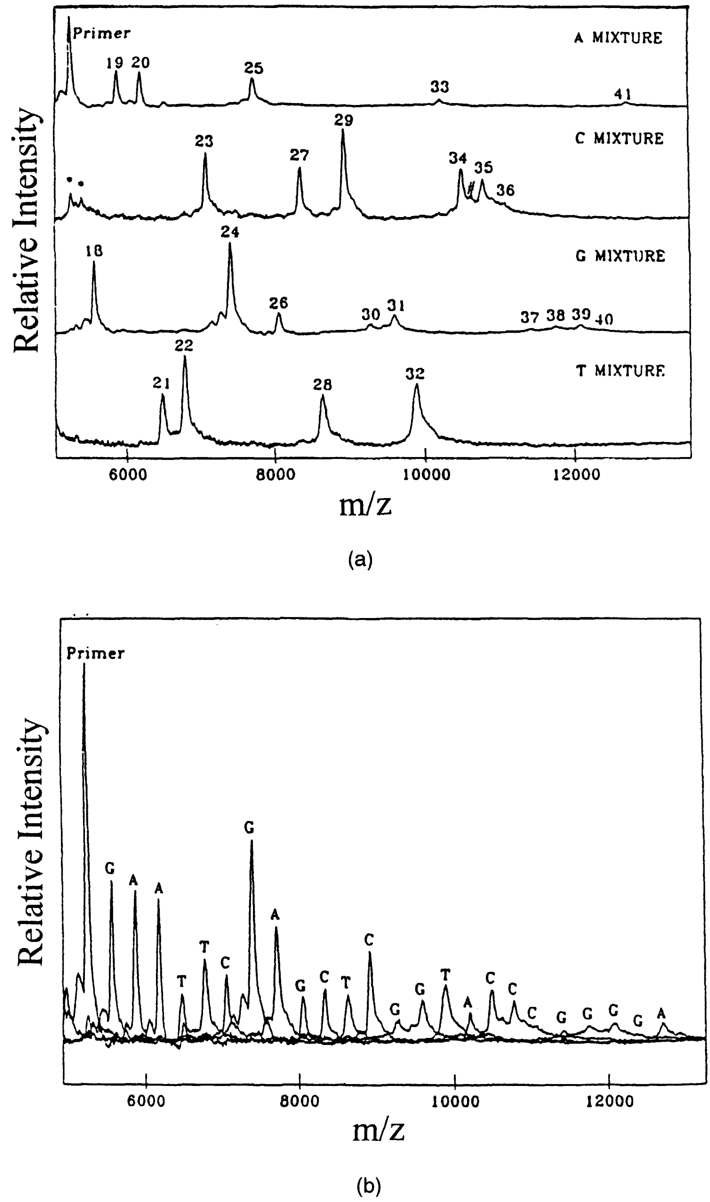
the element of interest has at least two stable or long-lived isotopes, a known quantity of a spike with a different isotopic composition can be added to the sample. Before the determination, the sample and the spike must be completely mixed. Then the ion intensities of two isotopes in the "isotope-diluted" sample are measured using mass spectrometry. From the measured isotope ratio, one can obtain the concentration of the element to be determined in the sample. IDMS can be applied in conjunction with most ionization methods. Table 6 summarizes the most important ionization methods used for elemental analysis by IDMS.

Note that because IDMS is an internal standard method, it provides high precision and accuracy (1% or better), as well as low detection limits (μg/g–pg/g). IDMS is applied in geochronology, radionuclear and isotopic work, certification of standard reference materials, and calibration of other analytical methods. For example, the measured concentrations and isotopic compositions of the noble gases helium, neon, argon, krypton, and xenon in Antarctic meteorites provide information about spallogenic isotopes produced by cosmic rays, trapped primordial or solar gas, and radiogenic ^{4}He and ^{40}Ar from natural decay of unstable potassium (^{40}K), uranium, and thorium. In ^{40}Ar/^{39}Ar age determination for minerals containing potassium, the sample is irradiated in a nuclear reactor. ^{40}Ar is generated by the ^{40}K decay, and ^{39}Ar is produced by the nuclear reaction with ^{39}K. The number of ^{40}Ar atoms generated in the sample can be expressed as $^{40}\mathrm{Ar} = (\lambda_e/\lambda)(e^{\lambda t} - 1)$, where λ and λ_e are the total decay and electron-capture constants for ^{40}K. With careful measurements, the ages of minerals can be determined out to several billion years.

Applications to molecular analysis show similar advantages, and in these cases there are additional choices as to the number and locations of the labeled atoms within the molecular spike. As a matter of convenience, it is customary to use multiple isotopic la-



(a)

(b)

FIG. 35. MALDI/TOF negative-ion mass spectra of mock products of sequencing reactions containing mixtures of synthetic oligonucleotides chosen to match the first 24 DNA fragments generated in typical sequencing reactions using a standard template for the primer oligonucleotide of sequence of d(GTAAAACGACGGCCAGT). (a) The four spectra displayed individually. (b) The spectra overlaid and displayed on the same mass scale. Signals due to doubly charged ions and matrix adducts are labeled * and #, respectively. (Fitzgerald *et al.*, 1993.)

bels in isotopically labeled compounds; this gives good mass separation of the ions due to the spike from the naturally labeled isotopes (especially ^{13}C) of the analyte. For example, a primary metabolite of δ-9-tetrahydrocannabinol, 11-nor-δ-9-carboxylic acid, is often determined in clinical laboratories by IDMS using the synthetic trideuterated analog as the spike.

3.6 Isotope-Ratio Mass Spectrometry

Isotope-ratio mass spectrometry (IRMS) is one of the oldest types of mass spectrometry. It finds use in accurate determinations of isotopic compositions of the elements and low-molecular-weight permanent gases such as H_2, CO_2, N_2, and SO_2, as well as more complex compounds. These values provide a

Table 6. Ionization methods for elemental analysis with IDMS.

Ionization method	Preferred analytes
Thermal ionization	
Positive ions	Metals
Negative ions	Nonmetals
Electron ionization	Noble gases
Spark source	All elements
Plasma source (e.g., ICP)	All metals and metalloids
Laser	All elements
SIMS	All elements

rich source of information on the prior physical and chemical history of the sample. The isotope ratios of hydrogen, carbon, nitrogen, oxygen, and sulfur in organic compounds can be determined after combustion. In recent work, separation (by GC) is carried out, and combustion and IRMS on individual compounds present in complex mixtures is performed on line. This experiment can reveal a great deal about the previous history of the compounds; e.g., the biological sources of "marker" compounds such as steranes used in petroleum exploration can be revealed.

In a typical experiment, the ion source is operated in the EI mode with an electron energy of 70 eV and a trap current of 300–600 μA. Gas sample introduction into the ion source is traditionally by means of a dual gas-inlet system. Viscous gas flow from the reservoir (~50 Torr) into the ion source is used to avoid an isotope shift in the reservoir sample over time. The isotope ratio of the sample is measured by direct comparison with a standard gas of known isotopic composition. The resulting molecular ions are usually analyzed by a magnetic sector because of its temporal stability and high precision. The individual ion beams are focused into separate Faraday collectors so that multiple isotopes of a single element may be collected simultaneously (e.g., $^{28}N_2$, $^{29}N_2$, $^{30}N_2$). Modern IRMS systems are operated under automatic control.

IRMS has a high sensitivity to differences in isotopic abundances. A relative standard deviation of 0.001% can be achieved under optimum conditions. The widespread use of stable isotopes has led to increasing development of mass-spectrometric assays of isotopic abundances in fluids, products of combustion, individual organic compounds, and isotopes of mineral elements. For example, stable-isotope–labeled analogs have been used as tracers to follow the metabolism and excretion of biological compounds and drugs. Figure 36 shows different ^{13}C-to-^{12}C ratios of natural carbonaceous materials measured by IRMS and expressed as delta values (differences in parts per thousand

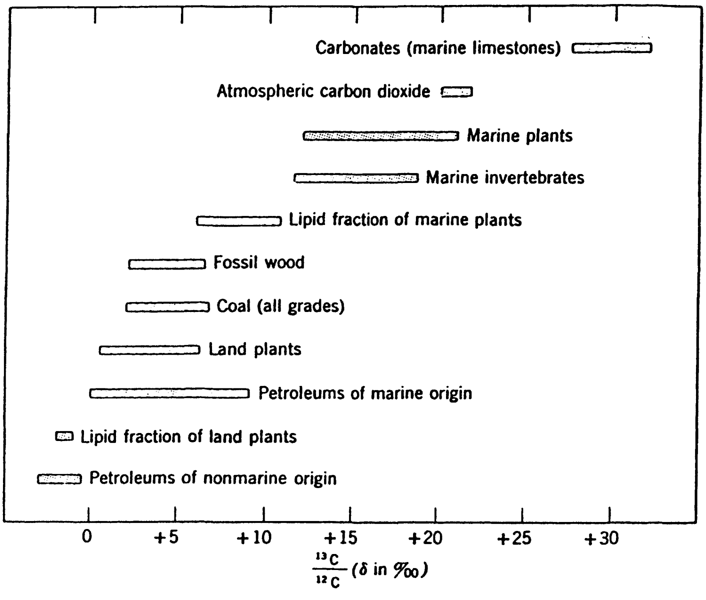


FIG. 36. $^{13}C/^{12}C$ δ-value ranges in natural carbonaceous materials (Craig *et al.*, 1964.)

from a standard material). IRMS continues to play an important role as a highly specialized tool in earth and atmospheric science, biochemistry, and physiology.

Another technique in mass spectrometry that also involves measurement of ratios of abundances of stable or radioisotopes is accelerator mass spectrometry (AMS). An accelerator operated at several million electronvolts is used to produce an ion beam, which is subjected to collisions during which charge-inversion, collision-induced dissociation, and charge-exchange processes may occur. By subjecting the beam to successive mass-to-charge ratio, momentum-to-charge ratio, or energy-to-charge ratio analyses, it is purified of even the smallest traces of molecular-ion contaminants before the isotope ratio of interest is measured. A typical setup is shown schematically in Fig. 37.

The entire instrument provides extremely high abundance sensitivity, viz., the ability to make measurements on specific isotopes even in the presence of other isotopes of the same element whose abundances differ by factors as large as 1:10^{15}. AMS has been applied to measurements of isotopes that are useful as tracers or chronometers including ^{10}Be/^{9}Be, ^{14}C/^{12}C, ^{26}Al/^{27}Al, and ^{36}Cl/^{35}Cl. In the best-known example, the measurement of radiocarbon (^{14}C) is used to determine the age of archeological and geological samples. The procedure only requires a small amount of sample (~1 mg), and with ^{14}C/^{12}C ratios of up to 10^{15}, age determinations up to 100 000 years can be made. Note that the method measures undecayed ^{14}C, *unlike* conventional dating methods that observe the number of decays of ^{14}C per unit time. The detection of tritium (^{3}H) with a half-life of 12.3 yr at a concentration of 1 part in 10^{14} of deuterium has been reported, and in this application the detection efficiency achieved by AMS is two orders of magnitude higher than that achieved by beta counting.

AMS is also used for fundamental studies in atomic and nuclear physics. A combined two-accelerator system at the Lawrence Berkeley Laboratory (U.S.A.) produced the first completely ionized uranium atoms, i.e., $^{238}U^{+92}$, a nucleus with no orbital electrons. Such fully stripped ions exist, for instance, in the interior of many stars and have been produced abundantly for most elements at velocities about 80–90% of the speed of light at the Heavy Ion Accelerator in Darmstadt, Germany. The masses of such nuclei have been investigated there as well as their half-lives. Because there can be no interaction between the atomic nucleus and the electronic shell in the fully stripped ions, their half-lives are different from those ions that possess at least part of their electron cloud.

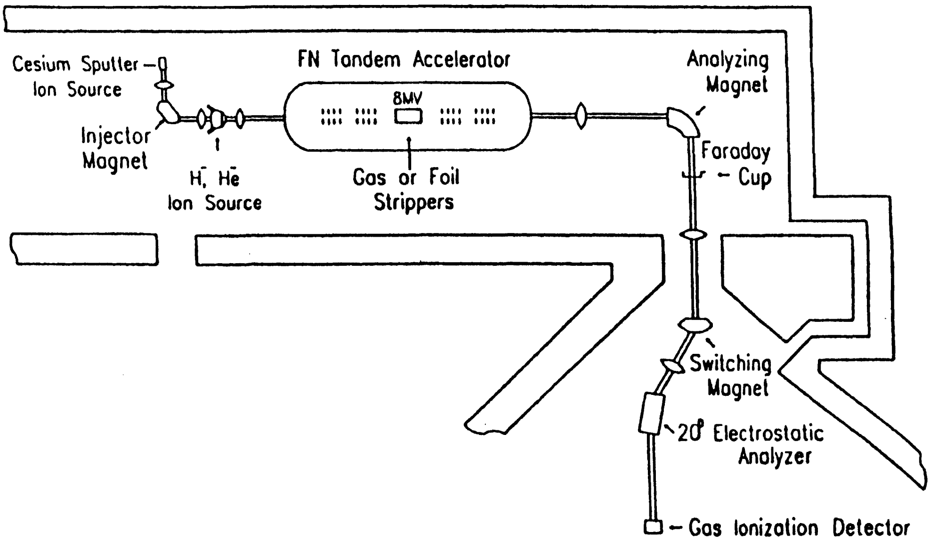

FIG. 37. Schematic diagram of the accelerator mass spectrometer at Purdue University.

3.7 Mass Measurements of Stable and Unstable Nuclei

Precise mass measurements of the isotopes of the elements were first made in experiments begun by Aston in 1919 using a sector-field mass spectrometer. These measurements revealed differences in the binding energies of the different isotopes of the elements, from which the nuclear shell structure was deduced. Even for isotopes of low abundance, such experiments have been conducted with mass resolving powers of about 10^6. For the investigation of difficult-to-produce short-lived neutron-rich or neutron-deficient isotopes, sector-field mass spectrometers have been operated as time-of-flight analyzers. In such systems more energetic and thus faster ions of the same mass-to-charge ratio are guided to the final ion collector so that single-mass ions of all energies arrive simultaneously, provided they started at the same time. Alternatively, the ion energies have all been made equal or been measured for every ion individually by a second sector-field analyzer. With such instruments the binding energies of about 2000 exotic nuclei have been investigated. Some of these exotic nuclei are short-lived but exist abundantly in nova and supernova star explosions, and they have had a major influence on the formation of all heavy elements in the universe.

3.8 Resonance-Ionization Mass Spectrometry

Resonance ionization is a photoionization process where atoms in the gas phase are ionized by successive absorption of photons that energetically match quantum-selected state differences of these atoms. Typically, a laser is tuned precisely to the wavelength required for the excited state, which is unique to the element (and isotope) being measured. Then additional photons of the same or another energy are used to photoionize this excited atom.

Resonance-ionization mass spectrometry (RIMS) is a very selective (even to particular isotopes) and highly sensitive technique since only the atoms of interest are ionized and yet all atoms of the selected element lying in the confines of the laser beam are ionized. The physical basis for the process makes this method yield highly predictable results. The elimination of isobaric interferences is possible in RIMS. The detection and analysis of every chemical element in the periodic table can be realized, and low detection limits in the parts-per-trillion range are normally obtainable. RIMS has found wide applications for elemental analysis in the semiconductor industry and in geological studies.

A technique in which mass spectrometry is used in conjunction with laser spectroscopy to obtain fundamental atomic and molecular information is photodetachment. In this technique, negative ions are generated in a hot-cathode or cold-cathode electric-discharge ion source. Then the mass-selected negative-ion beam is intersected by a laser beam, and the photodetachment spectrum is obtained by recording the number of electrons produced as a function of photon energy. The information obtained can be used to study the electronic structures of molecules. In addition, the electron affinities of atoms and some molecules can be measured precisely by this technique. Fundamental information regarding the electronic, vibrational, and rotational states as well as binding energies can also be provided. A related photoelectron technique is photoionization–photoelectron-coincidence spectroscopy (PIPECO) in which the product ions and photoelectrons are monitored simultaneously. If one performs this measurement while monitoring zero–kinetic-energy electrons, the internal energy distribution of ions can be determined by measurement of the total ion current as a function of the photon energy. Such experiments produce detailed spectroscopic information on gas-phase ions.

3.9 Mass Spectrometry in Surface Analysis

The sputtering process used in DI (Sec. 1.4) releases neutral and ionized species from a surface and can be used for elemental and molecular analysis. In addition, depth profiles are obtained by monitoring the abundance of particular ions as a function of the time of sputtering. The removal of surface layers depends on the current density of the energetic beam and the composition of the material surface. Figure 38 illustrates SIMS depth profiling of boron in

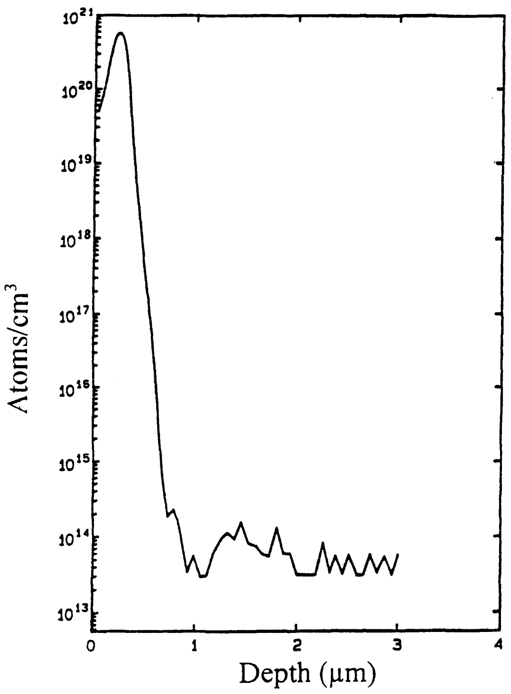

FIG. 38. SIMS depth profile of boron implant in silicon. Primary ions O_2^+. (Adams *et al.*, 1988.)

silicon, where the boron concentrations are recorded quantitatively with a sensitivity of the order of 1 part per billion and a dynamic range of more than seven orders of magnitude, while the depth is followed with a resolution better than ~5 nm. However, this is a destructive method of analysis; and since the percentage of sputtered ions to neutrals varies with compound composition and structure, high quantitative accuracy requires a very good understanding of the underlying processes. A complementary technique to SIMS is Rutherford backscattering spectroscopy (RBS), which employs scattering of high-energy ions, usually $^4He^+$ beams in the MeV energy range, to study the near-surface regions of solids, including implantation profiles, impurity distributions, and diffusion phenomena. Figure 39 shows the energy spectrum of the backscattered products of 2.0-MeV $^4He^+$-ion collisions at 150° from a self-supporting Al_2O_3 film. The result shows two well-resolved peaks corresponding (from the measured He/He$^+$ kinetic energy) to O and Al. RBS has been used to determine impurities in semiconductor devices and the uniformity and stoichiometry of solid-phase epitaxial films in microelectronics research. A lower-energy experiment, ion-scattering spectrometry, uses binary elastic collisions of ions to measure the masses of atoms lying at the surfaces of materials.

Two imaging techniques based on DI, the ion microprobe and ion microscope, have long been used for surface analysis. In the ion microprobe, the desired spatial resolution is achieved by rastering a focused primary beam (≤ 10 μm) across a surface and analyzing the desorbed ions of interest using a mass spectrometer, often a TOF instrument. The lateral resolution in the ion microprobe is essentially given by the beam size. The ion microscope utilizes primary ion beams of relatively large dimension (~5–500 μm). A one-to-one object-to-image transfer is achieved by an ion optical system that transports the desorbed ions from the sample to a detector while maintaining their original spatial relationships.

Another surface analysis technique that employs mass spectrometry is temperature-programmed desorption (TPD), in which the surface is heated at an appropriate rate so that adsorbed species are sequentially desorbed and then ionized and analyzed by mass spectrometry. The dependence of desorbed ion intensities on temperature provides information about the strength of surface binding, while the nature of the adsorbates on the surface at different temperatures is inferred from the ions that appear in the spectrum. Figure 40 shows TPD spectra following Ru (001) oxidation at 1465 K in $\sim 10^{-7}$ Torr O_2. It can be seen from the NO desorption signals that the nature of the adsorption changes between 1110 and 1520 K.

3.10 Ion-Mobility Spectrometry

Mass spectrometry has become a powerful tool in gaining fundamental understanding of atoms and molecules. Ion-mobility measurements in gases have been made for many years, but the recent use of mass-analyzed ion beams has demonstrated unexpected richness in this measurement.

A typical experimental arrangement is shown in Fig. 41. Mass-selected ions generated in the ion source are injected into a high-pressure drift cell (2–5 Torr helium).

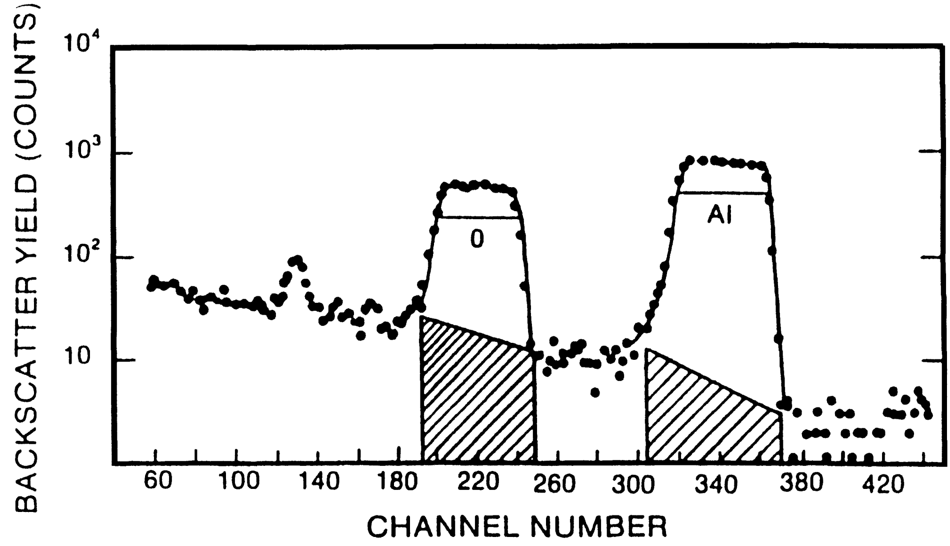

FIG. 39. Energy spectrum of 2-MeV ^{4}He backscattered from a 58 μg/cm^2 self-supporting Al_2O_3 film. The shaded area under each peak indicates the magnitude of the background correction. (MacDonald *et al.*, 1983.)

The ions then drift through the cell under the influence of a weak electric field (1–20 V/cm) and exit the cell through a small aperture. They pass through a quadrupole mass filter and are detected as an arrival-time distribution (ATD). Ions with the same mass but different collision cross sections will have different mobilities and hence drift times, giving rise to different peaks in the ATD. Differences in mobilities have been shown to be associated with differences as subtle as those due to different electronic configurations of transition-metal ions. Figure 42 shows bimodal arrival-time distributions for Co^+ ions generated from different compounds and under different EI conditions. Clearly, Co^+ ions are generated in different electronic states and can be distinguished by their arrival times. This observation offers a good opportunity to select and study reactivities of ions in different electronic states.

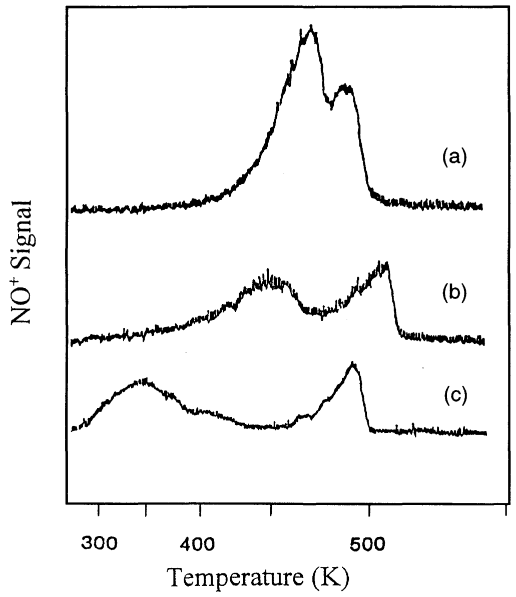

FIG. 40. Temperature-programmed desorption signal for NO released from oxidized Ru. Temperature of annealing (a) 1110 K, (b) 1310 K, and (c) 1520 K. Heating rate 10 K/s. (Vanselow and Howe, 1984.)

Not only can small atomic ions be characterized by their mobilities but large carbon clusters display drift times that depend on their structures. This method has been used to show that carbon atoms first assemble in linear chains, then form monocyclic planar rings at about C_{10}, and finally form families of planar bi-, tri-, and tetra-cyclic rings at C_{20}, C_{30}, and C_{40}, respectively. With advances in ionization methods, macromolecules can be easily ionized, and their structural characterization by mass spectrometry is possible (Sec. 3.4). Ion-mobility measurements hold

(Bowers *et al.*, 1993.)

great promise in distinguishing isomeric biological molecules and, more importantly, for identifying the specific conformations associated with the native states of biological compounds.

3.11 Analysis of Single Particles in Aerosols

The high sensitivity of mass spectrometry allows the determination of the chemical composition of single aerosol particles. In this experiment, aerosols are sampled directly using a differentially pumped mass-spectrometer inlet. The particle beam emerging from the inlet is intercepted by a continuous laser beam in the ion source region. Particles passing through the laser beam are detected by light scattering. The scattered radiation from each particle triggers a high-energy laser that ablates the particle in flight. Ions produced from the particle are analyzed by mass spectrometry. The chemical composition of the particle can be inferred from the distribution of ions observed in the mass spectrum. Figure 43 displays mass spectra of single 3.5-μm-diam sodium chloride particles. This technique permits exploration of atmospheric particle size, composition, and morphology, and thus the physical and chemical processes that transform the particles.

ACKNOWLEDGMENT

The authors would like to thank Carsten Weil for his help in preparing figures.

ACRONYMS

AMS: Accelerator mass spectrometry.

APCI: Atmospheric-pressure chemical ionization.

ATD: Arrival-time distribution.

CCD: Charge-coupled device.

CI: Chemical ionization.

CID: Collision-induced dissociation.

CZE/MS: Capillary-zone electrophoresis/mass spectrometry.

DI: Desorption ionization.

EI: Electron impact (ionization).

ES: Electrospray.

FAB: Fast-atom bombardment.

FD: Field desorption.

FT-ICR: Fourier-transform ion-cyclotron resonance.

GC/MS: Gas chromatography/mass spectrometry.

GD: Glow discharge.

ICP: Inductively coupled plasma.

IDMS: Isotope-dilution mass spectrometry.

IRMS: Isotope-ratio mass spectrometry.

ITR: Integrating transient recording.

LC/MS: Liquid chromatography/mass spectrometry.

LD: Laser desorption.

MAGIC: Monodispersed aerosol generator for introduction from liquid chromatography.

MALDI: Matrix-assisted laser desorption ionization.

MS/MS: Mass spectrometry/mass spectrometry.

MW: Molecular weight.

NCI: Negative-ion chemical ionization.

PA: Proton affinity.

PD: Plasma desorption.

PIPECO: Photoionization–photoelectron-coincidence spectroscopy.

RBS: Rutherford backscattering spectroscopy.

rf: Radio frequency.

RIMS: Resonance-ionization mass spectrometry.

SI: Spray ionization.

SID: Surface-induced dissociation.

SIM: Selected-ion monitoring.

SIMS: Secondary-ion mass spectrometry.

TDC: Time-to-digital converter.

TOF: Time of flight.

TPD: Temperature-programmed desorption.

TS: Thermospray.

GLOSSARY

Atmospheric-Pressure Chemical Ionization: A variant of chemical ionization performed at atmospheric pressure.

Charge Exchange: Process whereby one particle transfers an electron to another, e.g., $M + A^+ \rightarrow M^+ + A$.

Chemical Ionization: Method in which neutral molecules are ionized by ion–molecule reactions to generate a quasimolecular ion at a pressure of about 1 Torr.

Collision-Induced Dissociation: Process whereby a mass-selected ion is internally excited and caused to fragment by collision with a target gas.

Cyclotron Motion: Cyclic rotation of an ion in a fixed magnetic field.

Desorption Ionization: Method used to ionize nonvolatile solid samples by impact of energetic particles or photon beams.

Double Focussing: A combination of direction and velocity focussing in sector instruments used to achieve high resolution.

Elastic Collision: Collision in which internal energy is conserved.

Electron Affinity: Enthalpy change for the process $M^- \rightarrow M + e^-$.

Electron Capture: Ionization process in which a molecule or atom captures a thermal-energy electron typically in a CI source.

Electron Impact: Ionization method in which molecules are ionized directly by energetic electrons (usually 70 eV) at low pressure ($\sim 10^{-5}$ Torr).

Glow Discharge: Method used to ionize solid samples for elemental analysis by applying an electric field to create an energetic plasma.

Inductively Coupled Plasma: Method used to ionize solution samples for elemental analysis by a plasma.

Inelastic Collision: Collision in which internal energy is not conserved.

Ion Internal Energy: Total electronic, vibrational, and rotational energy referenced to ground state of the ion.

Ion Microprobe: Technique that uses a primary ion beam (≤ 10 μm) rastered across a surface to desorb ions for analysis by mass spectrometry.

Ion Microscope: Technique that uses a large ion beam (5–500 μm) to obtain one-to-one object-to-image transfer by ion-optic lenses that extract and transport the desorbed ions from the sample while maintaining their original spatial relationships.

Ionization Energy: Minimum energy required to remove an electron from a molecule.

Liouville's Theorem: Conservation law in ion optics that states that the product of velocity, angular dispersion, and beam dimension is conserved.

Magnetron Motion: Slow circular drift of an ion along a path of constant electrostatic potential; magnetron motion occurs in ICR as a result of the crossed radial electric field and axial magnetic field.

Mass Resolving Power: $m/\Delta m$, in which m is ionic mass and Δm is the width of the mass peak (typically taken as the full width at half-maximum mass-spectral peak height).

Mathieu Stability Diagram: Diagram showing the solutions to the Mathieu equation that correspond to stable ion trajectories displayed as a function of parameters related to operating voltages and mass and charge of the trapped ions.

Metastable Ion: Ion that fragments slowly and after emergence from the ion source; in sector instruments metastable ions give rise to signals that appear at unique m/z values related to the parent- and product-ion masses.

Molecular Ion: Ion derived from the neutral molecule by loss or gain of an electron.

Neutral-Loss Scan: An MS/MS experiment that records all parent ions that lose a particular neutral fragment.

Parent Ion: Any ion that fragments to a product ion.

Parent-Ion Scan: An MS/MS experiment that records all parent ions that produce a particular product ion.

Photodissociation: Process in which an ion fragments by absorption of one or more photons.

Product Ion: Ion generated by fragmentation of any parent ion.

Product-Ion Scan: An MS/MS experiment that records all product ions derived from a single parent ion.

Proton Affinity: Enthalpy change for the process $MH^+ \rightarrow M + H^+$.

Quasimolecular Ion: Ion that is simply derived from or related to a neutral molecule, e.g., $(M + H)^+$, $(M + Cl)^-$, $(M - H)^-$.

Secondary-Ion Mass Spectrometry: Mass spectrometry based on analysis of particles that are emitted when a surface, usually a solid, although sometimes a liquid, is bombarded by energetic (~keV) primary particles (e.g., Ar^+ and Cs^+).

Spray Ionization: Method used to ionize liquid samples directly by electrical, thermal, or pneumatic energy.

Surface-Induced Dissociation: Process whereby a mass-selected ion is excited and caused to fragment by collision with a target surface.

Tandem Mass Spectrometry: Two-stage mass-analysis experiment, used to study the chemistry of selected ions.

Thermal Ionization: Method used to ionize solid samples on a hot surface of a metal filament.

INTRODUCTION

Neutron spectrometers are valuable devices used for condensed-matter studies, for basic nuclear physics research, and for providing cross-section data for fission and fusion reactor programs. Many different kinds of neutron spectrometers have been developed since the discovery of the neutron in 1932 and have been used to explore a very broad energy range, from 10^{-6} eV to 800 MeV. Typically, a spectrometer is used to measure the energy of neutrons incident on and sometimes scattered by a sample. For nuclear physics research or cross-section measurements, this information is usually focused on the neutron–nucleus interaction as a function of the incident neutron energy. For condensed-matter research, the results provide information about the energy and momentum dependence of the neutron–sample interaction. This information is more of-

ten concerned with the internal properties of the sample; the neutron is simply being used as a probe of those properties.

The components of a spectrometer usually depend very strongly on the type of neutron source with which it is used, on the type of research being carried out, and on the neutron energy and energy resolution required by the research. There are two major classes of neutron sources, which differ primarily in the time structure of the neutron beam. Nuclear reactors produce a "steady-state" flow or current of neutrons, whereas accelerator sources usually produce a "pulsed" or chopped flow of neutrons. Both sources provide beams with a broad energy spread, often called a "white" source, and for both classes, the nuclear reactions responsible for producing the neutrons yield neutrons with energies in the MeV range. While neutrons with MeV energies are very useful for certain neutron–nucleus cross-section studies, keV- and eV-energy neutrons are also required. Research in condensed matter requires neutrons in the so-called thermal energy range from about 0.002 to 0.2 eV. Consequently, most neutron sources have moderators that serve to lower the average neutron energy of the beam from the source. For reactors, moderation of the neutron energy is required for sustaining the fission chain reaction even if no neutrons were being extracted for other purposes.

Moderation is achieved by allowing the energetic neutrons to enter a hydrogenous material such as water or heavy water, D_2O. Since the mass of the proton or deuteron is similar to that of the neutron, the neutron loses on the average a large fraction of its energy at each neutron–proton collision. After only about 30 such collisions, neutrons beginning with MeV energy will have an energy close to that of the mean thermal energy of the protons in the moderator material, i.e., $E_{\text{ave}} \propto kT$, which is typically about 0.03 eV. If thermalization is complete, they will also possess an energy distribution that is usually described quite well by a Maxwellian distribution appropriate for the temperature T.

For each source class there is a wide variety of spectrometer designs, each of which is optimized for measurements over only limited energy or momentum ranges. For steady-state neutron sources, it is necessary to have a device to select monoenergetic neutrons of desired energies from a neutron source with a broad energy spread. This energy can be varied systematically in order to make measurements as a function of neutron energy. Monoenergetic neutrons can also be produced directly from monoenergetic ion beams from some accelerators using thin targets, and the neutron energy can be varied by changing the energy of the ion beam. For a pulsed neutron source, the neutron energy is determined by the time-of-flight (TOF) technique by measuring the time taken for a neutron to travel from the source to a detector many meters away. Most neutron spectrometers are located at major neutron sources (see Tables 1 and 2).

Furthermore, there is a significant difference in the type of measurement required for nuclear cross-section research and for condensed-matter research that influences the spectrometer design. For condensed-matter research, one measures the *change* in energy $\Delta E = \hbar\omega$ and momentum $\hbar Q$ of neutrons that have been *scattered* by the sample. That is, we measure a scattering cross section $S(Q,\omega)$ that contains much information about the specimen. For example, one can determine the energy levels of vibrational and magnetic excitations with energies up to a few eV. The diffusive motions of atoms in solids and rotational–tunneling transitions corresponding to molecular reorientations with characteristic energies of only 10^{-6} eV can also be investigated. For all such experiments, the energy of the neutron is measured twice: before and after scattering. See NEUTRON SCATTERING.

For most neutron–nucleus cross-section research, it is the energy of the neutron beam that is *incident* on the sample or detector that is measured. The most striking feature of these measurements is the observation of sharp resonances due to the strong interaction between the target nucleus and the incident neutron at unique energies. These resonances correspond to excited states in the compound nucleus at an excitation energy of many MeV. The widths of these neutron resonances can vary from a few meV with an average spacing between resonances of a few eV for a heavy nuclide such as ^{235}U, to widths as large as many keV with average spacings of hundreds of keV for light nuclides. Detailed properties of these

[a] Characteristics of many other neutron sources (many no longer in operation) may be found in Rae and Good (1970), Firk (1979), Cierjacks (1983), and Whittemore and West (1983).

[b] Peak thermal neutron flux in moderator, n/cm^2 s.

excited states can be obtained from measurements of the total interaction from neutron transmission through the sample and from interactions producing neutron scattering, capture, fission, etc. as a function of incident neutron energy. Neutron spectrometers for nuclear physics must have very good energy resolution with high intensity to observe many resonances in a nuclide and especially to measure their widths.

Although not all spectrometers at a given source are designed alike, generally they consist of

1. a device to prepare the property of the neutron beam prior to the sample—the energy and its resolution, for example;
2. a device to hold and orient the sample in the beam;
3. a device for measuring the scattering angle and making a "post sample" energy analysis of the beam; and
4. a neutron detector and data-acquisition system.

1. NEUTRON SPECTROMETERS AT NUCLEAR REACTORS

A nuclear reactor is usually fueled with a uranium compound, such as UO_2, enriched in the isotope ^{235}U and placed in an aluminum-clad container. Thermal fission of the ^{235}U produces on the average 2.43 neutrons with a mean energy of about 1 MeV. Typically, the fuel is surrounded by a large tank of water, either H_2O or D_2O, for cooling and for moderating the neutron energy to much lower energies. In the neutron moderation process, an intense source of "resonance" energy neutrons is produced with a $1/E$ energy spectrum down to about 0.2 eV. This reactor source of neutrons is excellent for neutron spectroscopy in the energy range up to about 10 keV. Below 0.2 eV the thermal neutron energy spectrum is described by a modified Maxwellian distribution, and a typical example for a source moderated with D_2O is shown in Fig. 1 (Moon, 1985). This figure shows also that the energy spectrum of the source can be changed significantly by inserting either a cold source (e.g., liquid hydrogen) or a hot source (hot graphite block) in the moderator.

Surrounding the water tank is a thick concrete radiation shield through which are beam tubes that direct the moderated neutrons to the spectrometers. For condensed-matter research, some tubes will be oriented to "view" the cold source, others will view the hot source, and others will view the "room-temperature" moderator. A beam tube is typically a cylinder made of aluminum with an effective diameter of 10 to 15 cm. Because of shielding requirements, reactor beam tubes have a minimum length of several meters. Since the flux of neutrons falls off with the square of the distance from the source, short beam tubes would seem to be preferred for high intensity. However, the number of instruments would then be limited by the floor-space requirements of the instruments. One solution to this problem is the use of neutron guide tubes. For thermal and cold neutrons, guide tubes can transport a beam 30 to 100 m using the phenomenon of total reflection. The refractive index for neutrons in a material such as nickel is less than unity. Consequently, a critical angle θ_c exists below which the neutron beam is totally reflected with no attenuation. With two parallel mirrors, neutrons within the angle $2\theta_c$ will pass by multiple reflection, and the beam divergence will decrease much less with increasing distance than with normal beam tubes. A nuclear reactor source of these thermal- and subthermal-energy neutrons is invaluable for countless condensed-matter investigations.

1.1 Neutron Crystal Spectrometers

As indicated above, one component of a neutron spectrometer, whether it is used for cross-section or condensed-matter research, is a device or technique for determining the neutron energy incident on a sample. One of the best techniques for obtaining an intense beam of low-energy neutrons ($E < 10$ eV) with an energy spread (resolution) of about $\Delta E/E = 1\%$ to 5% is that of a single-crystal monochromator placed in a well-collimated beam of neutrons from a high-flux thermal-fission reactor. When a single crystal (such as beryllium, copper, or pyrolytic graphite) is properly oriented in the collimated neutron beam, neutrons of a discrete energy will be scattered elastically (diffracted) from a particular set of planes of atoms in the crystal through an angle of 2θ given by Bragg's law,

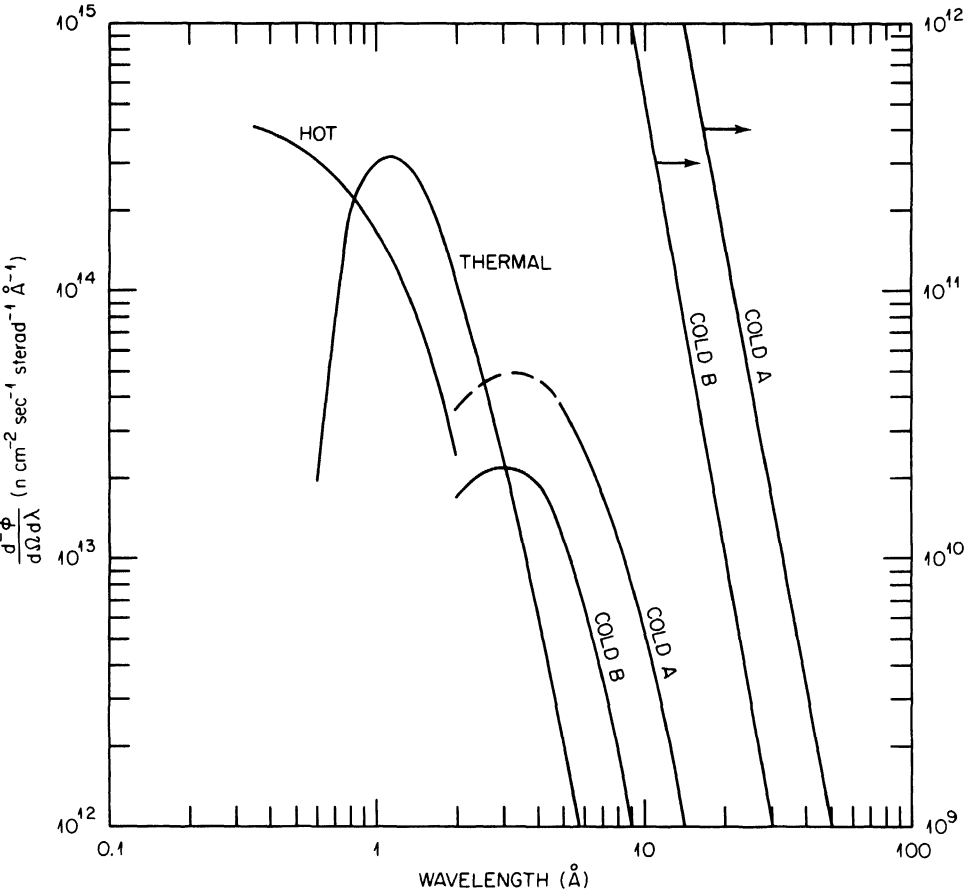

FIG. 1. Thermal-neutron flux distribution from a D_2O-moderated reactor source labeled as thermal and from hot and cold sources.

$n\lambda = 2d\sin\theta$. In this equation, the integer n is the order of the reflection, λ is the wavelength of the neutron, d is the spacing between a particular set of planes of atoms in the crystal, and θ is the angle between the direction of the neutron beam and the set of planes being considered. The neutron wavelength in centimeters equals $0.286 \times 10^{-8}E^{-1/2}$, where E is the neutron energy in eV. Also note that the magnitude of the neutron momentum is $|k| = \hbar/\lambda = \hbar E^{1/2}/0.286 \times 10^{-8}$, i.e., $E \propto |k|^2$. The energy of the diffracted beam can be varied by changing the orientation of the crystal with respect to the neutron beam in order to make measurements as a function of neutron energy.

To increase the intensity of the diffracted neutron beam, multiple parallel slits (called Soller slits) and large single crystals are used to produce a collimated beam with large area. The energy resolution of the beam is determined by the beam divergence and the angular spread (mosaic spread) of the crystal planes, both of which produce an uncertainty in θ. From Bragg's equation above and $n = 1$, one finds that for an angular variation $\Delta\theta$, $\Delta\lambda/\lambda = \Delta\theta \cot\theta$, giving $\Delta E/E = -2\Delta\theta \cot\theta$. The total energy spread from the combined effects of a beam divergence of α_0 and α_1 before and after the monochromator and a monochromator mosaic spread of η_M is

$$\frac{\Delta E}{E} = -2\cot\theta_M\left(\frac{\alpha_0^2\eta_M^2 + \alpha_1^2\eta_M^2 + \alpha_0^2\alpha_1^2}{\alpha_0^2 + \alpha_1^2 + 4\eta_M^2}\right)^{1/2}. \tag{1}$$

Focusing principles that are well known

from optics can also be applied to neutron spectrometer design with a great increase in intensity because samples are often much smaller than neutron beam dimensions. Beam focusing both parallel (usually horizontal) and perpendicular (vertical) to the plane of scattering has been utilized. The case of vertical focusing is easy to illustrate. If one imagines a monochromator crystal shaped in the form of a semicylindrical mirror with the axis horizontal, then neutrons from a point on the neutron source will be focused to a point on the sample if

$$1/L_0 + 1/L_1 = 2\sin\theta/R, \tag{2}$$

where L_0 and L_1 are the distances from the source to the monochromator and from the monochromator to the sample, respectively, R is the radius of curvature of the mirror, and θ is the Bragg angle of the diffracting planes. The intensity gain for a small sample can be expressed as $(h_M/h_s)(L_0 + L_1)/L_1$, where h_M is the height of the monochromator and h_s is the height of the source. This gain can be as large as a factor of 3.

1.1.1 Triple-Axis Spectrometer The monochromator described above is on the first axis of one of the most widely used neutron spectrometers ever designed for condensed-matter research, the triple-axis spectrometer pioneered by Brockhouse (1961), for which he received the 1995 Nobel prize in physics. A schematic diagram of a triple-axis spectrometer located at the High Flux Isotope Reactor of the Oak Ridge National Laboratory, Oak Ridge, Tennessee, is shown in Fig. 2. The neutron beam diffracted by the monochromator crystal is directed onto the specimen located on the second axis, and the energy of the neutrons deflected (scattered) by the specimen through the angle Φ is determined by Bragg diffraction in the analyzer crystal on the third axis. The neutron detector is usually a tube, e.g., 5 cm diam × 15 cm long, oriented with the axis vertical and filled with ^{3}He gas. Neutron detection is by means of the charged particles produced in the $^3\mathrm{He}(n,p)$ reaction.

The great advantage of this spectrometer is the capability it provides to measure, simultaneously and systematically, predetermined values for the momentum change $\mathbf{Q} = \mathbf{k}_i - \mathbf{k}_f$ and the energy change $\hbar\omega = E_i - E_f \propto |\mathbf{k}_i|^2 - |\mathbf{k}_f|^2$ of the neutron due to its interaction with the specimen. Furthermore, the measurements of the neutron intensity corresponding to a wide range of $\hbar\omega$ can be made for a fixed $\mathbf{Q}$. For illustration, if we consider a coordinate system with the x axis parallel to $\mathbf{k}_i$, then $Q_x = |\mathbf{k}_i| - |\mathbf{k}_f| \cos\Phi$ and $Q_y = |\mathbf{k}_f| \sin\Phi$, where Φ is the angle (see Fig. 2) of the scattered neutron relative to the direction of the incident beam. Many pairs of wave vectors $|\mathbf{k}_i|$ and $|\mathbf{k}_f|$ and angles Φ will give the same $\mathbf{Q}$ but different values for $\hbar\omega$. This capability of the spectrometer is particularly desirable for data analysis, because usually the comparison between theory and experiment is most easily carried out for fixed $\mathbf{Q}$. In a typical experiment, either $\mathbf{k}_i$ or $\mathbf{k}_f$ is fixed by selecting the Bragg angle of the monochromator, θ_M, or the analyzer angle θ_A. The other wave vector, and hence the energy transfer, are varied by scanning the appropriate angle. $\mathbf{Q}$ is fixed by simultaneously scanning Φ. If it is necessary to fix $\mathbf{Q}$ with respect to a reference coordinate system of the specimen, then the angle Ψ is scanned also along with the other angles. While such scans are complex, with the computer control of modern spectrometers many such scans are easily carried out automatically. See NEUTRON SCATTERING.

1.1.2 Polarized-Beam Triple-Axis Spectrometer The neutron possesses a spin of $\frac{1}{2}$ and a large magnetic moment. This magnetic moment can interact with and, thereby, provide much information about the magnetic moments of unpaired electrons within the specimen. The neutrons emerging from the reactor beam tube are unpolarized; that is, they can be considered to be equally distributed between up (↑ or +) and down (↓ or −) spin states. It is possible to replace the monochromator and analyzer crystals in the triple-axis spectrometer with crystals that are polarization sensitive. Both are magnetic devices that have zero reflectivity for (−) neutrons, for example. In addition, electromagnetic devices for maintaining or reversing the polarization (flippers) are positioned in the beam before and after the specimen. With both flippers off, the beam incident on the specimen is in the (+) spin state, and only those neutrons that are scattered without change of spin will be reflected by the analyzer. We thus measure a (+ +) scatter-

ing cross section. By setting the various states of the two flippers, we can measure four partial scattering cross sections: spin flip (+ −), (− +), and nonspin flip (+ +), (− −). We thus have a spectrometer that can be used for energy and spin spectroscopy, providing very detailed information about the magnetism of the specimen at the atomic level (Moon *et al.*, 1969).

1.1.3 Spin-Echo Spectrometer The spin-echo method is utilized in a polarized-beam spectrometer in which the energy transfers are measured directly instead of measuring a difference between specified incident and scattered energies. This method allows a very good resolution, of the order 10^{-9} eV, with good intensity (Mezei, 1979). The neutron spin is utilized for energy measurement in this spectrometer, not for measurement of the magnetic properties of the sample. The method is illustrated in Fig. 3. Neutrons from a cold source are monochromatized and then polarized by reflection from a magnetized neutron mirror. The neutron polarization is first rotated into the hor-

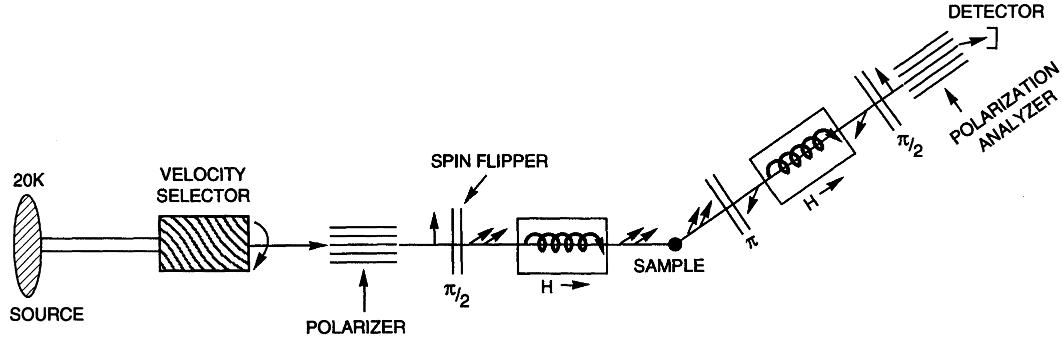

FIG. 3. A schematic illustration of the spin-echo spectrometer using polarized cold neutrons from a reactor.

izontal by a $\pi/2$ flipper. The incident neutrons then precess hundreds of rotations in a magnetic field aligned parallel to the beam path before the sample. The total rotation angle α is inversely proportional to the neutron velocity v_i of the incident neutron.

After the sample, the neutron spins are first rotated by π, and then the scattered neutron spins are passed through another precession field to reverse (unwind), or produce an "echo" of, the precessions that occurred in the incident beam. If the total unwinding angle is β, then the net precession angle θ from monochromator to the detector is $\theta = \alpha - \beta = \gamma HL(1/v_f - 1/v_i)$. Here H is the magnetic field strength and L is the path length of the beam in the field. The polarization P of the emerging neutrons gives the projection or cosine of the precession angle. For $v_i \cong v_f$, we insert $Q = 2mv_i \sin(\Phi/2)$ and $v_i - v_f = \hbar\omega/mv_i$; hence we can write

$$P_f = P_i \int S(Q,\omega) \times \cos[(2 \sin\Phi/2)^3(\gamma HL/\hbar^2 Q^3)m^2\omega]d\omega. \tag{3}$$

Thus the polarization gives directly the Fourier transform of the scattering function $S(Q,\omega)$. The argument of the transform is varied by varying the precession field H.

1.1.4 Beryllium-Filter Spectrometer If a thick polycrystalline block of beryllium is placed in a neutron beam, all the neutrons with energies above about 5 meV are diffracted out of the beam according to Bragg's law, discussed above. However, neutrons below that energy are transmitted with little attenuation because their wavelengths are too long to satisfy the Bragg law for any set of atomic planes in this material and because beryllium has a negligible neutron-absorption cross section. One therefore has a device that serves as a neutron window only for energies below 5 meV.

The beryllium-filter analyzer is an alternative to the analyzer crystal in a triple-axis spectrometer when the energy of the neutrons emerging from the sample is <5 meV. For an energy transfer $\hbar\omega$ much larger than this, for example, >100 meV, the 5-meV window does not deteriorate the resolution appreciably. In such experiments, the beryllium is simply inserted in the scattered-beam path in front of the detector. The high solid angle for this arrangement results in a large increase in intensity, albeit with a correspondingly poor Q resolution. The other limitation of the spectrometer results from the condition that $E_f \ll \hbar\omega$. This condition is equivalent to $k_f \ll k_i$ and, therefore, $Q \approx k_i \propto E_i^{1/2}$. Consequently, there is no flexibility of preselecting Q. Nevertheless, this type of spectrometer has been extremely useful for certain experiments requiring the measurement of high-energy and low-intensity peaks that are nearly Q independent.

1.1.5 Back-Reflection Analyzer Spectrometer In Sec. 1.1, the energy spread of a neutron beam due to the angular variation $\Delta\theta$ of the beam direction or of the diffracting planes in a crystal was shown to be $|\Delta E/E| = (2 \cot\theta)\Delta\theta$. Obviously for $\theta \approx 90°$, i.e., back reflection, the resolution can be extremely good. For example, by employing nearly back reflection in both the monochromator and analyzer that are made from perfect crystals of silicon, a resolution of up to 0.3

μeV is obtained for a neutron energy of about 2.1 meV. A schematic diagram of the IN10 spectrometer at the Institute Laue Langevin (ILL) is shown in Fig. 4. In this type of spectrometer, the energy of the incident or scattered neutron beam cannot be varied by scanning θ, as is done for the triple-axis spectrometer, since we want to keep θ as near to 90° as possible. One solution developed is to scan the incident energy by scanning the neutron velocity changes caused by the Doppler effect and an oscillating-crystal monochromator that moves parallel to the direction of the reactor beam (Birr *et al.*, 1971). The neutrons diffracted by the monochromator are then deflected (by diffraction) toward the sample by a crystal through which the reactor beam was transmitted before it encountered the monochromator. The neutrons scattered by the sample are subsequently backscattered from the array of analyzer crystals, which are focused on the detectors grouped around the sample. The chopper located in front of the sample provides a means, by the TOF technique (see Sec. 1.3 below), to distinguish neutrons that have been scattered by the sample directly to the detectors from those that have backscattered from the analyzer crystals.

An alternative to the Doppler effect is to place the monochromator crystal in a cryofurnace. In this configuration, the incident neutron energy is varied by heating or cooling the crystal, thereby changing the spacing d of the diffracting planes. For example, heating a KCl monochromator from liquid nitrogen to near its melting point provides an energy scan of $-160\ \mu\text{eV} < \hbar\omega < 16\ \mu\text{eV}$ with about 1.0-μeV resolution.

1.2 Mechanical Neutron Velocity-Selector Spectrometers

A mechanical neutron velocity selector is a device that produces a narrow velocity band of neutrons by mechanical means from a steady-state source of neutrons with a broad energy spread. This device is useful for neutron activation and scattering measurements using thermal- and subthermal-energy neutrons, since a crystal spectrometer may have problems in these low-energy regions from higher-order reflections. One technique for selecting velocities consists of several rotating disks of cadmium, containing radial slits, mounted many centimeters apart on a single axis, which is parallel to a collimated neutron beam from a nuclear reactor. The energy of the neutrons passing through the slits is determined by the spacing between the disks, the angular displacement of the slits in adjacent disks, and the speed of rotation. The intensity and energy resolution are determined by the width of the slits, their distance from the axis of rotation, and the rotational speed. For reasonable rotational speeds and with slit widths sufficiently large to give usable intensities, the energy resolution is about 10%.

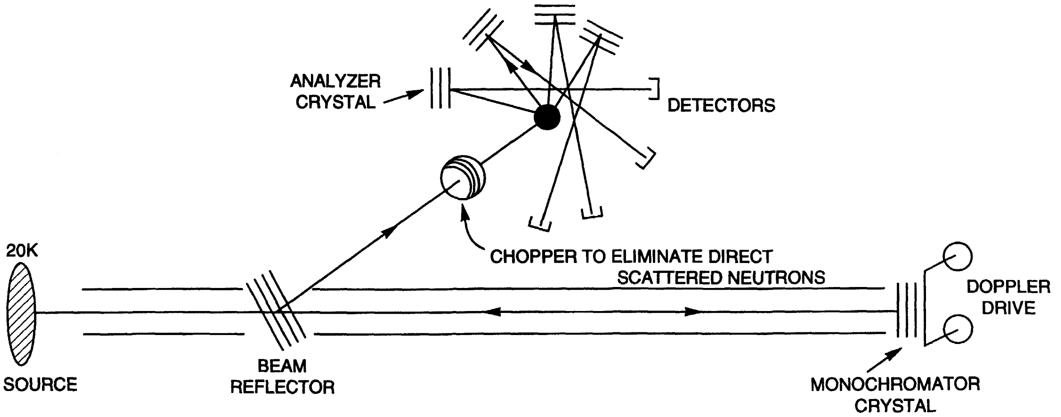

FIG. 4. A schematic diagram of the IN10 back-reflection analyzer spectrometer at ILL reactor, Grenoble, France.

1.3 Neutron Time-of-Flight Spectrometers

Another method to determine the energy of a neutron is to measure its velocity from the time interval that the neutron takes to travel a specified distance, called the time-of-flight (TOF) technique. This method requires the determination of well-defined beginning and ending times for the neutron's transit along the beam path. For a reactor source that is producing a continuous beam of neutrons, it is necessary to "chop" the beam by passing it through an opening in a rotating disk or cylinder to produce microsecond bursts of neutrons and to have an efficient neutron detector located many meters away at the end of a flight path to determine the neutron's flight time. Long flight paths must be evacuated to prevent serious loss of neutrons, and shorter ones often use helium gas, which has a small total cross section for eV and keV neutrons.

The energy resolution of a TOF spectrometer, ΔE, is equal to $2(\Delta t/t)E$, where Δt is the time width of the neutron burst plus the time spread in the neutron detector and electronics and t is the TOF of the neutron. This TOF in microseconds is $72.3L/E^{1/2}$, where L is the path length in meters and E is in eV. The resolution of a TOF spectrometer is often quoted in microseconds per meter. For low neutron energies, the energy resolution in eV is equal to $0.0277E^{3/2}(\Delta t/L)$, where E is in eV and $\Delta t/L$, the resolution, is in microseconds per meter. The time between pulses, the flight path length, and filters in the beam must be selected so that the low-energy neutrons from one pulse do not interfere with high-energy neutrons from the following pulse. By the use of a multichannel storage system utilizing a computer, the complete neutron spectrum consisting of thousands of data points can be obtained with good energy resolution over a broad energy range.

1.3.1 Fast–Neutron-Chopper Spectrometers Fast–neutron-chopper spectrometers are used for spectroscopy in the eV and keV neutron energy regions. A fast chopper consists of a rather massive rapidly rotating shutter in a well-collimated beam of neutrons capable of stopping, or greatly attenuating, neutrons of all energies and also gamma rays from the neutron source. A schematic section of the ORNL fast-chopper TOF spectrometer constructed by Block *et al.* (1960) is shown in Fig. 5. This chopper was capable of producing 1-μs bursts with sufficient intensity from the high flux reactor ORR (neutron flux of 4×10^{14} n/cm^2 s) for transmission measurements using a 180-m flight path. an array of 100 $^{10}BF_3$ gas proportional counters 3 cm in diameter and over 1 m long was used as the detector. This resolution of only 0.006 μs/m gives an energy resolution of 0.2 eV at 100 eV (less than the Doppler width of resonances at this energy) and 5 eV at 1000 eV, which is less than the average spacing of resonances for most nuclides and is sufficient for studying some nuclides up to about 10 keV. The low-energy cutoff for a chopper spectrometer depends on the width of the slits, the length of the slit in the rotor, the speed of rotation, and the curvature or shape of the slit along its length, as discussed by Chrien (1983). For partial cross-section measurements, spectrometers with wider slits and shorter flight paths must be used. A spectrometer installed at the BNL High Flux Beam Reactor by Chrien and Reich (1967) produced 5-μs bursts. This spectrometer had sufficient flux and energy resolution using a 22-m flight path for partial cross-section work including capture gamma-ray spectral measurements up to several hundred eV.

1.3.2 Slow-Neutron-Chopper Spectrometers A "slow"-chopper spectrometer (first used by Fermi in 1943) is a much simpler device than a fast chopper since thermal-energy neutrons can easily be stopped by a small thickness of cadmium. Also, detectors can be made that are very efficient for thermal-energy neutrons and inefficient for higher-energy neutrons and gamma rays. Burst widths of 20 μs and flight paths of only 2 m produce an energy resolution ($\Delta E/E$) of 3% at 0.01 eV, which is adequate for many measurements. For neutron measurements below 0.002 eV, filters of beryllium or graphite are often used since they are almost transparent to these low-energy neutrons and attenuate higher-energy neutrons.

Two slow-chopper spectrometers using TOF techniques have been used for condensed-matter research. One utilizes a crystal monochromator to produce a monoenergetic incident beam that is followed by a chopper to define the beginning time for the TOF measurement (Fig. 6). This design is analogous to the triple-axis spectrometer, with the function of the post-sample analyzer crystal replaced with the TOF measure-

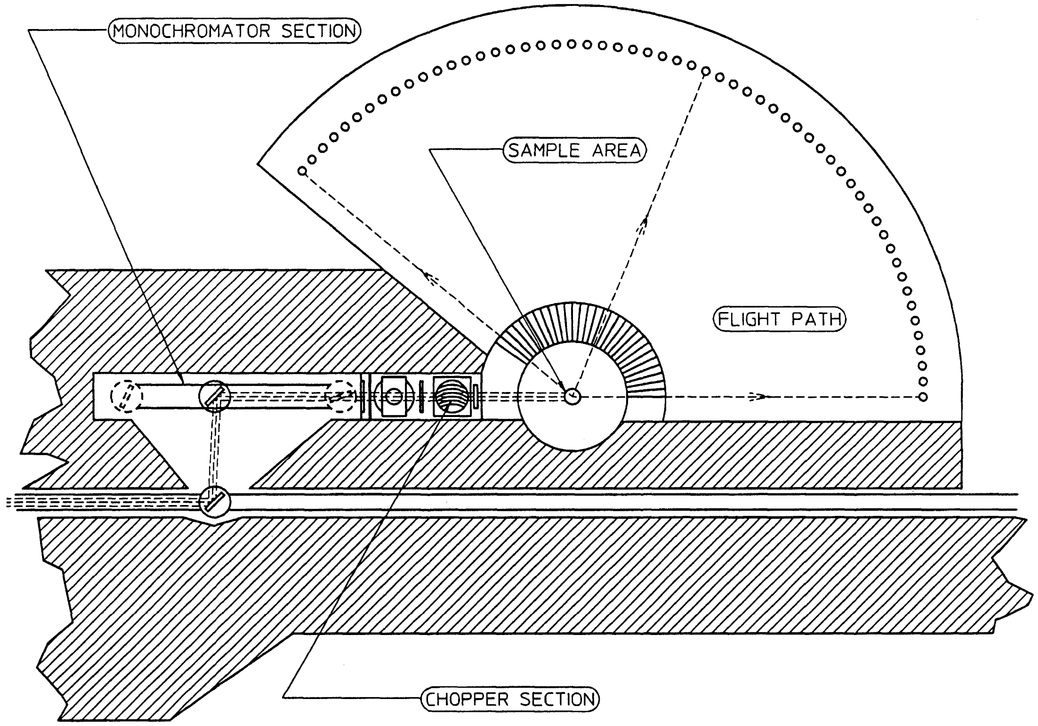

FIG. 6. A schematic of a combination of a crystal monochromator followed by a slow chopper at the National Institute of Standards and Technology reactor research facility.

ment. Such a design is very efficient for collecting spectroscopy data for many scattering angles, and therefore many values of *Q*, simultaneously. The large, space-consuming analyzer-crystal machinery and shielding is replaced with many small detectors located in an evacuated flight path. Each detector measures the time spectrum, and hence the energy spectrum, of the neutrons scattered at the angle corresponding to that detector. Note, however, that constant angle is not constant *Q*.

For the second spectrometer the neutron energy incident on the sample is determined from the preselected transit time between two (or more) choppers separated by a known distance. The first chopper produces a burst of neutrons with a broad distribution of energies. A second chopper is needed to produce a pulsed beam with an acceptable energy resolution and to determine the zero of time for the subsequent TOF spectroscopy of the neutrons scattered by the sample. The neutron energy incident on the sample can be varied by changing the relative phase of the rotations of the choppers, i.e., the time the second chopper is open relative to the time the first chopper is open. If additional choppers are placed before the sample, one can reduce the energy spread incident on the sample, to improve the signal-to-noise ratio and to suppress frame overlap problems (Copley and Udovic, 1993).

2. NEUTRON SPECTROMETERS AT ACCELERATORS

Intense sources of fast neutrons have also been produced from the bombardment of thick targets of heavy elements such as tantalum or uranium with high-current beams of MeV protons, deuterons, and electrons from accelerators. For 50-MeV deuterons on a heavy-element target, neutrons are produced mainly from a nuclear evaporation process and have a Maxwellian energy distribution that extends from about 0.1 MeV to tens of MeV with a peak at about 1 MeV. About 0.3 neutron is produced per deuteron. With 800-MeV protons on a heavy-element target, neutrons are produced by a spallation process, which results in tens of neutrons per proton with energies up to 800 MeV. With an electron linear accelerator with an energy >50 MeV, neutrons are produced by a photoneutron process from bremsstrahlung generated from the electrons striking a heavy-element target. Approximately one neutron is produced for twenty 140-MeV electrons with a thick tantalum target. Most accelerators produce narrow time pulses of charged ions or electrons, and, hence, the fast neutrons are also produced in short time pulses, of the order of nanoseconds, which are needed for TOF spectroscopy for MeV neutron energies. Neutron moderators, which are used to produce intense sources of neutrons below 100 keV and down to thermal energies, increase the pulse width of the moderated neutron pulse.

Useful sources of monoenergetic neutrons down to about 50 keV are produced from the bombardment of thin targets of light elements such as ^{7}Li or ^{3}H with monoenergetic MeV proton or deuteron beams from Van de Graaff or other higher-energy accelerators.

2.1 Variable-Energy Neutron Source Spectrometers

When monoenergetic neutron sources are used for neutron spectrometry for nuclear physics research, measurements are made at a specific neutron energy, then the energy is changed by a small amount (only 0.1% to 1.0%), and a second measurement is made. The process is repeated until the entire energy region of interest is covered. For most of these measurements with monoenergetic MeV neutrons, a pulsed source is not needed. However, for nuclear inelastic neutron-scattering measurements, a technique has been developed that requires nanosecond pulses of monoenergetic MeV neutrons.

2.1.1 Van de Graaff Accelerator Spectrometer Monoenergetic neutrons from Van de Graaff accelerators were the principal source for neutron spectroscopy in the energy range from a few keV to 20 MeV during the 1940s and 1950s. The most useful (*p*,*n*) reactions to cover the neutron energy range from a few keV to a few MeV are those on ^{7}Li and ^{3}H targets, as reviewed by Uttley (1983). The (*d*,*n*) reaction on deuterium is useful from about 1 to 10 MeV, and the (*d*,*n*) on tritium from about 12 to 20 MeV. In the energy range up to 1 MeV, an energy resolution of about 1 keV is possible, which is not adequate for most measurements below about 50 keV neutron energy. The measurement of a complete neutron cross section of a nuclide up to 1 MeV may require up to several thousand sequential energy measurements at slightly different energies, each requiring several minutes. Monoenergetic neutron sources above about 0.1-MeV neutron energy are invaluable for activation measurements that cannot be made using the TOF technique and for nuclear inelastic scattering measurements. See ACCELERATORS, POTENTIAL-DROP.

2.1.2 Cyclotron and Proton Linear-Accelerator Spectrometers For neutron energies above about 21 MeV, truly monoenergetic sources are not possible since additional excited states in the final nucleus are populated for the three most popular targets used for lower neutron energies. Also, multiparticle breakup of the incident particle (if deuterons or tritons are used) produces an intense source of lower-energy neutrons. Hence, even though the intensity of the $^7\mathrm{Li}(p,n)$ monoenergetic neutron source with about 1% resolution up to 300 MeV is comparable to that from the LANL-WNR pulsed neutron source discussed in Sec. 2.2.4, the TOF technique is usually favored for this high-energy region. See CYCLOTRONS and ACCELERATORS, LINEAR.

2.2 Neutron Time-of-Flight Spectrometers

In the late 1930s and early 1940s, accelerators with microsecond pulses and neutron moderators were used for TOF spectroscopy up to only about 100 eV. However, after short-pulse high-intensity cyclotrons, high-current electron linear accelerators, and spallation sources were developed, high-resolution TOF nuclear data could be obtained up to hundreds of MeV. The TOF technique is the only method for high-resolution neutron spectroscopy in the keV energy region. Moderators, which are used to increase the intensity of neutrons below about 100 keV, increase the width of the neutron pulse. For a dense hydrogenous moderator, this time spread of the low-energy leakage neutrons in nanoseconds is about $2000/E^{1/2}$, where E is in eV. This time spread is equivalent to a flight-path distance spread ΔL of about 3 cm for low-energy neutrons and increases to about 7 cm for 100-keV neutrons. Hence, adding this moderation length to the accelerator pulse width (Δt) results in an energy resolution that can be written as $\Delta E/E = 2[(\Delta t/t)^2 + (\Delta L/L)^2]^{1/2}$.

2.2.1 Proton Van de Graaff Accelerator Spectrometer In order to span the neutron energy region from a few keV (the upper limit of a fast-chopper spectrometer) to about 50 keV (the useful lower limit of the variable-energy monoenergetic Van de Graaff source), a pulsed Van de Graaff TOF neutron spectrometer was developed at the ORNL by Good *et al.* (1958). With a proton-bombarding energy about 20 keV above the threshold energy of 1.88 MeV for the $^7\mathrm{Li}(p,n)$ reaction and a moderately thick $^7\mathrm{Li}$ target, 1-ns neutron pulses can be produced with well-defined upper and lower energy limits, from about 3 to 80 keV. Using a flight-path length of only 1 m results in a nominal resolution of only 0.001 μs/m, which corresponds to a percentage energy resolution of 0.4% at 20 keV and 0.8% at 80 keV. However, using a 1-cm-thick $^{10}\mathrm{B}_4\mathrm{C}$ slab with a NaI crystal directly behind as the neutron detector with such a short flight path limits the energy resolution to 2% over the entire energy region. With no low-energy neutrons and short flight paths, high repetition rates up to nearly 10^6 pps can be used without problems from overlap neutrons produced from few-keV neutrons from the previous pulse.

The initial incentive to produce short nanosecond pulses of protons was to obtain monoenergetic MeV neutrons to investigate the excited states of nuclei from inelastic neutron scattering. Various techniques have been developed to produce nanosecond pulses with repetition rates up to 10^6 pps and to measure neutron flight times with nanosecond accuracy up to a few microseconds. The TOF technique to measure the energy of neutrons scattered from a target bombarded with nanosecond pulses of monoenergetic incident neutrons has been the major source of inelastic neutron-scattering data, which are valuable for basic nuclear physics and needed for applied reactor programs.

2.2.2 Electron-Accelerator Photoneutron Source Spectrometers Although electron accelerators were initially built for nuclear physics research such as electron-scattering and photonuclear studies, they have been adapted to be excellent pulsed sources for neutron spectroscopy (Rae and Good, 1970, p. 23; Firk, 1979, p. 550). Electron linear accelerators for pulsed neutron sources have energies from 40 to 180 MeV but have very high peak currents (tens of amperes) in short pulses. Above about 100 MeV electron energy, little is gained in neutron production per kilowatt of electron beam power, and above 200 MeV meson production can cause unwanted backgrounds. Electron linear accelerators have been built at several laboratories in the United States and in other countries mainly for neutron research and have provided the bulk of neutron cross-section data over the entire energy region. See ACCELERATORS, LINEAR.

The latest electron accelerator designed specifically to be used for neutron spectrometry is the Oak Ridge Electron Linear Accelerator (ORELA) [described in review articles by Cierjacks (1983), p. 113, and Bockhoff *et al.* (1990), p. 194]. This accelerator is capable of producing 15-A pulses of 140-MeV electrons, representing a power in the pulse of over 2000 MW. With 24-ns-wide pulses, a beam power of 50 kW is obtained at the maximum repetition rate of 1000 pps. Neutrons are produced from these high-energy electrons by bombardment of a tantalum target (about 4 cm thick) that produces bremsstrahlung, and these high-energy gamma rays then produce neutrons via the (γ,n) reaction. The neutron energy spectrum has a maximum at about 1 MeV and extends from about 10 keV to 80 MeV. The maximum neutron production rate at the ORELA spectrometer in narrow pulses (3–24 ns) is 4×10^{18} n/s. The average production rate is 10^{14} n/s at a repetition rate of 1000 pps and 24-ns-wide pulses.

A schematic of the ORELA facility is shown in Fig. 7. Ten evacuated flight paths with 18 underground stations ranging from 9 to 200 m enable many different experiments to be carried out simultaneously. The target room is also evacuated to eliminate a background due to neutrons scattering from air near the target. A resolution of 0.02 ns/m can be realized using unmoderated neutrons and the 200-m flight station for total and scattering cross-section measurements, which corresponds to a percentage energy resolution of 0.05% at 1 MeV.

The water-cooled tantalum target with a water moderator that is used at ORELA is shown in Fig. 8 (Macklin, 1971). The moderated neutron spectrum has an $E^{-0.78}$ energy distribution down to thermal neutron energies. Below about 300 keV, more usable neutrons are available from the water moderator than from the tantalum target. For most low-energy measurements, "shadow" bars are located in the flight paths or collimation is used to prevent gamma rays (or reduce their intensity) from the tantalum target from reaching the detector directly. The addition of a 5-cm-thick polyethylene moderator on the side of the ORELA target increases the neutron intensity below a few electron volts by up to a factor of 6.

A second target at ORELA, consisting of a thin tantalum converter separated by about 30 cm from a large block of beryllium, is also used for specific MeV neutron measurements. Collimators are designed so that detectors at the ends of flight paths do not "see" the gamma rays from the tantalum converter. Above about 3 MeV, more usable neutrons are available for a neutron transmission measurement from this target than from the thick tantalum target.

Other electron-accelerator spectrometers use somewhat different fast-neutron targets and moderator arrangements. The Geel Electron Linear Accelerator (GELINA), Belgium, has neutron production capabilities very similar to ORELA (Bensussan and Salome, 1978). A unique feature of this facility is a post buncher installed on the accelerator in the mid 1980s that compresses 10-ns, 10-A pulses from the accelerator into 0.6-ns pulses of over 100-A peak current with negligible beam loss. In addition to a stationary uranium target for producing neutrons, a rotating target is used for electron-beam powers above 6 kW. Both are cooled by liquid mercury to avoid neutron moderation. From a thick uranium target, about 0.06 neutron is emitted for each 100-MeV electron. A heterogeneous uranium–beryllium target was also constructed that increased the neutron yield above 10 MeV by a factor of 2 to 3. At GELINA, in addition to polyethylene or water moderators placed close to the uranium target, a liquid-methane moderator has been developed (Bockhoff *et al.*, 1990). This moderator enhances the intensity of neutrons below 0.01 eV by up to a factor of 5 over that

from a water moderator. The GELINA facility has 31 detector stations and flight-path lengths from 8 to 400 m.

2.2.3 Deuteron-Cyclotron Source Spectrometer The addition of a deflection bunching system to the 50-MeV isochronous cyclotron at Karlsruhe resulted in intense pulses of deuterons only 1 ns in width (Cierjacks, 1983), which is excellent for a neutron spectrometer from 0.3 MeV to about 30 MeV. The peak deuteron current in the pulse of 1.5 A at a repetition rate of 2 × 10^4 pulses/s produces a neutron intensity of 2.2 × 10^{17} n/s sr in the forward direction with a uranium target. Neutrons from the bombardment of a heavy-element target such as tungsten, lead, or uranium with 50-MeV deuterons are produced mainly from (*p,xn*) or (*d,xn*) processes, where *x* specifies the number of neutrons produced in the reaction. The neutrons are produced by an evaporation process and have a Maxwellian energy distribution with a maximum at about 1 MeV and extending from about 0.1 MeV to tens of MeV. Neutrons are also produced up to tens of MeV from direct reactions and from the breakup of the bombarding deuterons. Detector stations at the Karlsruhe facility are located at distances of 12, 56, and 190 m from the neutron source. With a fast efficient detector for neutrons above 300 keV, measurements have been made up to 30 MeV with very good energy resolution. The nominal energy resolution is only 0.04% at 4 MeV using the 190-m flight path. No moderator is used with this Karlsruhe spectrometer since even at 100 keV, the time width of the neutron pulse produced by the moderator would be increased to 5 ns and would require a much lower repetition rate to prevent overlap. See CYCLOTRONS.

2.2.4 Proton Spallation Source Spectrometers The 385-MeV proton synchrocyclotron at Columbia University (built for meson physics research) was the first spallation source used for neutron TOF measurements (Rainwater *et al.*, 1964). A deflected 300-mA proton beam pulse 25 ns wide on a water-cooled lead target produces spallation neutrons with an intensity of 1.6×10^{19} *n*/s at a repetition rate of 60 pulses per second. These properties are best suited for high-resolution neutron spectroscopy below 10 keV and, hence, a 4-cm-thick polyethylene moderator was used to increase the intensity of neutrons in this energy range. The neutron detector was a ^{10}B slab 30 cm high, 120 cm wide, and 4 cm thick and contained 15 kg of ^{10}B located at 200 m with four large NaI crystals either above the slab for most measurements or directly behind for low-energy measurements resulting in a higher efficiency. With a 200-m flight path, the nominal resolution is 0.13 ns/m above about 5 keV, where the moderation time equals the 25-ns pulse width. The resolution at 5 keV is less than the Doppler widths of resonances of even the heaviest nuclides and is sufficient for interesting studies on medium- and lightweight nuclides up to 100 keV.

The 800-MeV proton linear accelerator at the Los Alamos National Laboratory (LANL) has also been used as an intense pulsed neutron source for neutron spectroscopy for neutron energies up to 800 MeV (Lisowski *et al.*, 1990). The Weapons Neutron Research (WNR) facility uses the microstructure of the proton beam from the Los Alamos Meson Physics Facility (LAMPF), i.e., 0.2-ns pulses separated by a few microseconds, to produce neutron pulses having a width of about 1 ns from a tantalum target. Each micropulse contains about 3×10^8 protons and, depending on the experiment and the flight-path length, more than 10 000 micropulses/s may be used. With a thick tungsten target, about 17 neutrons are produced per proton at 800 MeV. Flight-path lengths of the six flight paths are from 9 to 90 m. This unmoderated neutron source is excellent for neutron measurements in the energy region from about 0.3 to 800 MeV. See article on ACCELERATORS, LINEAR.

In the late 1980s, a Proton Storage Ring (PSR) was installed at the 800-MeV proton linear accelerator at LANL (LAMPF) for condensed-matter research. The PSR accumulates an unpolarized H^- beam for about 450 μs and then extracts it in a single 250-ns burst at a repetition rate of 20 pulses per second. This bunched beam of about 80 μA is channeled to a target area to produce an intense source of moderated neutrons. The layout of the Los Alamos Neutron Scattering Center (LANSCE) is shown in Fig. 9 (Lisowski *et al.*, 1990). LANSCE has a split tantalum target with several water moderator and reflector assemblies. One moderator is liquid parahydrogen operated at about 20 K, which results in an increase of 100 in intensity for neutrons below 0.01 eV. The time spread in microseconds of epithermal neutrons is approximately $7/E^{1/2}$, where E is in eV, and the intensity varies as $1/E$. Above 1 keV the resolution for neutron spectroscopy is determined by the pulse width from the PSR. Most of the flight paths at LANSCE are devoted to condensed-matter research, but some are used for basic nuclear physics such as parity violation. The extremely high neutron intensity and low pulse rate make LANSCE very useful for thermal and epithermal neutrons up to 1 keV and even to 100 keV if good energy resolution is not required. In fact, the intensity is so high that for some experiments individual neutron pulses are not counted, but a current as a function of time produced by the detector is recorded.

The most powerful spallation source for condensed-matter studies at the present time is the ISIS facility located at Rutherford Appleton Laboratory in England. At this facility an ion source produces H^- ions, which are accelerated to an energy of 70 MeV prior to injection into a proton synchrotron. The synchrotron then further accelerates the protons to an energy of 800 MeV before they are extracted (50 times a second) and sent to the target station. The target is either tantalum or depleted uranium. For an 800-MeV proton beam, there are typically 30 neutrons per proton from a uranium target.

For condensed-matter research at ISIS, an array of hydrogenous moderators is located around the target. These moderators are at various temperatures to produce different spectral distributions for different types of experiments, much like the situation depicted for reactors in Fig. 1. The moderators are at ambient temperature (316K, H_2O), liquid methane (100K, CH_4), and liquid hydrogen (20K, H_2). Neutron beams are transported through beam tubes from the moderators to various spectrometers and diffractometers as discussed for reactor

sources. The pulsed generation of neutrons in a spallation source means that TOF is the natural method to use for spectrometers at such sources. Two general categories of standard spectrometer designs are the most common at pulsed sources: direct geometry and indirect or inverted geometry. Several of the spectrometers located at the ISIS facility are described in Secs. 2.2.5 and 2.2.6. However, similar instruments are also in operation at other spallation sources around the world, such as LANSCE at LANL, IPNS at ANL, and KENS at KEK, Japan (see Table 2).

2.2.5 Direct-Geometry Chopper Spectrometer The direct-geometry chopper spectrometer utilizes the pulse of the source to define the initial time of each neutron's flight. However, the energy distribution of the neutron pulse is as broad as that provided by the moderator. As with many of the reactor-source experiments, it is often necessary to know accurately the neutron energy incident on the sample. Consequently, a slow chopper is located several meters from the source before the sample to monochromatize the incident beam. The High Energy Transfer Spectrometer (HET) at ISIS utilizes a Fermi chopper rotating at frequencies in the range 400–600 Hz for this purpose. Coupling the chopper pulse with the ISIS pulse gives an energy resolution of about 1% in the energy range 0.020–2.0 eV. The energy of the beam that passes through the chopper can be varied at will by altering the phase of the chopper rotation, i.e., altering the time at which the chopper is open relative to the time of the source pulse. Neutrons scattered by the sample are detected by one of many detectors mounted in an evacuated flight path downstream from the sample position, as illustrated previously for the analogous reactor-based spectrometer in Fig. 6. For polycrystalline or liquid samples, a great increase in intensity is achieved on HET by utilizing detectors mounted on annular rings centered on the axis of the incident beam. All detectors on the same ring measure the neutron-scattering spectrum for the same scattering angle and, hence, the same $|\mathbf{Q}|$. The energy of the detected neutron is determined from the total flight time from the Fermi chopper to a detector.

2.2.6 Crystal-Analyzer Time-of-Flight Spectrometer The inverted-geometry spectrometer utilizes an analyzer crystal after the sample to specify accurately the energy of the scattered neutrons. A substantial fraction of the energy spectrum of the white beam emerging from the moderator of a spallation source can be utilized by a spectrometer that has multiple analyzer crystals, each with a given detector, as is illustrated in Fig. 10. This multianalyzer crystal configuration was first used on the KENS spallation source in Japan. A similar version, the PRISMA spectrometer, is located at ISIS. Analogous to the triple-axis spectrometer, each analyzer crystal is set to diffract a preselected energy, but the energy scan is accomplished by measuring the TOF from the source to each detector. The energy transferred to the sample is determined by comparing the total energy from the TOF measurement with that corresponding to the energy of the analyzer setting.

Such a spectrometer has some of the desirable features of a triple-axis spectrometer, while also utilizing the time structure of the pulsed source and multiple analyzers set at many different scattering angles. By appropriate settings of the scattering angles ϕ and analyzer angles θ_A, scans through numerous preselected values of Q,ω can be carried out, thereby achieving a high rate of data collection. The PRISMA spectrometer is described in detail by Steigenberger *et al.* (1991), and a more complete description of indirect-geometry TOF spectrometers is given by Robinson and Pynn (1988).

2.2.7 Pulsed Fission- and Fusion-Source Spectrometers In order to increase the neutron output over that normally obtained from a tantalum or uranium target with an electron linac, a unique target consisting of a small subcritical assembly of ^{235}U was installed on the Harwell accelerator (described by Rae and Good, 1970, p. 34). This "booster" assembly consists of a small cell (about one cm^3) of flowing mercury, which can dissipate up to 5 kW of electron beam power, and several cylinders of ^{235}U. This mercury target (primarily for bremsstrahlung generation) is backed by a solid cylinder of ^{235}U, and both together are surrounded by a set of concentric hollow cylinders of ^{235}U. The total fission power of the booster assembly is about 2.5 kW and gives a factor of 10 enhancement of neutron output over a natural-uranium target. The neutron production rate in the 100-ns burst is 7×10^{18} n/s for 5 kW of 128-MeV electrons. At the maximum repetition rate of 390 pulses per second, the peak neutron yield is 3×10^{14}.

Several "booster" assemblies have been built at Dubna in the USSR and have been used for neutron spectroscopy (described by Whittemore and West, 1983, p. 169; Firk, 1979, p. 554). A neutron multiplication factor of 100 has been accomplished with a plutonium target on an electron accelerator source with a burst width of about 1.7 μs. The Intense Burst Reactor IBR-30 facility operating in a booster mode with a multiplication factor of 200 produced 4-μs pulses 100 times a second. Pulsed reactors (such as the IBR-2) have fast-neutron pulse widths of about 200 μs. Moderators are used with these sources for measurements below about 10 keV.

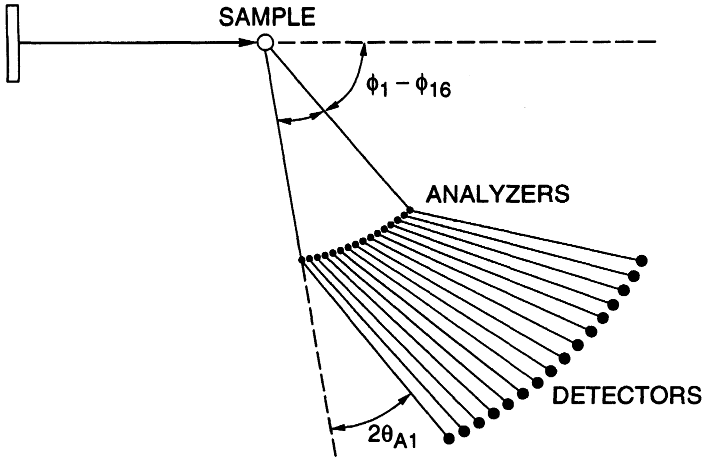

FIG. 10. A schematic of PRISMA, a crystal-analyzer TOF spectrometer at the ISIS facility at the Rutherford Appleton Laboratory, England.

The most intense pulsed neutron source that has been used as a TOF neutron spectrometer is a nuclear fission or fusion explosion. The burst width is about 80 ns, and moderated neutrons extend down to about 20 eV. Flight paths up to 300 m long result in energy resolutions that are poorer in the keV energy region than what is attainable from pulsed accelerators. However, with the extremely high intensity, measurements can be made on highly radioactive materials, on samples with very small cross sections, and on samples only available in very small quantities.

2.2.8 Pulsed-Source Slowing-Down Neutron Spectrometer A unique neutron spectrometer with a broad energy resolution but high intensity was developed in the USSR in the 1960s from a pulsed fast-neutron source located near the center of a large 1-m cube of lead. Fast neutrons are slowed down by scattering from lead nuclei, and the median energy of these moderated neutrons is a function of the slowing-down time. The Rensselaer Intense Neutron Spectrometer (RINS) system (Maguire *et al.*, 1985) consists of a lead slowing-down–time spectrometer coupled to the Rensselaer Polytechnic Institute 80-MeV electron linac. The median neutron energy in electron volts for this RINS system equals $165/(t + 0.3)^2$, where t is the slowing-down time in milliseconds. The percentage energy resolution is about 30% in the electron volt energy region but increases to about 50% at 10 keV. This spectrometer is valuable for measuring fission cross sections of samples available only in very small amounts of nuclides with very small cross sections.

3. NEUTRON DETECTORS

3.1 Neutron Detectors for Spectrometers

Since neutron spectrometers cover a very wide energy span, it is not surprising that a multitude of neutron detectors have been developed, and a variety of techniques have been used for these spectrometers. The important characteristics for these neutron detectors are size, efficiency, timing resolution, discrimination against gamma-ray backgrounds, and discrimination against neutrons whose energies are outside the region of interest. For most spectrometers used in nuclear physics research, the detectors should be quite large (100 cm^2), and efficiencies should be as high as possible (hopefully greater than 10% for the neutrons of interest). For some spectrometers the absolute efficiency of the detector may need to be known to a few percent, but for most spectrometers the relative efficiency as a function of neutron energy is sufficient.

Gas proportional counters using $^{10}BF_3$ or ^3He or thin ^6Li glass scintillators are used for most condensed-matter research spectrometers since they are relatively simple and have high efficiency for thermal-energy neutrons. Inorganic scintillation detectors, which detect charged particles from neutron-induced reactions such as $^{10}B(n,\alpha)$, $^6Li(n,\alpha)$, or $^3He(n,p)$, or the 478-keV gamma ray from the $^{10}B(n,\alpha\gamma)$ reaction, are valuable for neutron spectrometers below about 500 keV.

Since most high-resolution neutron spectrometers for nuclear physics research today use the TOF technique with a pulsed white neutron source, the timing of the detector and electronics should be less than the pulse width of the source in order not to degrade the energy resolution, hence less than a nanosecond for the MeV energy region, but microsecond timing is adequate below 1 eV.

Organic scintillation detectors, which may be a liquid or plastic containing hydrogen, are the most valuable detectors for neutron energies above about 100 keV. Neutrons are detected from the light resulting from recoil protons when neutrons are elastically scattered from hydrogen atoms in the scintillator. Improved low-noise photomultipliers and electronics have made it possible to achieve >10% efficiency for 5-keV energy neutrons and >50% above 20 keV with a scintillator a few centimeters thick (Harvey and Hill, 1979). Very large organic scintillation detectors (called black detectors) have also been constructed that have efficiencies of over 90% up to 10 MeV known to an accuracy of <1%. See DETECTORS, SCINTILLATION.

3.2 Neutron-Detector Spectrometers

In addition to simply detecting neutrons, some detectors are also able to determine the energy of the neutron that induced the event. For example, for an organic scintillator, the pulse height is directly related to the energy of the recoiling proton. The pulse-height distributions for many sizes of organic scintillators have been calculated by Monte Carlo techniques for neutron energies from 0.1 to 70 MeV. For a 4.6-cm × 4.65-cm-diam organic scintillator, the neutron energy resolution is about 10% up to 14 MeV neutron energy. The energy resolution of a thin organic scintillation spectrometer with a transmission of about 50% can range from 10% at 1 MeV to about 3% at 20 MeV. For very large scintillation detectors, the energy resolution is about 30%.

Both ^{3}He gas ionization chambers and ^{3}He gas and liquid scintillation detectors have been used as spectrometers for neutrons whose energies are somewhat greater than the 0.764-MeV Q value for the (n,p) reaction. With a ^{3}He-gas cylindrical gridded ionization chamber of 6.0-cm diam filled with 6 atm of ^{3}He, 3 atm of Ar, and 1 atm of CH_4, an energy resolution of about 2% has been obtained for incident neutrons around 3 MeV. A gas scintillator containing 90% ^{3}He and 10% Xe at a gas pressure of 20 atm has yielded a pulse-height resolution of about 14% in the MeV energy range. A liquid-^{3}He scintillator that has an efficiency of several percent for MeV neutrons has a percentage neutron energy resolution from 0.8 to 8.5 MeV of $21/(E + 0.764)^{1/2}$, where E is the neutron energy in MeV.

GLOSSARY

Cold Neutrons: Neutrons with energies <0.002 eV.

Doppler Broadening: The broadening of a nuclear resonance due to the thermal motion of the target nucleus.

Epithermal-Energy Neutrons: Neutrons with energies >0.2 eV.

Fast Chopper: A massive rotating shutter to produce microsecond bursts of eV and keV neutrons.

ISIS: Spallation neutron source located at the Rutherford Appleton Laboratory, England.

Monochromator: A device for selecting monoenergetic neutrons from a white neutron source with a broad energy spread.

Monoenergetic: $\Delta E/E$ from about 0.001 to 0.1.

Neutron Energy, E: $= 939.553\,[(1 - v^2/c^2)^{-1/2} - 1]$ MeV, where v is the velocity of the neutron and c is the speed of light. For neutron energies below 1 MeV, the approximation $E = mv^2/2$ or time of flight in μs/m $= 72.298/E^{1/2}$ is adequate.

PRISMA: A multiple–analyzer-crystal TOF neutron spectrometer located at the ISIS spallation neutron source.

Slow Chopper: A shutter of cadmium for producing pulses of thermal and subthermal neutrons >10 μs wide.

Spallation: A nuclear process for producing MeV energy neutrons from nuclei bombarded by energetic protons >100 MeV.

Subthermal-Energy Neutrons: Neutrons with energies <0.002 eV.

Thermal-Energy Neutrons: Neutrons with energies from 0.002 to 0.2 eV.

White-Neutron Source: A neutron source with a broad range of energies, often many decades.

4.1
Introduction

X-ray spectrometers are devices designed to study X-ray beams, with the goals of determining the wavelengths (or equivalently the energies) and the fluxes of the incident X-rays. Although spectroscopy of a sort was done from within a few years after Röntgen's discovery of X-radiation (1895), an enormous breakthrough was achieved when crystal diffraction revealed the first detailed X-ray spectrum (Bragg and Bragg, 1913). The Bragg technique has been refined over the years but is still used extensively and, for many purposes, gives the most useful results (see Section 4.3.1). Since that time X-ray spectroscopy has been applied, with great success, in many branches of pure and applied science (Agarwal, 1991). X-ray spectrometers have improved significantly, and new classes of such instrumentation are evolving rapidly (Tsuji, Injuk and van Grieken, 2004; Janssens, Adams and Rindby, 2000). In this chapter, the tools of X-ray spectroscopy are briefly described and the most common spectrometer devices are discussed. The strengths and limitations of the various spectrometers are indicated, and brief examples of applications and the kinds of devices that might be appropriate for real-world experiments are provided.

To some degree, all X-ray detectors are spectrometers, since all have some ability to determine wavelengths and measure fluxes. However, here we concentrate on those detectors (and spectroscopic devices) that have moderate spectral resolving powers (roughly, the resolving power $E/\Delta E$ must be better than about 20 over at least some of the spectral range). This criterion excludes, in general, proportional counters, microchannel plate devices, and scintillation detectors. Useful discussions of these classes of detectors (including their spectroscopic capabilities) can be found in the books by Fraser (1989), Knoll (1989), and Michette and Buckley (1993).

The survey here is further restricted to the energy (wavelength) range of 100 eV (124 Å) to 100 keV (0.124 Å). Lower and higher energy spectrometers are discussed in articles and books on ultraviolet and γ-ray spectroscopy. Photons with energies above the creation threshold for electron–positron pairs ($E \geq 1.02$ MeV) interact with matter by initiating a cascade shower. Measurements on these hard photons allow their total energy, arrival position, and arrival time to

ISBN: 978-3-527-40773-6

be determined (Sauli, 1992; Ramana Murthy and Wolfendale, 1993). Although this chapter is mainly concerned with the energy range up to 30 keV, we briefly consider, at this point, the range beyond this up to 511 keV, that is, half the electron–positron creation threshold. The resolving power of high-purity germanium (HPGe) detectors (see Section 4.1.2) is typically several hundreds, which is excellent for resolving lines of the highest energy atomic transitions and the lower energy nuclear transitions. The disadvantage of germanium detectors, which progressively worsens as energies increase, is that the percentage of photons that convert via the photoelectric effect becomes smaller with higher energies (about 75% at 100 keV to about 10% at 511 keV). Consequently, the full energy efficiency becomes small.

Sophisticated X-ray spectrometers have been recently designed to study X-ray emission of new types of hot plasma flashes in order to learn about space- and time-dependent ion distributions as well as electron density and temperatures (see Section 3.1.3). Commercially available X-ray spectrometers register X-ray fluorescence of a wide range of samples being irradiated either by an X-ray source or directly by an electron beam in order to obtain their elemental composition. Well-developed X-ray spectrometers with powerful, water-cooled X-ray tubes of many Kilowatts power now compete with small spectrometers equipped by air-cooled X-ray minitubes of a few up to 50-W power and adapted focusing optics (e.g., polycapillaries).

Finally, X-ray spectrometers have been constructed to study X-ray absorption of species in experiments with bright synchrotron and hot plasma sources. The X-ray absorption fine structure provides information about the geometrical distribution of electrons in the vicinity of the absorbing atom. Some recent practical applications are outlined in Section 4.5.

4.2
General Concepts

The primary figure of merit of most spectrometers is the resolving power:

$$R = \frac{\lambda}{\Delta\lambda} = \frac{E}{\Delta E} \tag{4.1}$$

where $\Delta\lambda$ is the full width at half maximum (FWHM) (in wavelength units) of the spectrometer response to a monochromatic X-ray of wavelength λ. The energy E is related to λ by $E = hc/\lambda$, where h is Planck's constant and c is the speed of light. The relationship $E\lambda \sim 1.24$ (E in kilo electronvolt and λ in nanometer units) is often useful in X-ray spectroscopy. Note that X-ray spectroscopists also rely on the older units (angstroms and electronvolt or kilo electronvolt) for wavelength and energy. In this chapter, we typically use these as well, since the interested reader will find them in most of the standard references. To convert to SI units, note that $1\ \mathring{A} = 0.1$ nm and $1\ \text{eV} = 1.60218 \times 10^{-19}$ J.

Besides the (i) resolving power, other relevant performance parameters of X-ray spectrometers, which may, in fact, be decisive in the selection of an instrument for a particular experiment, are as follows: (ii) sensitivity (or instrumental efficiency); (iii) linearity of (or at least information on) spectral response; (iv) maximum counting rate of the detector; (v) breadth of spectral coverage; (vi) field of view; (vii) physical size; (viii) simplicity of operation; and

(ix) cost. The strengths of various spectrometer types are illustrated as they are discussed later.

X-ray spectrometers can be divided into two general categories. The first is the dispersive spectrometers that use X-ray diffraction to spread out the incident spectrum (a prism is an optical analogy). A detector can then read off the dispersed X-rays and associate a wavelength to the position of the detected photons. Dispersive spectrometers are sometimes called *wavelength-dispersive spectrometers* (*WDSs*).

Nondispersive spectrometers, on the other hand, convert the energy of an incident X-ray to a number of "particles" (electron–ion pairs, electron–hole pairs, phonons, superconductor quasiparticles, etc.), and the energy resolution of the spectrometer is determined by the statistical fluctuations of the number of particles (this statement holds only for ideal detectors; no actual device is free of systematic uncertainties). All designs of nondispersive spectrometers suffer from the problem of "dead time," the time required to process an X-ray absorption event. Note that some authors refer to nondispersive spectrometers as *energy-dispersive spectrometers* (*EDSs*), generalizing the word "dispersive" beyond simple spatial separation.

Broadly speaking, dispersive spectrometers work by taking advantage of the wave nature of the X-rays (interference produces the diffraction) and nondispersive (energy-dispersive) spectrometers work by taking advantage of the particle nature of the X-rays (photons ionize or otherwise interact with the detectors). Of course, this comment is overly simplistic, since dispersive spectrometers always use photon detectors to read out the dispersed spectrum. In fact, it is often useful to combine dispersive and nondispersive spectrometers, such as diffraction gratings and solid-state detectors (Sections 4.3.2 and 4.4.1), so as to combine the strengths of the different devices.

In Section 3, the two types of dispersive X-ray spectrometers, Bragg crystal diffractors and diffraction gratings, are discussed. In Section 4.4, the nondispersive detectors (those with reasonably high resolving powers) are considered.

Dispersive Spectrometers

4.3.1
Bragg Crystal Devices

4.3.1.1 Bragg's Law

Figure 4.1 illustrates the elementary derivation of the fundamental equation of crystal diffraction, that is, Bragg's law,

$$n\lambda = 2d\ \sin\theta \left(1 - \frac{\delta}{\sin^2\theta}\right) \tag{4.2}$$

where λ is the wavelength of the incident X-ray, d is the spacing between the planes of the diffracting atoms, often called *net planes*, θ is the angle of incidence (and reflection) of the X-ray beam onto the crystal surface, and n is a positive integer, namely, the order of diffraction. Bragg's law states that only X-rays with wavelengths that satisfy Eq. (4.2) will be efficiently reflected from the crystal. Figure 4.1 shows how Bragg's law is derived: X-rays of wavelength λ are incident on a crystal surface with a glancing angle θ_{in}. Although each scattering site scatters in all directions, only those rays that satisfy $\theta_{\text{in}} = \theta_{\text{out}}$ will constructively interfere and result in a significant reflected flux (this is,

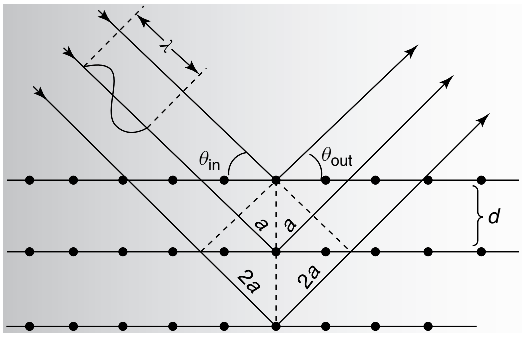

Fig. 4.1 Derivation of Bragg's law.

of course, consistent with the general law of reflection in geometrical optics). Furthermore, a second constraint on the reflected ray arises from the requirement that X-rays diffracted from each crystal plane must also interfere constructively (since the X-rays have relatively high energies, they can typically penetrate through hundreds to thousands of crystal planes). The X-rays penetrate the crystal surfaces and are scattered by the various crystal molecular planes (the planes are separated by d). The differences in the path lengths between the X-ray waves reflected off the various planes are $2a$, $4a$, $6a$, ... Clearly, there will be constructive interference between the various waves only if the path-length differences are integral multiples of the wavelength λ, that is, if $n\lambda = 2a$, where n is a positive integer. Simple trigonometry shows that $a = d \sin\theta$, thereby giving Eq. (4.2).

The crystal lattice parameter of silicon was linked to the SI meter base unit by combined optical and X-ray interferometry experiments with an experimental uncertainty error of about 10^{-8} (reviewed in Becker (2001)). For practical purposes, the lattice parameters (or net plane distances d) of any crystal can be derived at lower accuracy from a high-resolution X-ray diffractometer experiment. Here, the Bragg angles θ of the silicon gauge crystal are compared with those of the crystals being measured (Klöpfel *et al.*, 1997). In such thorough evaluations of crystal parameters, several correction factors have to be considered, for example, refraction effects on the boundary between air and crystal. This leads to a correction of Bragg's law:

$$n\lambda = 2d\ \sin\theta \left(\frac{1-\delta}{\sin^2\ \theta}\right) \tag{4.3}$$

where $1-\delta$ is the real part of the index of refraction of the crystal at the wavelength of interest. Other effects must also be considered for a rigorous treatment of the Bragg diffraction – such as

1. extinction (the primary beam cannot reach deeply into the crystal since it is reflected by intervening crystal layers);
2. absorption (again, the primary beam is absorbed by intervening crystal layers); and
3. multiple reflection (crystal layers reflect both "up" (toward the surface of the crystal) and "down" (away from the surface)).

Thorough discussions of these topics are beyond the scope of this chapter but may be found in some detail in the books by Compton and Allison (1967), Pinsker (1978), James (1982), and Authier (2001).

4.3.1.2 Flat Crystal Bragg Spectrometer

Figure 4.2 is a schematic drawing of a generic X-ray spectrometer based on the Bragg principle. Here, X-rays are collimated so that they strike the diffracting crystal at the Bragg angle for X-rays of wavelength λ. Only those X-rays that satisfy Eq. (4.2) are reflected and registered in the detector. Since (presumably) the spacing d and incident angle θ are known, the wavelength of the diffracted X-ray can be determined to be within a factor of $1/n$ (n is the diffraction order). Removing order ambiguity is an issue for all dispersive spectrometers. Techniques for determining the actual X-ray wavelength (i.e., removing the $1/n$ uncertainty) are discussed later.

To be useful as a spectrometer, it is necessary for a device to cover a range of wavelengths. This is achieved for the generic device in Figure 4.2 by mounting the crystal and the detector on coaxial rotary stages, so that the crystal can present a range of incident angles to the X-ray beam. Any rotation of the crystal by an angle $\Delta\theta$ is accompanied by a rotation of the detector by $2\Delta\theta$, so that the diffracted X-rays fall on the detector. To study a single X-ray emission line, for example, the crystal must be rotated over a range of angles that cover the response of the crystal to a monochromatic line. It should be apparent, from this discussion, that a Bragg device can only measure X-rays with wavelengths in the range $0 \leq \lambda \leq 2d$ (i.e., when $0^\circ \leq \theta \leq 90^\circ$); in practice, however, both the short- and long-wavelength limits are restricted by geometrical constraints. To measure longer wavelengths, one requires crystals (or multilayer diffractors discussed below) with larger $2d$ spacings.

From Bragg's law, the angular dispersion ($d\lambda/d\theta$) can be easily derived: after division by the reflection order n, the wavelength λ is a product of a constant factor ($2d/n$) and $\sin\theta$. If this factor is expressed by $\lambda/\sin\theta$ in the derivative, we obtain

$$\frac{d\lambda}{d\theta} = \frac{\lambda}{\tan\theta} \tag{4.4}$$

Thus, the angular dispersion is inversely proportional to $\tan\theta$, which means that the resolving power R is directly proportional to $\tan\theta$. If we have a set of

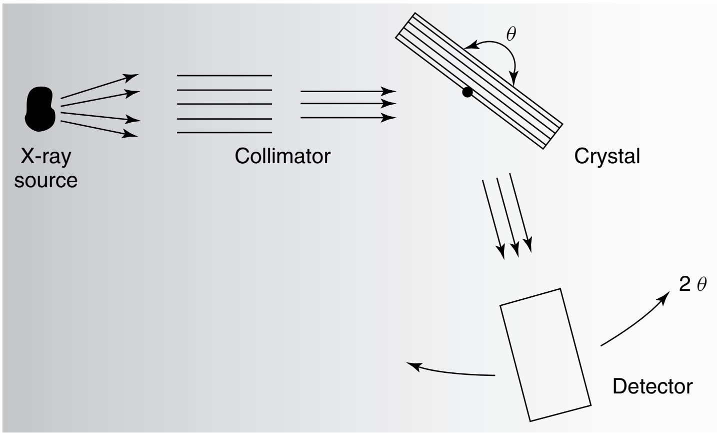

Fig. 4.2 Schematic drawing of a generic crystal spectrometer.

crystals with different net plane distances d, we should choose a plane with $2d$ slightly larger than λ to obtain the highest resolving power R.

The FWHM of the response function of an ideal crystal spectrometer is dominated by the natural resolving power of the crystal (the angular dispersion of the collimated X-rays also contributes, however, and in some cases will dominate). The response function of the crystal alone is called the *rocking curve*, because the complete response of the crystal to a monochromatic X-ray is measured by rotating (rocking) the crystal over a small angular range. The FWHM is the rocking curve width. Very early on, Compton and Allison (Becker, 2001) had derived a general theory of X-ray spectrometers. In the case of Figure 4.2, the relation between the X-ray emissivity J, the rocking curve C, and the reflected intensity P holds with some minor simplifications:

$$P(\lambda) = \int d\lambda' J(\lambda - \lambda') \int_{\alpha_{\min}}^{\alpha_{\max}} d\alpha \times \int_{\phi_{\min}}^{\phi_{\max}} d\phi \cdot C\left(\alpha - \frac{\phi^2}{2} \tan\theta_0 - \frac{\lambda' - \lambda_0}{\lambda_0} \tan\theta_0\right) \tag{4.5}$$

where the divergence angles α and ϕ describe the angular source emission in and out of the reflection plane (Figure 4.2). To minimize the broadening of X-ray emissivity J by convolution with the rocking curve C, the FWHM of C should be much smaller than the divergence $(\alpha_{\max} - \alpha_{\min})$ in order not to lose X-ray photons in the Bragg reflection. The meridional divergence (multiplied by the angular dispersion of Eq. 4.4) should, in addition, be much smaller than the FWHM of X-ray emissivity J. This is normally realized in WDSs, if the resolving power is high and the collimator is well adapted (cf. Figure 4.2). For small sagittal divergences $(\phi_{\max} - \phi_{\min})$, this broadening influence in Eq. (4.5) can be neglected since it depends on the second order of ϕ.

If the absorption in the spectrometer crystal is very small (which holds for hard X-rays), the rocking curve C has the form of a cylinder head (Darwin curve) with a flat top of almost unity reflection (i.e., in the range of interference total reflection). For the general case of structurally perfect crystals, the rocking curves can be computed using the dynamical theory of X-ray interferences (see the book by Authier (2001) and references therein). A narrow FWHM of the rocking curves leads not only to a good spectral resolution but also eventually to a loss of X-ray photons on the detector, whereas a wide FWHM provides many photons at the cost of spectral resolution.

Finally, the sensitivity of the Bragg devices must be known if one wishes to determine the incident flux as a function of wavelength (this is not always the case; sometimes, experimenters may be primarily interested in the locations (i.e., wavelengths) of spectral features or in the relative intensities (as opposed to the absolute fluxes)). To determine the flux in an X-ray line, the crystal must be rocked over the nominal Bragg angle of the line, covering a $\Delta\theta$ range that includes the response of the crystal (most of the width of the rocking curve), as well as contributions due to the dispersion of the incident beam. With the knowledge of the crystal reflectivity as a function of the angle (and other parameters such as the detector quantum efficiency), the incident flux in the X-ray line can be computed. The parameters of interest for computing the flux are not always easy to determine, however, particularly at all energies.

As noted above, Bragg's law permits a residual uncertainty in the X-ray wavelength because of the reflectivity of various diffraction orders of *n*. (This uncertainty is also present for grating spectrometers.) This ambiguity may be minimized or eliminated in a number of ways. The simplest way of eliminating it is to use a detector that has a sufficient inherent spectral resolution that the orders may be distinguished by the detector. Even low-resolution devices such as proportional counters can separate orders sufficiently in a wide energy range. Other techniques are to use filters and/or X-ray optics (which do not reflect efficiently at higher energies) to minimize the contribution from higher orders.

Collection and diffraction efficiency of a flat crystal spectrometer can be improved if parallel beam X-ray optics is incorporated. A diverging beam originating from the X-ray source is parallelized by polycapillary and grazing-incidence optics. The now parallel beam impinges on the spectrometer crystal (Love, 2002). This results in a much larger solid angle of X-rays that can be collected. The wavelength-dispersive unit can, for example, be incorporated in a scanning electron microscope.

4.3.1.3 **Bent-Crystal Spectrometer**

Besides the industrial applications of X-ray spectrometers where a high X-ray flux is often available, there are tasks in which the detector flux is rather limited. This is the case for X-ray diagnostics of high-temperature plasmas and for electron-beam X-ray microanalysis (see Section 4.3.1.4). There is, therefore, a need for additional X-ray optic elements to collect and focus X-rays to the detector. Depending on the required resolving power and luminosity as well as the geometry of spectrometer, different X-ray optics, grazing-incidence mirrors, capillaries, bent gratings, bent crystals, and so on must be selected.

Bent-crystal spectrometers employ, in the simplest form, a cylindrically bent crystal (instead of a flat one) as the dispersing element and a detector that is positioned on the circumference of the Rowland circle (see Figure 4.3(a) and (b)). The curvature of the reflecting net planes is twice that of the radius of the Rowland circle in this (Johann-type) spectrometer. Equation (4.5) is still applicable when the rocking curve is corrected for crystal bending (Uschmann, Malgrange and Förster, 1997) and modified relations are used between the divergence angles α, ϕ, and the wavelength λ'. Since rocking curves are usually wider and bent crystals accept a diverging beam of X-rays, photon numbers on the detector can be increased by 1 or 2 orders of magnitude in comparison to the flat crystal spectrometer. Figure 4.3(c) shows the dominant resonance lines of hydrogen-like and helium-like aluminum ions together with intercombination and satellite lines on a relatively low continuum emission. The electron density and temperature can be obtained from plasma physics models from ratios of selected spectral lines (Attwood, 1999).

The highly excited aluminum ions were produced by focusing high-power Nd : glass laser pulses (200 J, 1 nanosecond) on solid aluminum target (Renner *et al.*, 1994).

If the cylindrical crystal is rotated by 90° around its central surface normal, then X-rays are collected in the ϕ angle (instead of the α angle) direction. Figure 4.4(a) shows the von Hamos-type spectrometer in which the distances from the crystal to the source and the detector are equal. By bending a thin crystalline wafer in two dimensions, spherical, toroidal, or ellipsoidal crystals can be produced with curvature radii down to 10 cm. As shown in Figure 4.4(b) and (c), luminous X-ray spectrometry and quasimonochromatic X-ray imaging can be performed. Mißalla *et al.* (1999) have discussed reflection and focusing properties of these schemes when short X-ray pulses in the kilo electronvolts range are considered.

A cylindrically bent analyzer crystal can be combined with a flat position-sensitive detector in the von Hamos geometry (see Section 4.4.1.4). This makes parallel data collection possible for light elements in WDSs (Love, 2002). Toroidal crystals combine focusing in both sagittal and meridional directions if the ratio of the respective radii is $\sin^2\theta$. They are characterized by high resolving power and efficiency but require much careful preparation and testing.

An even higher spectrometer efficiency can be achieved by applying ellipsoidal highly oriented pyrolithic graphite (HOPG) crystals if a wider reflection curve (a 10th of a degree) is tolerated.

All the spectrometer types discussed so far are based on the Bragg equation and its corresponding angular dispersion ($d\lambda/d\theta = \lambda/\tan\theta$). There is, however, a special variant of a Johann spectrometer in which a point source and film are both located on the Rowland circle (Figure 4.5(b)).

Assuming that the X-ray wavelength λ_0 is reflected by the cylindrical crystal in the Rowland circle plane, X-rays with nonzero sagittal angles ϕ impinge on the crystal under slightly smaller Bragg angles. Geometrical considerations lead to the following relation between

wavelength λ and the divergence angle ϕ:

$$\lambda = \lambda_0 \cos\phi \tag{4.6}$$

where the maximum wavelength λ_0 can be simply changed by moving the X-ray source and the film along the Rowland circle. This leads to a high luminosity and a high spectral resolving power (Renner *et al.*, 1994), which is needed for sophisticated X-ray plasma diagnostics, but is limited to a small spectral coverage. There is also a simple extension of the flat crystal spectrometer to a double-crystal spectrometer in which wavelengths are determined by Eq. (4.6). It suffers, however, from a very low luminosity and is therefore applicable only for strong X-ray sources. Table 4.1 summarizes some key parameters of the X-ray spectrometers of Figures 4.3(a) and (b) and 4.5(a) and (b), respectively.

4.3.1.4 Bragg Spectroscopy with Synthetic Crystals (Multilayers)

Most Bragg diffractors are either natural crystals or crystals grown in the laboratory according to certain chemical and thermal specifications. Crystals of this kind have $2d$ spacings in the range 0.2–2.7 nm and can be used to cover energies between ~500 eV and 35 keV (Attwood, 1999). For lower energies, synthetic multilayer diffractors sometimes called *layered synthetic microstructures* (*LSMs*) or simply multilayers are frequently used, replacing in most cases, the Langmuir–Blodgett soap films used for many years. Multilayer diffractors are made by depositing layers (using the sputtering or evaporation techniques of semiconductor technology) of alternating high-Z and low-Z materials (e.g., carbon and tungsten) with precise thicknesses so as to perform the same functions as one-dimensional crystals. In the multilayer case, the effective spacing d is the sum of the thicknesses of the high-Z and low-Z materials. Up to several hundreds, layers can be laid down in this way (more layers are of little value since the relatively low-energy X-rays cannot penetrate deeper). Multilayers can now be deposited on curved substrates (up to 30-cm lateral size), even with gradients in depth and lateral thickness in order to optimize imaging performance. A comparison of focusing optics for femtosecond X-ray diffraction with Cu Kα line radiation shows differences in the key parameters, focus size, flux, and photons per second (Bargheer *et al.*, 2005). The authors considered a toroidally bent Ge Crystal, multilayer optics, ellipsoidal monocapillary, and polycapillary X-ray optics.

A clear advantage of using multilayer films is that the spacing *d* can be selected to be any desired value (although *d* spacings smaller than about 25 Å are difficult to fabricate). Generally, the resolving power of multilayer diffractors is limited to about 50, which is superior to many other kinds of spectrometers but will not be adequate for some applications. As shown in Figure 4.6, effective methods are available to change the form of the multilayer reflection curve. By using higher reflection orders *n*, the FWHM of the reflection curve can be reduced to obtain higher resolution. In contrast, the FWHM can be broadened by using depth gradients in layer thicknesses to obtain higher spectrometer sensitivity on the expense of peak reflectivity.

In recent years, multilayers have been used as the reflecting surfaces of many different optical devices, providing enhanced reflection at certain soft X-ray wavelengths (i.e., those wavelengths in which the Bragg condition is met). For example, traditional X-ray telescopes utilize grazing incidence ($\theta <$ a few degrees) on polished metallic surfaces (Fraser, 1989). Such telescopes are difficult to fabricate and typically have a relatively small collecting area. More traditional telescope geometries (i.e., those with nearly normal incidence) can be used, however, if the reflecting surfaces are coated with multilayers. The resulting telescope forms sharp images over a narrow wavelength band. Figure 4.7 shows an image of the sun obtained with an X-ray telescope coated with layers of cobalt and carbon with a period of 31.8 Å. At nearly normal incidence, the mirrors reflect efficiently at a wavelength of 63.5 Å. The bandpass of 1.4 Å encompasses the wavelengths of two bright X-ray emission lines from ions of highly ionized Mg and Fe, which are sensitive diagnostics of the plasma temperature in the range $(1-3)\times10^6$ K, in which these ions are abundant. The figure shows the high-temperature material in the solar corona, in contrast to the much cooler photosphere that appears relatively dark

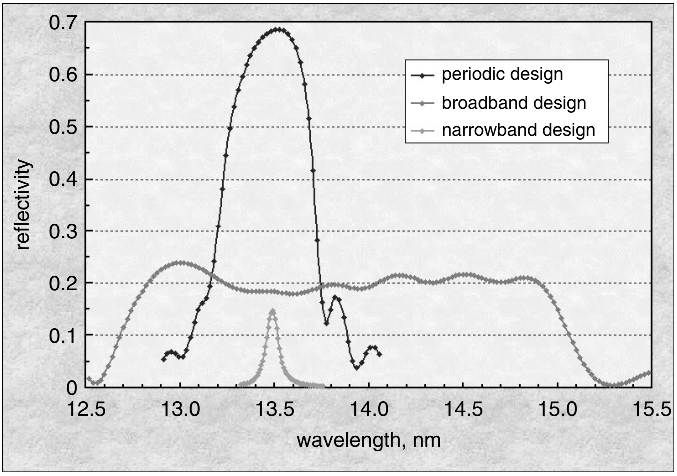

Fig. 4.6 Change in Mo/Si multilayer reflection curves to obtain higher resolution and higher sensitivity, respectively. (courtesy of Torsten Feigl and Sergij Yulin.)

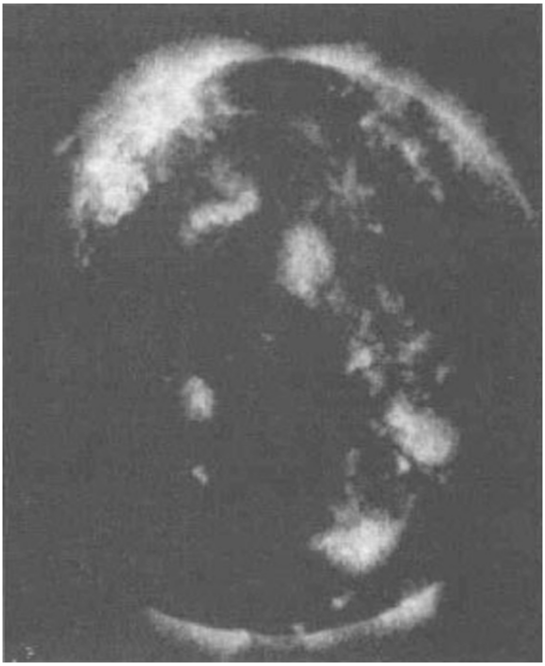

Fig. 4.7 Image of the sun taken on 11 July 1991 at $\lambda = 63.5$ Å with a bandwidth of 1.4 Å. The hot solar corona is seen clearly, while the cooler surface of the sun is relatively dark at this wavelength. (courtesy of Leon Golub.)

at this wavelength (Golub, Zirin and Wang, 1994).

4.3.2
Diffraction Gratings

Diffraction gratings are similar to crystals in that a periodic structure sets up an interference pattern that disperses the X-rays according to wavelength. They differ from crystals in that the structure is periodic only on the surface of the diffractor instead of both on the surface and within the body of the diffractor, as for crystals. As a result, diffraction gratings reflect (or transmit) incident X-rays at all wavelengths regardless of the incidence angle.

Gratings disperse light according to the grating equation:

$$n\lambda = p(\cos\beta - \cos\alpha) \tag{4.7}$$

where the incident and diffracted angles (α and β) are defined in Figure 4.8 for the two types of gratings: reflection and transmission gratings. As was the case for crystal spectrometers, n is the integer order of diffraction (except that for gratings, n can be positive, negative, or zero). For gratings, p is the period of the grating lines or grooves. X-ray reflection gratings operate at small incidence angles ($\alpha < 2°-3°$) because surfaces reflect X-rays efficiently only at grazing angles (unless enhanced with multilayer coats; see Section 3.1.4 and (Spiller, 1994)). Transmission gratings generally operate at nearly normal incidence ($\alpha \sim 90°$) where the transmitted efficiency is greatest, although they can be used with moderate efficiency over a large range of angles.

Ordinary ruled reflection gratings were among the first X-ray spectroscopic

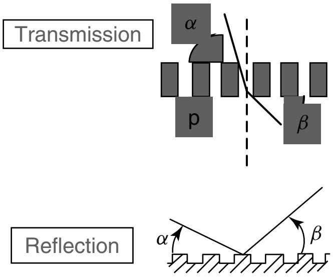

Fig. 4.8 Schematic illustration of the two kinds of X-ray gratings, the transmission and the reflection gratings. Although not indicated in the diagram, both kinds of gratings can be blazed to enhance the efficiency in some of the orders.

instruments, although they have been limited, until recent years to the longer wavelengths ($\lambda > \sim 20$ Å) since it is difficult to rule gratings with sufficiently small periods. In recent years, maturing technology (essentially, replacement of the mechanical ruling method by lithography or holography) has led to reflection gratings that can be used at wavelengths as short as ~5 Å. As is the case for reflection gratings used at optical wavelengths, X-ray gratings can be blazed (i.e., can have asymmetric reflecting surfaces) so as to enhance reflections into particular orders.

X-ray transmission gratings are a relatively recent development. Originally conceived for applications in X-ray astronomy (Gursky and Zehnpfennig, 1966), they have also been applied as spectrometers in synchrotrons and in X-ray lasers, and as interferometers in atomic diffraction experiments. Advantages of transmission gratings are their light weight and that they are typically used at normal incidence so that the spectrometer can be more compact than for a reflection grating. Effective transmission gratings must be thick enough so that the grating bars are at least partially opaque to the X-rays and must have small enough periods so that the dispersion angle is large enough to be useful. Figure 4.9 shows a sketch of a transmission grating developed for X-ray astronomy.

Transmission gratings are made with the techniques of semiconductor technology (microfabrication and nanofabrication). Periodic patterns are generated from holographic interference techniques or from mechanical ruling for larger period gratings. The periodic pattern is transferred to thicker metallic grating bars (gold is most often used). The first-generation transmission gratings were used primarily at lower energies ($E < 3$ keV) because the grating–bar thicknesses were too small (gratings became transparent at higher energies) and/or the bar periods were too large (dispersion angles were small). Recent developments have extended the effective energy range of transmission gratings to ~10 keV (Schattenburg *et al.*, 1991).

Transmission gratings are usually fairly small (a few square centimeters, Figure 4.9), but individual gratings can be combined into a larger assembly. For X-ray astronomy applications, for example, grating areas of over 1000 cm^2 have been used at the objective of X-ray telescopes to provide a large collecting area for spectroscopy of cosmic sources. For laboratory applications, free-standing gold bars with up to 5000 lines mm^{-1} have been produced where the gold bars were fixed on a periodic gold support

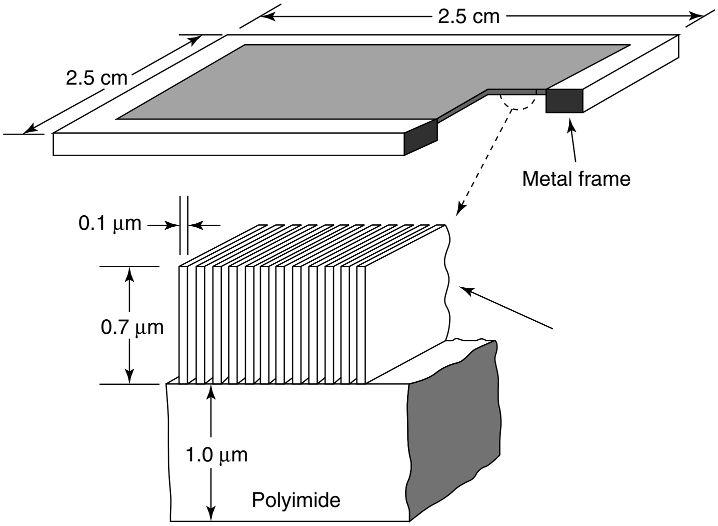

Fig. 4.9 Schematic of a high-energy grating facet being built for the US observatory Advanced X-ray Astrophysics Facility (AXAF). The gold grating bars (period = 2000 Å) are supported by a thin (1-µm) plastic film.

grid with 17 µm × 17 µm active areas. In combination with a toroidal grazing-incidence mirror, these transmission gratings were used in X-ray spectroscopy of both laser-produced plasmas and scattered radiation from a soft X-ray free electron laser (Jasny *et al.*, 1994; Höll *et al.*, 2007).

Like Bragg spectrometers, grating spectrometers can, in theory, achieve extremely large resolving powers. The theoretical maximum resolution for diffraction order n is given as

$$R = \frac{E}{\Delta E} = nN \qquad (4.8)$$

where N is the number of grating grooves or lines illuminated by the X-ray beam. For a grating with 1000 lines mm^{-1} (routine for transmission gratings), a 5-mm-wide X-ray beam can achieve a resolving power of 5000. It is, however, difficult to fabricate perfect periodic gratings, so that the variation in the grating period usually limits the resolving power to $p/\Delta p$, where Δp is the variation in the grating period over the illuminated surface of the grating.

Note that both classes of dispersive spectrometers (crystals and gratings) can, with relatively minor modifications, be used as monochromators as well as spectrometers, that is, they can select a narrow energy band out of a broad spectrum and transfer this band for further processing and analysis. Both grating and crystal monochromators are employed (generally, the crystals at the shorter wavelengths, where the gratings are less effective) in this way.

As was noted in the discussion of crystal spectrometers, there are potential benefits to curving the diffractors. In such a design, the incident X-rays can diverge from a point (parallel or nearly parallel beams have been tacitly assumed for the flat diffractors discussed above), and the curved gratings perform both energy dispersion and focusing. In the Rowland configuration (which is the most commonly used for curved diffractors), a point source at the entrance slit will focus to a (slightly curved) line at the exit slit, each wavelength focusing to a different position as shown in Figure 4.4(b) and (c). More complex curvatures (spheres, ellipsoids, and toroids) can improve the focusing properties at some wavelengths, although it can be more difficult to fabricate the curved diffractor elements (Michette and Buckley, 1993).

4.4
Nondispersive (Energy-Dispersive) Spectrometers

4.4.1
Semiconductor Devices

Semiconductor-based detectors, sometimes simply called *solid-state detectors,* have been used as X-ray spectrometers for more than 30 years. A basic description of how such devices work can be found in Tsuji, Injuk and van Gieken (2004); Fraser (1989); Knoll (1989). The fundamental principle is that an X-ray will liberate electron–hole pairs as it interacts within the semiconductor. The number of such pairs is given on the average by $N = E/w$, where E is the X-ray energy and w the ionization energy. For silicon and germanium, the ionization energies w are approximately 3.62 and 2.96 eV, respectively, and are slightly temperature dependent. An X-ray photon with energy 1 keV, therefore, will liberate on average several hundred electron–hole pairs. This free charge can then be gathered, as in a gas ionization detector, by applying an electric field to the ionized region. The amount of charge gathered is proportional to the energy of the incident X-ray.

Figure 4.10 shows a schematic diagram of a generic semiconductor detector. Two thin surfaces are heavily doped so as to be n-type (where electrons are the majority charge carriers) and p-type (where holes are the charge carriers). A central region, considerably thicker than the n- and p-types, is relatively free of charge carriers and is called the *depletion region*. The key feature of the depletion region is that it has a nonzero electric field, so that electrons and holes that are produced by photon interactions are easily separated. For X-ray detectors, the depletion region can consist of either an extremely pure semiconductor (typically germanium or silicon) or a volume of a semiconductor into which an element of opposite polarity (n- or p-type) has been diffused to compensate for the excess of electrons or holes (lithium drifted into p-type silicon or germanium is the most common). This compensated region (often called the *intrinsic region* since the layer has physical properties similar to pure, intrinsic semiconductors) is where the X-ray interaction takes place. To be effective as an X-ray detector over a broad energy range, the depletion region (whether naturally free of charge carriers or compensated) should be adequately thick (so that high-energy X-rays will be stopped), and any dead or absorbing layers (the n- or p-type regions or other nondetecting layers) should be thin.

When an X-ray enters the depletion layer (assuming that the layer is thick enough), it interacts with the semiconductor to produce electron–hole pairs. A voltage is applied to the surfaces to attract the electrons and holes, which migrate rapidly to the electrodes.

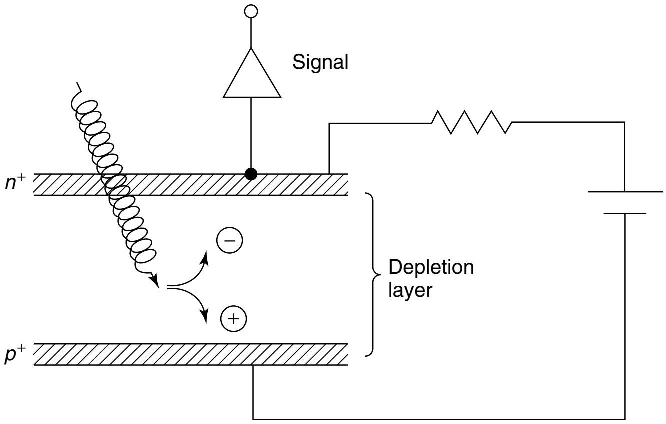

Fig. 4.10 Drawing of a (very) generic semiconductor spectrometer detector.

The heavily doped n- and p-type regions serve as barriers to any leakage current (the current that would flow in an undoped semiconductor as a result of the finite resistivity of the material). The leakage current must be suppressed for any prospect of detecting the small signal arising from an X-ray interaction. The signal goes to a preamplifier as shown in Figure 4.10 and is then processed electronically.

The collected charge following an X-ray photoelectric interaction is $N = E/w$ electrons (and holes). The deviation in the collected charge is related to X-ray energy according to

$$\Delta E = 2.354\, w \left(\frac{FE}{w} + K^2 + D^2 \right)^{0.5} \quad (4.9)$$

where ΔE is the FWHM response to a monochromatic X-ray line (see Eq. (4.1)), w is the ionization energy, E is the energy of the incident X-ray, K arises from the system electronic noise, and D is the dark current (the flow of electrons and holes that is present, owing to various impurities and imperfections in the device, even when there are no X-rays incident on the detector). Both K and D are measured in equivalent free electrons. F is the so-called Fano factor (Fano, 1947), which relates the statistical fluctuations in the number of electrons liberated to the expected number (E/w). (Fano factors for semiconductors have values of about 0.1, although there is an uncertainty in F of at least 50% due to the difficulties in precisely measuring this parameter.) Most semiconductor devices are operated at low temperatures (liquid nitrogen is typically used in the laboratory with $T = 77$ K), which helps to limit the dark current. The resolving power $E/\Delta E$ for a lithium-drifted silicon [Si(Li)] detector with system noise $\sqrt{K^2 + D^2}$ of 10 electrons is about 20 for 2 keV and grows to about 60 for 10 keV. At higher energies, the resolution is limited by the statistical fluctuations in the electron number; at low energies, the system noise dominates. Figure 4.11 shows a spectrum obtained with an Si(Li) device (see below), indicating the usefulness of a semiconductor device. The spectrum is the result of X-ray fluorescence of a sample consisting of thin films of gold,

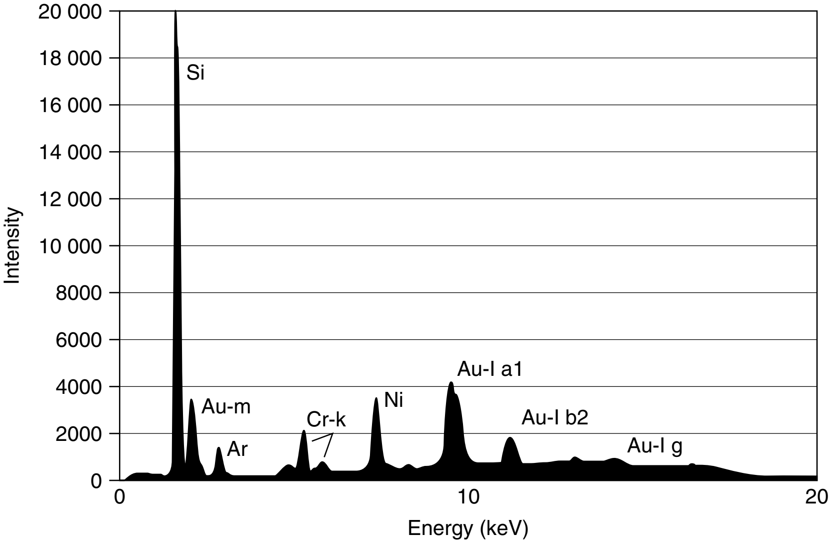

Fig. 4.11 Spectrum obtained with an Si(Li) detector.

nickel, and chromium deposited on a silicon substrate. The intensities of the various fluorescent lines can be used to determine the thicknesses of the films. Note that the resolving power of the semiconductor device is adequate for the quantitative analysis required.

There are a number of semiconductor devices that are used for X-ray spectroscopy. Here, four general types are listed, giving some of the strengths and weaknesses of the various classes. All of these devices are available commercially. See Knoll (1989) and Fraser (1989) for good introductory discussions on these devices and more detailed references.

4.4.1.1 Lithium-Drifted Silicon [Si(Li)] Detectors

Si(Li) detectors have depletion layers of thickness of a few millimeters to ~1 cm, manufactured by introducing ("drifting") a lithium dopant into slightly p-type silicon. The net result of this drifting process (which can take several weeks) is to produce a compensated depletion region that is essentially free of charge carriers. Si(Li) detectors can have significant efficiencies for energies up to about 30 keV. At lower energies, the dead layers limit the performance to energies greater than about 0.1 keV. For many commercial detectors, furthermore, a vacuum-tight window of 1-μm polymer with a cover of 30-nm aluminum is now used.

4.4.1.2 Germanium Detectors

Lithium-drifted germanium detectors [Ge(Li)] were used for many years, particularly at higher energies. In more recent years, extremely pure germanium crystals have been grown (HPGe) that have relatively few free charges and hence can be used directly as a depletion layer without the introduction of a compensating dopant. HPGe detectors complement Si(Li) detectors by having efficiencies at significantly higher energies (up to tens of mega electronvolts; see Section 4.5), but are usually not preferred at lower energies ($E < 20$ keV) since the Si(Li) detectors have better resolution and less prominent escape peaks.

4.4.1.3 Silicon Drift Detectors (SDDs)

A drift chamber detector is a large semiconductor wafer of, for example, high-resistivity n-type silicon; it is fully depleted from a small n^+ ohmic contact, which is positively biased with respect to the p^+ contacts covering both wafer surfaces. By implanting a parallel p^+ strip pattern and applying an electrical field on both wafer sides, electrons are forced to move to the central n^+ readout anode (Strüder *et al.*, 1998). The silicon drift detector (SDD) incorporates an on-chip amplifier and has a very low capacitive loading; energy resolution is 127 eV for 6 kcal at $-20°$. A particular advantage is that commercially available SDDs (Röntec) can be employed for high X-ray counting rates in the range of 400 000 counts per second. The idea for this new detector scheme originated from Gatti and Rehak (1984); the SDDs are fabricated for a wide field of applications, for example, for several synchrotron radiation experiments (Strüder *et al.*, 1998).

4.4.1.4 Charge-Coupled Devices (CCDs)

Charge-coupled devices (CCDs) are silicon-based detectors used extensively in television technology but are also effective (with some modifications) in the X-ray regime. While having spectral resolving powers similar (or even superior) to the best Si(Li) and HPGe devices, they are also excellent imaging detectors, with pixel sizes typically <20 μm and array dimensions 1024 × 1024 pixels or greater. The most common CCD design is a two-dimensional array of Metal-Oxide-Semiconductor (MOS) capacitors on the surface of a semiconductor. (An alternative, first proposed by Gatti and Rehak (1984), is to use an array of pn junctions on the surface of n-type silicon.) The charge from an X-ray interaction in the depletion layer of the semiconductor is stored, momentarily, in the nearest capacitor. By varying the surface voltages, the charge can then be passed onto adjacent capacitors until it reaches the edge of the detector, at which point it can be read out (in practice, the charge packet is read into a perpendicular register once it reaches the edge of the array, and is further transferred in this perpendicular direction; in this way, only a single amplifier circuit is required to read out an entire CCD chip). This charge transfer, or coupling, gives the device its name.

The depletion regions of CCDs are significantly shallower than that of the other semiconductor devices discussed here (of order of tens of microns), primarily because of the lower voltages required for the charge transfer. Consequently, currently available X-ray-sensitive CCDs are used most generally at energies $E < 10$ keV since higher energy X-rays simply pass through the device. The capacitor structure on the front surface, furthermore, acts as a dead layer that can absorb photons with $E < 0.5$ keV.

4.4.1.5 Room-Temperature Devices

The solid-state devices described above operate most efficiently when cooled to temperatures <77 K (liquid-nitrogen temperatures). A class of detectors composed of semiconductor compounds (HgI_2, CdS, CdTe, and GaAs) is actually more effective at room temperatures than when cooled significantly. These materials have larger band gaps (than Si or Ge), so that thermal fluctuations result in a much lower leakage current. Furthermore, because all of these compounds have a much higher effective atomic number, a viable detector can be much thinner (have a thinner depletion layer) and still detect higher energy photons. Unfortunately, the room-temperature devices are difficult to work with, have poor mobility (particularly for holes), and have a generally inferior resolving power. In spite of some clear benefits, the various room-temperature detectors are not as commonly used as the silicon- and germanium-based devices.

4.4.2
Cryogenic Devices

A relatively recent advance in X-ray spectroscopy is the development of what are often called *cryogenic detectors*. These devices convert incident X-rays into thermal-acoustic quanta (phonons) or superconductor quasiparticles (broken Cooper pairs). The energy w required to create such a particle is quite small (10^{-5}–10^{-3} eV) so that extremely high resolving powers are possible in principle (the number of particles is large and thus the relative uncertainty in their number is small). To achieve the optimal resolution of such devices (theoretically ΔE can be as small as $\sim$1 eV), various noise sources must be suppressed by operating at extremely low temperatures ($T < 100$ mK typically) and, hence, the generic name for such detectors – *cryogenic devices*. Although cryogenic detectors are not yet available commercially, they hold significant promise for future applications.

Two basic classes of cryogenic detectors have been developed in recent years: calorimeters and quasiparticle detectors. The calorimeters measure the temperature in a low-temperature substrate due to the absorption of a single X-ray photon (hence, they are phonon detectors). The quasiparticle detectors most often discussed for X-ray spectroscopy are superconducting tunnel junctions (STJs) for which the mean particle energies are 0.001 eV. The quasiparticles are detected by their quantum-mechanical current tunneling through a thin oxide layer. Although the STJ devices are promising, they have not achieved, to date, the resolving power of the calorimeters and thus are not discussed further (see (Labov and Young, 1993) for some recent articles on this topic).

The microcalorimeter has undergone extensive development over the past decade. Resolutions as high as $\Delta E \sim 2$ eV at 1.5 keV (Newbury *et al.*, 2002) have been achieved. Thus, the microcalorimeter has a resolving power that is 10–50 times better than that of the best semiconductor devices. A schematic diagram of a generic calorimeter is shown in Figure 4.12. Basically, a calorimeter absorbs an incoming X-ray and converts the X-ray energy to heat (phonons), which raises the temperature of a cryogenically cooled substrate. The increase in temperature is measured by a thermometer connected to the absorber. After a period of time, the equilibrium temperature is restored through the contact of the substrate with a cold bath. The increase in temperature is proportional to the energy of the X-ray.

The energy resolution of an ideal X-ray calorimeter is given as (Moseley, Mather

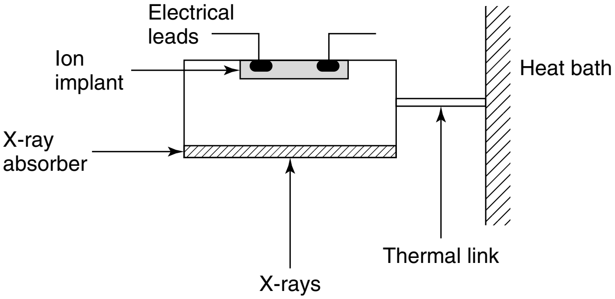

Fig. 4.12 Schematic diagram indicating the operation of an X-ray calorimeter. (Holt, 1987.)

and McCammon, 1984)

$$\Delta E = 2.35\xi\sqrt{kT^2C} \tag{4.10}$$

where T is the equilibrium temperature, C is the heat capacity of the device, k is Boltzmann's constant, and ξ is a nearly constant parameter with magnitude ~1 to 3. The parameter ξ is derived from the temperature variations of the heat capacity and thermal conductivity of the device, and the properties of the thermometer (Kelley *et al.*, 1988). For small detectors ($0.5 \times 0.5 \times 0.1\ \text{mm}^3$ are typical dimensions), cooled to ~0.1 K, Eq. (4.10) yields $\Delta E \sim 1$ eV, but, in practice, additional noise terms in the thermometer limit the current actual performance of calorimeters to ~7 eV. Note that the size of the detector is an important issue since ΔE scales as $C^{1/2}$. Also note that heat capacity often scales as T^3, so that the operating temperature is also of great importance; the best calorimeters built to date operate at about 0.1 K.

The obvious advantages of an X-ray calorimeter are as follows:

1. its grasp of a wide energy range (since it is nondispersive) and
2. its extremely high resolving power.

The resolution ΔE is essentially a constant; thus, the resolving power ($E/\Delta E$) varies as E varies. Figure 4.13 shows the resolution E_{res} as a function of the X-ray energy E_ν for several types of X-ray spectrometers. If digital processing of microcalorimeter signals is performed, energy resolutions comparable to those of the Bragg crystal devices in some spectral ranges (Newbury *et al.*, 2002) can be obtained.

The practical disadvantages of the X-ray calorimeter are as follows:

1. its small size (although mosaic detectors have been designed) and
2. the need to have a complex cryogenic system for the detector to function optimally.

The latter is a particular problem for space applications in which weight and risk are always a matter of concern. For typical designs, a large Dewar flask of liquid helium and an additional refrigeration stage are required.

X-ray microcalorimeters may not be the optimal choice of spectrometer in an environment in which an extremely high counting rate is expected, because of the relatively long time required to process each event (several milliseconds).

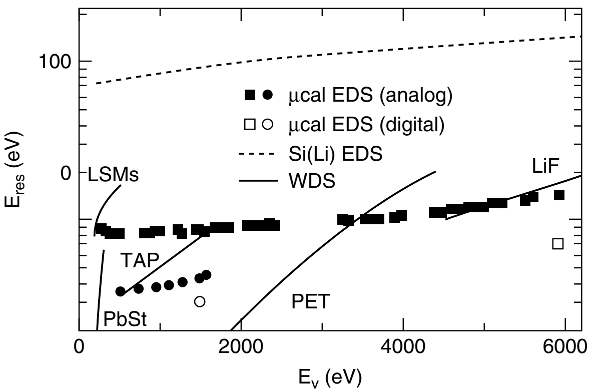

Fig. 4.13 Energy resolution (FWHM) of different types of X-ray spectrometers: microcalorimeter (energy-dispersive spectrometer (µcal EDS)) with analog and digital data processing, lithium-drifted silicon detector (Si(Li) EDS), and wavelength-dispersive spectrometer (WDS). Dispersive elements for WDS are LSMs, thallium acid phthalate (TAP), pentaerythrol (PET), lithium fluoride (LiF), and PbSt (lead stearate). (Newbury *et al.*, 2002.)

4.5
Applications

X-ray spectrometers are used in virtually every area of pure and applied science. Extensive discussion of specific applications can be found in the references following this chapter. In a general sense, however, X-ray spectrometers are employed

- to measure the properties (such as the temperatures, ionization states, and elemental compositions) of hot (>10^6 K) plasmas, both cosmic and laboratory (Silver and Kahn, 1993), where in extreme conditions time evolution and spatial distribution of laboratory plasma parameters have been obtained (Golovkin *et al.*, 2002);
- to determine compositions of various materials (qualitative and quantitative analysis via the monitoring of characteristic lines from X-ray fluorescence or direct bombardment with electrons or other charged particles; see, e.g., (Jenkins, 1988)); and
- to measure and interpret the absorption spectra of various solids at high resolution in order to determine the distribution of electrons. The study of X-ray absorption fine structure (XAFS) has blossomed in recent years with the advent of bright, monochromatic X-ray beams available from synchrotrons (Koningsberger and Prins, 1988). Ultrafast time-resolved X-ray absorption spectroscopy is a nascent technique that permits study of photoinduced processes on many systems down to the subfemtosecond time domain (Bressler and Chergui, 2004).

Depending on the application, some of the various spectrometers discussed earlier may be more appropriate than others. For example, semiconductor devices, with their moderate resolving powers and relatively broadband energy response, are often used for X-ray fluorescence analysis (see Figure 4.11), since the fine structure of the spectral features is not generally an issue. When extremely high resolution is required, at least at the lower energies, crystal spectrometers are still the instruments of choice (the spectrum in Figure 4.3, for example, would be extremely difficult to unravel with a semiconductor spectrometer). When low flux (or short exposure times) is an issue and/or a significant energy band is desired, the narrow bandpass of the crystal spectrometers argues in favor of a nondispersive device (or a grating spectrometer in which the entire dispersed spectrum can be read off simultaneously with an imaging detector). The desire for a broad bandpass and high resolution may lead the user to a calorimeter, in spite of its size, weight, and complexity. For some applications, the expected counting rate may be so high as to rule out some of the energy-dispersive detectors. For example, in many synchrotron applications, the detector of choice may be a photodiode (which measures current and not individual photons), and a dispersive device will be used as the spectrometer. Besides these complex and high-resolution experiments at synchrotron radiation centers, portable equipment for X-ray fluorescence analysis has been developed. The technological progress is based upon on miniature and air-cooled X-ray tubes, often polycapillary optics, thermoelectrically cooled X-ray detectors, multichannel analyzers, and dedicated software (Tsuji, Injuk and van Grieken, 2004). All components have small weight and are incorporated in a pistol-like housing. This portable energy-dispersive X-ray fluorescence equipment has been employed in many applications, such as archaeometry, analysis of lead in paint, environmental analysis, analysis of industrial alloys, soil analysis even on Mars, and so on.

Another factor that affects the choice of spectrometer is the nature of the optical system of which it is a component. For example, the small size of a calorimeter detector requires a tightly focused beam. Flat dispersive spectrometers (as in Figure 4.4) must receive all the radiation at the same incident angle; otherwise, the dispersed image will be blurred (thus effectively reducing the resolving power). As noted in Section 3.1.3, for some applications, crystals and gratings are curved so that the incident radiation will strike the crystal at nearly the same angle.

Acknowledgments

Thomas H. Markert is grateful to Richard Aucoin, Daniel Dewey, Keith Gendreau, George Clark, and Una Hwang for helpful discussions.

Eckhart Förster wishes to thank Ingo Uschmann, Oldrich Renner, Konrad Goetz, and Michael Wendt for their critical remarks and is also grateful to Jana Brusberg and Richard Hutcheon for their help in the preparation of the chapter.

Glossary

Blazed Gratings: Gratings for which the bar, groove, or line shape is structured so as to enhance reflection into a particular order.

Cryogenic Devices: A relatively new class of X-ray spectrometers that operates at very low temperatures ($T < 2$ K typically). Such devices are capable of extremely high resolving powers ($\Delta \mathrm{E} \sim$ 7 eV has been demonstrated at 5.9 keV for at least one such device).

Diffraction: Modification of the intensity and/or phase of an electromagnetic wave by the presence of an object (such as a slit, hole, edge, etc.) in the path of the wave.

Dispersive Spectrometer: An X-ray spectrometer that employs wavelength dispersion. X-rays are dispersed (i.e., spatially separated) by the effects of diffraction. Dispersive spectrometers are sometimes called *wavelength-dispersive spectrometers*. The two classes of dispersive spectrometers are Bragg devices and diffraction gratings.

Escape Peak: For monochromatic incident X-ray photons with an energy E_x smaller than that of the absorption edge of detector atoms, the pulse height output is proportional to E_x. However, when the energy E_x of the monochromatic incident X-ray photons exceeds the absorption edge of the detector atoms, the output may contain two pulse height distributions. The additional or escape peak has a mean pulse height proportional to the difference between the energies of the incident photons E_x and the escaping (from active detector volume) photons $E_{\mathrm{K}\alpha}$.

Monochromators: Devices used for producing radiation at a single wavelength (or, more realistically, in a narrow range of wavelengths). The elements of dispersive spectrometers (crystals and gratings) can also be used as X-ray monochromators.

Multilayers: Synthetic crystals formed by sputtering or evaporating alternating layers of high-Z and low-Z materials onto a substrate. Multilayers can be used as spectrometers or monochromators and can be a part of an X-ray optics system to enhance the performance of the system over a narrow band and is also called *layered synthetic microstructures* or *LSMs*.

Nondispersive Spectrometer: An X-ray spectrometer that does not employ wavelength dispersion. Such devices generally operate by converting the photon energy into some other sort of particle or quasiparticle (e.g., electron–ion pairs or phonons). Nondispersive spectrometers are often called *energy-dispersive spectrometers*.

Resolving Power: The resolving power of a spectrometer (at an energy $E = hc/\lambda$) is usually defined as the ratio of the energy (or wavelength) of interest to the width of the response function of the spectrometer to a monochromatic X-ray line, that is, $R(E) = E/\Delta E = \lambda/\Delta\lambda$. The width of the line is usually chosen to be the FWHM of the spectral response function. Note that some authors invert this definition of resolving power so that it equals $\Delta E/E = \Delta\lambda/\lambda$ and often quote it as a percentage.

Rocking Curve: In crystal spectrometers, the rocking curve is a measure of the spectral resolving power of the crystal, independent of any geometric effects introduced by the geometry of the spectrometer. Specifically, it is the FWHM in degrees of the response of the crystal (as it is rotated or rocked) to a monochromatic X-ray beam.

Rowland Circle Configuration: This configuration is common in focusing X-ray spectrometers. The diverging X-ray source, the diffraction grating, and the detector all lie on a circle (the Rowland circle, after Henry Rowland) that has a diameter equal to the radius of curvature of the curved diffractor. Such a configuration gives one-dimensional focusing and disperses the spectrum along the circle. A variation, using a curved crystal rather than a grating, allows for imaging of small fields along the circle.

19.1
Introduction

As lasers have developed, they have become a common and important tool for spectroscopy. Applications range from probing samples remotely at great distance to generating transient species. In this chapter, we confine ourselves to linear spectroscopic techniques. In general, therefore, the signal response is proportional to the laser power. The only exceptions to this are when saturation spectroscopies and other two-photon techniques are considered. Here, the overall signal response is no longer directly proportional to the laser power but the absorption of each individual photon is still in the linear regime.

It is the unique properties of laser radiation that have made it such a powerful spectroscopic tool. Continuous wave (CW) lasers can be constructed such that their linewidth is very narrow (below 1 MHz), thus enabling high-resolution measurements. The high spectral brightness of lasers increases the probability that two or more photons may interact with the same absorber, which also makes multiple photon spectroscopies possible. In addition, the very well defined temporal envelopes produced by pulsed laser systems allow time-resolved measurements to be carried out on a range of timescales. Finally, the highly directional nature of laser radiation makes optical manipulation very simple and allows some measurements to be made remotely.

No distinction has been made here between samples. The techniques outlined can be applied to a variety of samples: not exclusively atomic or molecular. Many of the techniques, however, lend themselves to application in the gas phase where the full resolution of laser sources may be applied. Liquid, solid, or solution phases have, however, not been excluded.

This chapter is divided into two main sections. The first deals with applications that detect laser intensity directly. To monitor a small change on what is often very high laser intensity reliably, a detector has to be capable of a very high dynamic range. For this reason, many laser interactions are detected indirectly by means of a side effect. These techniques are here referred to as *proxy techniques* and are described in the second section.

A short concluding section deals with examples of named techniques that straddle these rather artificial boundaries or may be used with a variety of

approaches. This is by no means meant to be an exhaustive list and neither is it designed to describe these methods in great depth. The reader can use the citations and review articles to obtain further details.

19.2
Direct Techniques

19.2.1
Direct Absorption

The very high spectral brightness of laser sources means that direct absorption measurements are generally limited by the dynamic range of the detector. In many cases, the signal in which we are interested is a small change in a large detected intensity, hence limiting the overall sensitivity. Methods have been developed to overcome this disadvantage, which either increase the proportion of the sample response or detect the response as a function of time.

One method to increase the proportion of sample response is simply to increase the length over which the sample and laser radiation interact. This is of special importance in dilute samples of low-pressure gases. Pressure broadening studies or measurements of small concentrations of atmospheric absorbers might require such an approach. The length of the sample cell can only be extended if the sample itself is stable and the physical dimensions of the laboratory allow this. Frequency measurements of pure rotational transitions in vibrationally excited H_2O molecules (Matsushima *et al.*, 2006) have used the latter approach with a single pass in a 1.8-m sample cell.

19.2.2
Multipass Techniques

In many cases, it is not possible simply to increase the length of the sample. This may be a result of the physical limitations of a laboratory or the spatial extent of the sample. Few laboratories can accommodate sample cells much longer than 2 m and transient species are often confined to a small region of space. In order to overcome such limitations, or to maximize path length when the sample can only be produced in a limited region, the laser radiation may be passed through the sample many times. In the simplest of these, a pair of plane mirrors may be arranged such that the light is redirected through the sample as many times as possible before reaching the detector. The low divergence of a laser source is a great benefit in these experiments (Qian and Howard, 1997).

More sophisticated approaches use systems of curved mirror cells such as the White (White, 1942) and Herriott (Herriott, Kogelnik and Kompfner, 1964; Herriott, 1963) cells. These optical arrangements are designed to minimize losses in order to produce a much longer effective path length than with plane mirrors. The beam path, however, imposes some geometrical constraints with the result that a given solution is not universally appropriate: a laser beam in a traditional White cell arrangement, for example, tends to probe a single plane. A White or Herriott cell would be a good choice if the sample were sufficiently stable to fill the cell. On the other hand, a multipass arrangement with fewer reflections from plane mirrors may well prove to be a more sensitive solution for a transient sample, which is confined to a small region of space.

19.2.3
Cavity Ring Down

Cavity ring-down spectroscopy (*CRDS*) might be considered close to the ultimate multipass technique, which is reviewed in Berden, Peeters and Meijer (2000). The sample is contained in a high-finesse optical cavity that is designed to minimize losses from diffraction and scattering. Laser light is coupled into the cavity and then quickly switched off. CW lasers are generally coupled to the cavity using an active control to scan or lock the CRDS cavity and often require active switching of the light. On the other hand, the broad bandwidth of a pulsed laser generally overlaps with at least one of the closely spaced cavity modes without the need for active cavity length adjustment. As a result, what the arrangement lacks in resolution it more than makes up for in simplicity.

Once the cavity excitation stops, the stored intensity leaking through one of the mirrors may be monitored as a function of time. A compromise has often to be reached between the wavelength range over which the mirrors are highly reflective and the reflectivity of the mirrors. In general, the more highly reflective the mirrors are, the smaller the wavelength range over which they are highly reflective.

In a CRDS cavity, the number of round trips, n, required for the light to reach $1/e$ of the original intensity is given by $n = -1/[2\ln(R)]$, where R is the mirror reflectivity. The intensity of light confined in a cavity bounded by mirrors of reflectivity $R = 0.9999$ will fall to $1/e$ of the original intensity after 5000 round trips. Thus, a cavity with such mirrors separated by 1 m and filled with sample produces an effective path length of around 10 km.

Active switching of light out of (or into) the cavity is obviously not necessary if pulsed lasers are used; for CW lasers, the switching is usually effected by deflecting the beam with an acousto-optic modulator. The intensity leaking from the cavity decays exponentially with a time constant that is determined by cavity losses and may be as long as tens of microseconds. The difference in time constant between an empty cavity and one containing sample gives a direct measure of the absorption coefficient of the sample. One elegant feature of this technique is that the signal is, at least in principle, immune to power fluctuations in the laser. Part of the absorption spectrum of the iodine monofluoride radical recorded using CRDS is shown in Figure 19.1.

19.2.4
Cavity-Enhanced Absorption

The technique of CRDS has been developed further to avoid switching the laser out of the cavity. This has become known as *cavity-enhanced absorption spectroscopy* (*CEAS*) or *integrated cavity output spectroscopy* (*ICOS*). The laser may be scanned rapidly and sometimes repeatedly over a portion of the sample spectrum and the absorption recorded is the integrated output of the cavity. This has the advantage of simplicity compared to cavity ring-down as the decay of intensity is not recorded as a function of time. It does, however, lose the immunity to power fluctuations of the light source. Off-axis cavity designs have recently become popular as the alignment becomes very robust, which is attractive when designing field instruments (Moyer *et al.*, 2008).

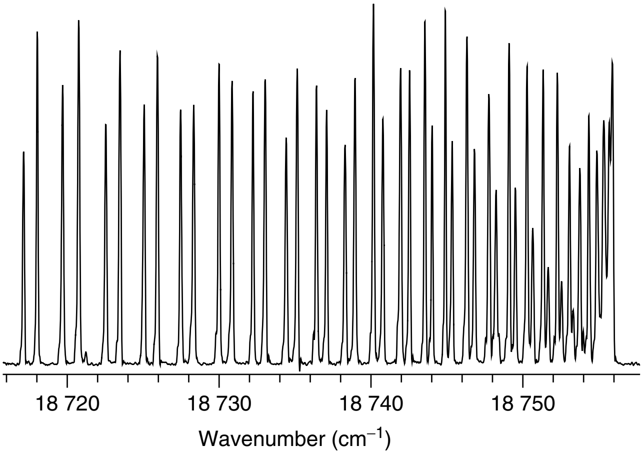

Fig. 19.1 A portion of the absorption spectrum of the iodine monofluoride radical produced by the flash photolysis of CF_3I recorded using cavity ring-down spectroscopy. (Ashworth S.H., Joseph D.M. and Plane J.M.C. *unpublished*.)

The integration of the cavity output and the need for stable lasers means that CEAS requires CW lasers or at least quasi-CW lasers. In common with CRDS, the technique may be applied over a wide wavelength range. It has been applied to make a portable spectrometer to measure ratios of carbon isotopes of CO_2 in the 2 μm region (Wehr *et al.*, 2008) and also to detect atmospherically important species in the ultraviolet region (Mejean, Kassi and Romanini, 2008).

19.2.5
Intracavity Techniques

In some cases, the sample may be usefully placed within a CW laser cavity. The technique is often known as *intracavity laser absorption spectroscopy* (*ICLAS*). These samples may be thought of as being exposed to an infinite number of round trips of the laser light. A small loss due to absorbance has a large effect on the gain of the laser (Peterson *et al.*, 1971). Such a description is, however, deceptively simple. Although the signal is obtained simply by monitoring the laser output, sensitive measurements are only possible with very stable laser sources. The laser itself needs to have been modified. The cavity quality factor, Q, has probably been reduced and the alignment changed by the introduction of a sample cell. Second, the signal itself is a result of a further change in Q as the measurement is taken. Consequently, active stabilization of the laser can become challenging. Nevertheless, the technique is capable of extremely sensitive measurements (Ding *et al.*, 2005).

19.2.6
Laser Magnetic Resonance Spectroscopy

Laser magnetic resonance (*LMR*) is a technique used in spectral regions where laser radiation is not easily tunable. This is the case in the mid- and far infrared. The mid-infrared carbon monoxide laser and a number of far infrared gas lasers operate over a range of discrete frequencies. The gases are lasing on one of many molecular transitions so the output may be one of a range of discrete frequencies. Therefore, these discretely tunable lasers are known as *line tunable lasers*.

The samples under investigation rarely have absorptions that coincide with individual laser transitions, so in the absence of tunable laser light the molecular transitions themselves are tuned. The sample must, therefore, be a radical species in order that the magnetic field may interact with the sample. This selectivity may be used to advantage to detect radical species in a complex mixture. The sample is arranged so that it may be exposed to a magnetic field either between the poles of an electromagnet or within a solenoid. The spectrum is recorded as a function of field. A small, sinusoidal magnetic field is superimposed on the scanned magnetic field and phase-sensitive detection is generally used.

In the far-infrared, gases such as methanol, hydrazine, and CF_2H_2 are used as lasing media. They are generally pumped by CO_2 lasers and give a range of discrete lines with wavelengths in the 50–500-μm range. The gases are lasing on rotational transitions and isotopic variants give access to a range of alternative laser frequencies. The frequencies of known laser transitions are independently measured and periodically tabulated (Inguscio *et al.*, 1986; Zink *et al.*, 2008). New laser transitions are occasionally discovered and have to be precisely measured before they may be used for high-resolution measurements. The development of frequency combs has meant that complicated frequency chains are no longer necessary for accurate frequency determinations (Beverini *et al.*, 2005).

Most LMR spectrometers are designed with the sample within the laser cavity and thus LMR is usually an intracavity technique. The signal is obtained by monitoring the laser output as a function of magnetic field. Figure 19.2 shows part of an LMR spectrum recorded during a study of the HSS radical in the far infrared.

The spectrometer can, however, be designed so that the laser is remote from the sample. The intracavity advantage is lost in this case, so it may be necessary to construct a multipass cell around the magnet (Hinz *et al.*, 1985). On the other hand, this arrangement allows the Faraday (*vide infra*) or Voigt effects to be exploited, which increases the detection sensitivity (Gillett, Cooksy and Brown, 2006).

19.2.7
Raman Spectroscopy

The narrow linewidth and intensity of laser sources has enabled *Raman spectroscopy* to become a mainstream technique. Raman spectroscopy enables vibrational spectra to be recorded using visible radiation albeit with rather different selection rules than apply to infrared absorption. Energy may both be removed from (Stokes) or added to (anti-Stokes) the incident radiation field from ground state and excited vibrational modes, respectively. These inelastic scattering processes may conveniently be pictured as absorption to, and emission from, a virtual state. A single-frequency CW laser is generally used and scattered light is collected and dispersed. The shifts in frequency are generally small as

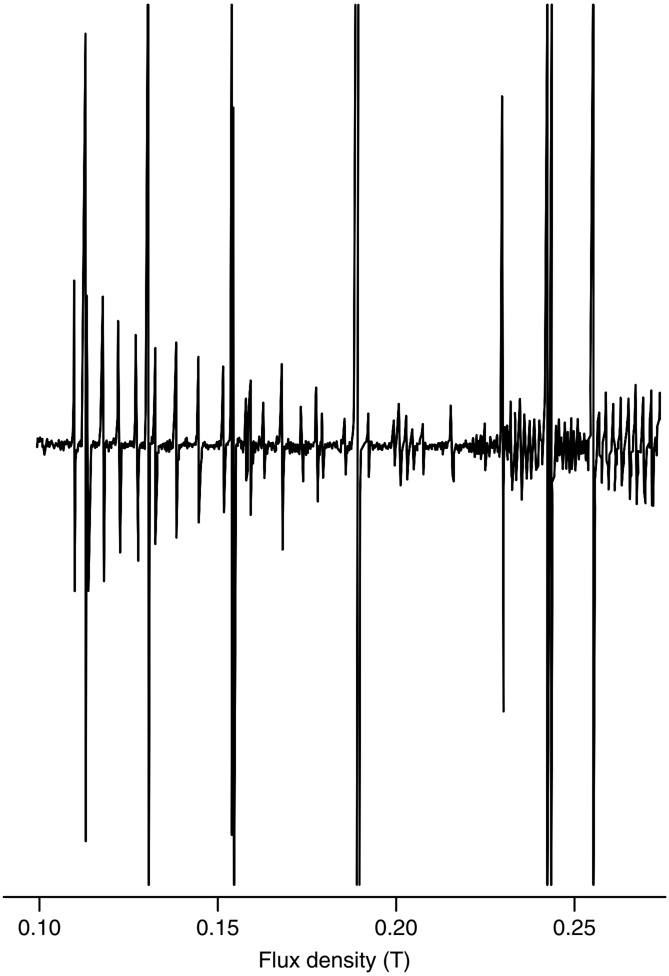

Fig. 19.2 Part of a far-infrared LMR spectrum recorded during a study of the HSS radical using the 203 μm laser line of $^{13}CH_3OH$. The first derivative lineshape is a result of the phase-sensitive detection used. (Ashworth S.H., Brown J.M. and Evenson K.M. *unpublished*.)

they usually correspond to vibrational spacings in the sample.

Rayleigh scattering is far more intense than the Raman shifted components of the scattered light and care must be taken to reduce the intensity of this light reaching the detector. Double and even triple monochromators may be employed for this. Advances in coating technologies, however, mean that filters can now be produced with extremely sharp cutoffs between high and low optical density, which makes experimental arrangements much simpler.

Naturally, the region where the Stokes lines are sought in a Raman spectrum is exactly the region where one might expect intense fluorescence. This is a problem, which often occurs because fluorescence is generally orders of magnitude more intense than the Raman shifted signals. This can be avoided by depositing the sample on a suitable substrate (e.g., graphite), which efficiently quenches fluorescence, or by using a sufficiently long excitation wavelength that the sample is not electronically excited. The latter approach cannot, of course, be applied to more sophisticated variants of the technique such as resonance Raman spectroscopy (Mak and Kincaid, 2008).

A suitable surface, such as rough silver, may increase the signal by orders of magnitude. This constitutes *surface-enhanced resonance Raman spectroscopy* (*SERRS*) (Smith, Faulds and Graham, 2006). Coherent anti-Stokes Raman spectroscopy (CARS) is strictly a nonlinear technique but should at least be mentioned here (Zheltikov, 2000). The CARS signal has the advantage of being highly directional and is therefore relatively straightforward to manipulate optically, to achieve high rejection of unwanted light.

19.2.8
Polarization Spectroscopy

Polarization spectroscopy may be implemented in a number of ways. In the simplest form, the sample is placed in a strong magnetic field, directed along the laser axis, between crossed polarizers. The Faraday effect in an isotropic sample, such as a gas, causes absorptions to rotate the plane of polarization of the laser light. Signals are thus detected against a very low background making this potentially a very sensitive technique.

In a second application, counterpropagating beams of unequal intensity from a narrow bandwidth laser may be used. The higher intensity pump beam is circularly polarized and the weaker probe beam is linearly polarized. The sample is placed between crossed polarizers through which the probe beam is directed. Absorption of the pump beam produces in a nonequilibrium population of magnetic sublevels. This disequilibrium is referred to as an *orientation* and in turn leads to a rotation in the polarization of the probe beam. The detector, behind the crossed polarizer, therefore, only detects signal when both pump and probe interact with the same population. This only occurs when the interaction is with the fraction of the population, which has no component of velocity along the laser axis, and is thus an inherently sub-Doppler technique (Demtröder, 2008).

An extension of this is known as polarization labelling spectroscopy. In this variant, the two beams are no longer derived from the same laser (and as a result the technique is not sub-Doppler). Like other double-resonance techniques (see below), it is usually applied to spectroscopic problems to use secure assignments from one set of bands to gain information about the assignment of a second set (Adohi-Krou *et al.*, 2008). The known transition is pumped with the first, fixed, laser and only transitions in the second set of bands with common electronic states are observed on scanning the second laser.

19.3
Proxy Techniques

The techniques considered up to now have required that a change in laser power be detected in some manner after interaction with a sample. An alternative and sometimes more sensitive approach is to detect a process that results from the absorption of a photon. Care must be exercised with what are here referred to as *proxy techniques*, as they will tend to yield different information from, and have a more limited range of applicability than, direct absorption.

19.3.1
Laser-Induced Fluorescence

The technique of *laser-induced fluorescence* (*LIF*) relies on the fate of the excited state formed on absorption. The word fluorescence itself implies that the upper state is an excited electronic state. As a result, the majority of LIF applications are in the visible and ultraviolet regions of the spectrum.

If the sample has a nonzero quantum yield of fluorescence, the total fluorescence intensity measured as a function of wavelength produces an excitation spectrum, which is a proxy for the absorption spectrum. The spectrum thus formed is a measure of the production of fluorescing, excited state molecules. The fluorescence signal may be shown to be proportional to the number of molecules present in the sample and, in the absence of other wavelength-dependent effects, the signal faithfully reproduces the absorption spectrum.

The absorption spectrum is not faithfully reproduced if other pathways to dispose of the excitation are available. In the gas phase, at low pressure, examples of potential pathways are dissociation and predissociation; the energy of the photon is sufficient to cause bond rupture. Often the fragments are not electronically excited and thus unable to emit, thereby reducing or even completely quenching the overall fluorescence intensity. At higher pressures in the gas phase or solution phase, collisional quenching may become sufficiently important that the efficiency of LIF is reduced.

A great advantage of LIF is that it is essentially a zero background technique. Fluorescence emission is collected off-axis from the excitation source (usually at right angles), so a highly sensitive detector may be used. Unfortunately, a lot of effort and careful experimental design are required to collect more than only a small proportion of the emission. In most cases, the detection sensitivity is sufficient so that it is unnecessary to make this additional effort. The most sophisticated arrangements implement collection optics that not only increase the efficiency of collection but may also provide spatial filtering, which helps discriminate against other sources of light. One of the most efficient systems reported uses spherical mirrors and collects around 30% of the emitted light (Korter *et al.*, 2001).

Scattered light from the excitation source is often the hardest to reject but LIF may also be applied in environments where other sources of light are visible to the detector. LIF is readily applied to furnaces, plasmas, and flames. Such sources may generate a continuum of frequencies where others may generate a structured emission or a combination of the two. A variety of techniques are used to reject unwanted signal at the detector. Some, such as time gating, lock-in detection, and phase-sensitive detection, use a well-defined time dependence of signal – either a modulation or a pulse – to discriminate against both noise and unwanted light. These techniques are, however, of no use if the detector itself is swamped by unwanted illumination.

The sensitivity of LIF, the fact that the signal is proportional to the number of emitters, and above all the selectivity of the technique means that it is easily applied to analytical and kinetic measurements. When observing changes in concentration using LIF, the laser source is not scanned and the signal will often be normalized to take account of variations in the laser power. Once again background light, including laser scatter, may be a problem. In such cases, bandpass filters are effective means to reduce the unwanted light intensity reaching the detector. A monochromator is a very convenient adjustable filter, both in terms of wavelength and bandpass.

When the band of wavelengths detected includes the laser wavelength, this is known as *resonant fluorescence detection*. Nonresonant fluorescence detection is possible if there is a well-defined transition to another energy level. The band of wavelengths required to detect fluorescence emission now no longer includes the laser wavelength. The great advantage of nonresonant fluorescence detection is, therefore, the high rejection of scatter from the excitation source.

19.3.1.1 Imaging

One of the benefits of a laser source is that the radiation need not be in the form of a beam on interaction with the sample. If the laser light is transformed into a sheet, fluorescence may be excited in a plane in the sample. The fluorescence may then be imaged onto a two-dimensional detector allowing dynamic processes, such as combustion, to be probed (Luong *et al.*, 2008). If the sheet of light is arranged so that it may be scanned in a direction perpendicular to the plane of light, a three-dimensional image may be built up.

19.3.1.2 Dispersed Fluorescence

A natural extension to the technique of nonresonant LIF detection mentioned above is to measure the fluorescence intensity as a function of emission wavelength. This is known as *dispersed* or *resolved fluorescence* and gives information on the ground state of the sample, shown schematically in Figure 19.3. Given that the collection efficiency of fluorescence is generally rather low, dispersed fluorescence usually requires quite careful alignment and sensitive equipment.

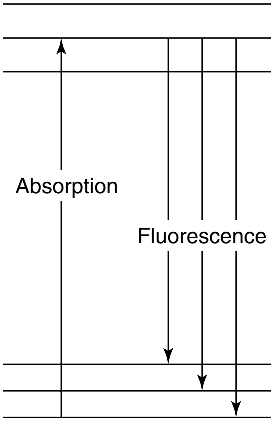

Fig. 19.3 The principle of laser-induced fluorescence. The excitation spectrum is recorded by scanning the absorbed photon and recording the total fluorescence. The wavelength dependence of the emission recorded with a fixed absorption wavelength forms the dispersed (or resolved) fluorescence spectrum.

The resolution is generally determined by the recording instrument. Any systems that are capable of resolving the fluorescence may be used to record dispersed fluorescence. Compact charge-coupled device (CCD) spectrometers offer low resolution rugged devices, whereas the highest resolution is more likely to be afforded by Fourier transform spectrometers (Hodges *et al.*, 2007), but these are much less rugged. The instrument of choice is often dictated by a compromise between the required resolution, fluorescence intensity, and the robustness that is required of the equipment.

19.3.1.3 **Stimulated Emission Pumping**

An alternative to dispersed fluorescence is the technique of *stimulated emission pumping* (*SEP*). A first photon fixed at one wavelength, as in dispersed fluorescence, is used to excite fluorescence. When a second photon incident on the sample is resonant with a downward transition, emission is stimulated or pumped. This leads to a decrease in the excited population and hence a decrease in the fluorescence intensity. The signal level is monitored as a function of the wavelength of a second photon. The signal is usually displayed as the ratio between fluorescence intensity before and after the pump laser as shown by the shaded areas in Figure 19.4. A good example is given in Mukarakate *et al.* (2008) where the normally downward going lines have also been reversed for clarity. The additional complexity of the technique in that it requires two lasers is compensated by the resolution, which is generally limited only by the pump laser.

19.3.1.4 **Intermodulated Fluorescence**

Intermodulated fluorescence is one of the techniques that may be used to reach sub-Doppler resolution. It involves single photon absorption from counterpropagating laser beams. The beams are chopped at different frequencies ω_1 and ω_2. When the beams are probing the same population, a signal is produced at the sum frequency $\omega_1 + \omega_2$. The only population that is probed by both beams simultaneously is that which has no velocity component along the laser beams. Thus the signal is inherently sub-Doppler and is often used to investigate hyperfine structure (Manke *et al.*, 2008).

19.3.1.5 **Saturation Dip Spectroscopy**

Saturation dip spectroscopy has many names and incarnations. In simple terms, the sample is exposed to counterpropagating beams of sufficient intensity that at line center the signal intensity drops because the lower state population has been depleted. This

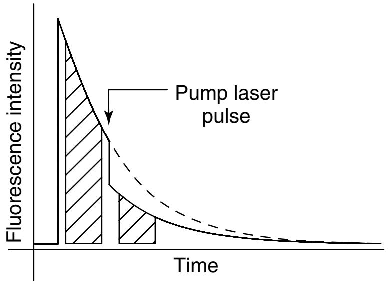

Fig. 19.4 The shaded areas show the areas to be compared in stimulated emission pumping. When the second (pump) laser interacts with the initially excited population, the fluorescence intensity is reduced.

sort of spectroscopy is variously referred to as *Lamb dip, saturation dip,* and *hole burning spectroscopy* in different fields and applications. It is treated in depth in Demtröder's classic book (Demtröder, 2008).

Saturation spectroscopy may be relatively straightforward if the sample is within the cavity of a standing wave CW laser as it is naturally exposed to collinear, counterpropagating radiation.

19.3.1.6 Quantum Beat Spectroscopy

The observation of quantum beats may be thought of as an analog of the observations in a Young's double slit experiment. Closely spaced molecular energy levels may be excited simultaneously by a single, usually pulsed, laser. The laser bandwidth obviously has to be sufficiently broad to excite two or more levels and form a coherent superposition (Ishii, Takeuchi and Tahara, 2008). Modulation at a frequency corresponding to the difference between the excited energy levels is superimposed on the exponential decay of fluorescence. The principle is illustrated in Figure 19.5. A Fourier transform of the beat frequency reveals the energy difference of the levels involved and produces a Doppler-free spectrum even when the energy difference is smaller than the Doppler width of the fluorescence.

19.3.1.7 Single-Molecule Spectroscopy

In many cases, spectroscopic signals are averaged over a large number of molecules, each of which is in a slightly different environment. This averaging effect is known as *heterogeneous broadening* as the signal is made up of contributions from many different individual absorptions. In environments where absorbers are constrained to a small region of space, it is possible to overcome this by recording signal from a single molecule or a single emitter, such as a quantum dot. Obviously, the fluorescence signal will tend to be weak in comparison with ensemble spectroscopy so a single molecule has to be pumped many times to its excited state in a single measurement. The field of view is constrained and the concentration of emitters kept low so that on average only one emitter may be detected at a time. Single-molecule spectroscopy may be used to investigate guest–host interactions and the homogeneity of the local environment. Wustholz *et al.* (2008) and Wirth and Legg (2007) have reviewed this extensive area.

19.3.1.8 Light Detection and Ranging (LIDAR)

Backscattered radiation from a laser directed through the atmosphere may be

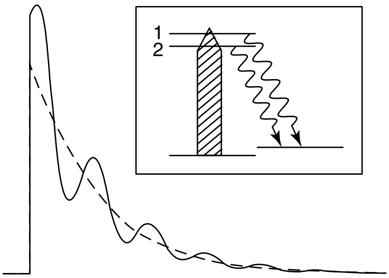

Fig. 19.5 Quantum beats (solid line) superimposed on a simple exponential decay (broken line). The inset shows the associated energy level scheme. The laser excites states 1 and 2 simultaneously and the interference results in quantum beats.

collected and, under favorable circumstances, used to measure the quantity and range of airborne substances. Rayleigh scatter is the strongest signal and is the result of inelastic scattering from all molecules in the atmosphere. This scatter is often carefully screened from detectors in order to allow detection of atomic and molecular signals. On the other hand, the Rayleigh scatter itself may be used to measure important quantities (Schoch, Baumgarten and Fiedler, 2008). The intensity of the scatter is proportional to gas density, the width of the scattered peak is related to gas temperature, and, in addition, one component of bulk velocity results in a shift of the peak wavelength of the scatter.

Resonant atomic fluorescence is perhaps the next strongest source. This allows the concentration of species such as iron and sodium to be measured in the mesosphere, at a range of around 85 km, from ground-based measurements (Gardner *et al.*, 2005). Even a highly collimated laser irradiates a substantial area at this range and very large and efficient collection optics are required to detect the very weak signals involved. Indeed, the signals are often so weak that astronomical telescopes are employed to collect the signal. Closer to home LIDAR is routinely mounted on mobile platforms and may be used to map atmospheric constituents, for example, plumes from volcanoes (Neri *et al.*, 2008) or chimneys.

19.3.2
Photoacoustic Spectroscopy

In an appropriate sample, the absorption of laser radiation results in a pressure wave. This can be detected using the simple expedient of a microphone. Care must be taken, however, that windows and other optical components in the sample cell do not also contribute to the signal. In order to avoid these effects when using a pulsed laser, the cell must be carefully designed (Rabasovic *et al.*, 2008). A CW laser obviously has to be modulated in order to produce a pressure pulse. This may be turned to advantage by ensuring that the sample chamber is resonant at the modulation frequency of the laser. Further isolation may be achieved by using buffer volumes as acoustic filters (Li *et al.*, 2008). This method has been combined with fluorescence detection to enable the quenching mechanisms in solution to be investigated (Kamath, Kartha and Mahato, 2008). *Photoacoustic spectroscopy* appears to be particularly suited as a detection method of absorption in the midlinfrared region (5–12 μm) (Patel, 2008).

19.3.3
Photoelectron Spectroscopy

Photon absorption may transfer enough energy to the sample to liberate an electron. The excess kinetic energy of the electron so liberated may be measured and thus the energy of the resultant ion state inferred. The resolution is limited by the electron energy analyzer and the radiation source but is usually high enough to resolve vibrational structure. The difference between the excitation energy and the kinetic energy of the electron gives information on the electronic structure of the resulting ion as shown in Figure 19.6. *Anion photoelectron spectroscopy*, on the other hand, allows the electronic state of the resulting neutral to be determined.

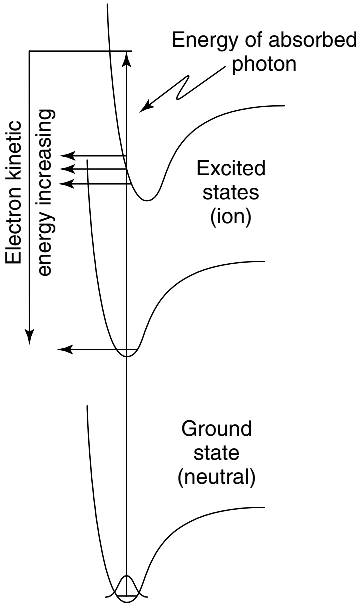

Fig. 19.6 In photoelectron spectroscopy, the ground state of the absorber undergoes a vertical transition to the ionization continuum. The electron carries away the difference in kinetic energy between the absorbed photon and the resultant ion state as indicated by arrows. The pattern of peaks gives information on the geometry change on ionization.

Traditionally, the hard ultraviolet light from a helium discharge has been used to generate photoelectron spectra. The advent of lasers and the availability of synchrotrons have widened the wavelength range over which photoelectrons may be generated and also reduced the linewidth of the exciting light.

The high resolution and tunability of laser sources may be employed to measure the yield of photoelectrons generated just at the ionization threshold. These electrons have a single value of kinetic energy, which is essentially zero, and makes the electron analyzer redundant. This is known as *zero electron kinetic energy* or *ZEKE* spectroscopy (Cockett, 2005). In ZEKE spectroscopy, the electrons produced with nonzero kinetic energy are allowed to disperse before an electric field is applied to the sample region to extract those that remain. The principle of ZEKE was first demonstrated by Chewter and coworkers (Chewter, Müller-Dethlefs and Schlag, 1987). The advantage of this approach is that the resolution is no longer limited by the electron analyzer; instead, it is limited by the laser resolution and the electric fields used to extract the electrons.

19.3.4
Resonance-Enhanced Multiphoton Ionization

Detection of ions is generally much more efficient than the detection of photons. In the simplest implementation of *resonance-enhanced multiphoton ionization* (*REMPI*), the sample is arranged so that it is exposed to a laser whose energy is capable of ionizing the

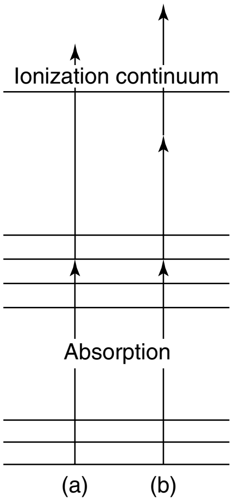

Fig. 19.7 The principle of REMPI. When absorption results in population in an upper state further photons are able to ionize the sample so absorption is detected as an increase in ion current. The second photon may be (a) the same wavelength as the first or (b) a different wavelength.

sample from the upper state of a transition of interest but not directly from its lower state. Another photon, which may result from the same source or a different source, excites the transition of interest results in an increased ion current. Both situations are illustrated in Figure 19.7. The spectrum is recorded as ion current as a function of laser wavelength.

Not only is detection of ions more efficient than the detection of photons, but also time of flight techniques may be used to assist in the identification of ions and fragments. In fact, ionic fragments may be detected by imaging using a two-dimensional detector at the end of a flight tube (Ashfold *et al.*, 2006). These techniques allow the kinetic energy release of the fragments to be reconstructed so that both energetic and dynamic information may be obtained.

19.3.5
Optogalvanic Spectroscopy

A plasma, such as that found in a hollow cathode lamp, is a complex system of excited states and energetic electrons. With a given electrical power input, the system remains in equilibrium. If light whose energy corresponds to an absorption in one of the plasma species, be it an ionic or neutral species is incident on the plasma, the equilibrium is perturbed. This perturbation leads to a change in the power demand from the power supply. The effect was first described in the mid-1920s (Penning, 1928) but not used with lasers until the 1970s Green *et al.* (1976a,b).

Plasmas are generally run at moderately high voltages and a very simple method to obtain the optogalvanic signal is to AC couple the voltage. Thus, the small voltage fluctuations as a result of irradiation are readily detectable. Given that the change in voltage on absorption is often on the order of millivolts, the stability of the power supply is important. Examples of one- and two-photon absorption along with the waveform observed in a commercial hollow cathode lamp are given in Omidyan *et al.* (2008).

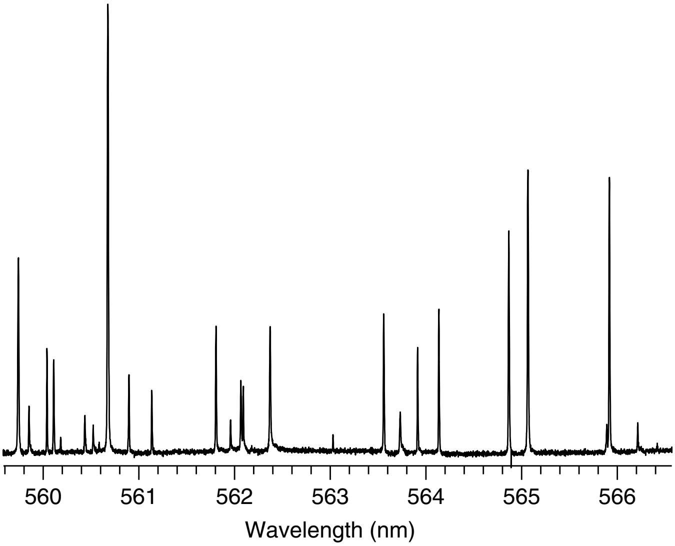

Fig. 19.8 Part of the spectrum of argon atoms recorded using the optogalvanic effect in a commercial hollow cathode lamp. (Greenacre C. and Ashworth S.H. *unpublished*.)

The technique is very straightforward to implement with commercial hollow cathode lamps and is routinely used as a calibration method for pulsed tunable lasers. Part of the spectrum of atomic argon in a commercial hollow cathode lamp is shown in Figure 19.8. Optogalvanic detection can also be applied to plasmas excited by radiofrequency discharges and has been used to detect attomole quantities of $^{14}CO_2$ (Murnick, Dogru and Ilkmen, 2008).

19.3.6
Frequency Modulation Spectroscopy

A laser beam may have sidebands superimposed on it by the use of an electro- or acousto-optic modulator or, in some cases, by direct modulation of the laser itself. The dominant sidebands are 180° out of phase and shifted in frequency from the carrier $\pm\omega$ Hz, where ω is the frequency of the local oscillator. Both sidebands and carrier are directed through the sample and incident on the detector. Off resonance, there is no absorption so the sidebands cancel exactly. This is also the case with the carrier at the absorption line center as both sidebands are absorbed to the same extent – given that the absorption line is symmetric. With the carrier frequency at any other position in the absorption one sideband is preferentially absorbed. The asymmetric absorption of the sidebands results in an AC signal at the detector as shown schematically in Figure 19.9.

One of the first demonstrations of frequency modulation (FM) spectroscopy was on sodium vapor and molecular iodine (Bjorklund, 1980). It is now routinely applied to high-resolution and high-sensitivity measurements in both

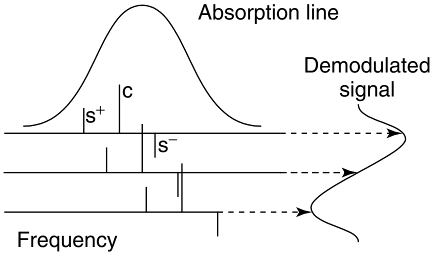

Fig. 19.9 An illustration of FM spectroscopy. The carrier frequency (c) and the sidebands (s+ and s−) which are 180° out of phase are scanned across an absorption line. The resultant demodulated signal is a first derivative lineshape.

spectroscopy and kinetics (Friedrichs, 2008). Combined with cavity enhancement it is known as *noise-immune cavity-enhanced optical heterodyne molecular spectroscopy* or *NICE-OHMS* (Foltynowicz *et al.*, 2008).

19.3.7
Thermal Lensing Spectroscopy

The *thermal lensing* technique relies on the change in density of a sample on interaction with laser radiation. For this reason, it is usually applied to dilute samples in the solid or solution phase. Laser energy is absorbed by the chromophore under investigation, which subsequently undergoes energy transfer. Energy released to the immediate environment results in local heating and thus a change in density. The thermally induced lens causes the laser beam downstream of the target to change its divergence. The irradiance is measured as a function of time by measuring the total energy passing through a small aperture. Thermal lensing may be detected in the excitation beam or in a second probe beam, which is not absorbed by the sample. It has been shown that the influence of solvent (Proskurnin *et al.*, 2008) and the experimental matrix (Georges, 2008) may be important in the interpretation of results. Recent reviews detail the application to detection in flow injection analysis and separation (Franko, 2008) and food analysis and environmental research (Franko, 2001).

19.4
Generally Applicable Techniques

The remaining techniques may find application in situations where either direct or proxy detection schemes are used.

19.4.1
Velocity Modulation

The study of molecular ions either by direct or proxy techniques is often complicated by the presence of neutral species. Such interferences are especially prevalent in the spectroscopy of plasmas and discharges where concentrations of ions may be orders of magnitude lower than that of neutral species. This difficulty was first overcome by Gudeman *et al.* (1983) by the expedient of modulating the electric field responsible for the discharge. The Doppler shift imparted by the sinusoidal variation of the drift velocity acts as a selective frequency modulation. By detecting at the same frequency, by either lock-in or phase-sensitive detection, only the signals resulting from ions are detected.

19.4.2
Double Resonance

SEP *wide infra* is an example of a double-resonance technique. Signal is only observed when two resonant conditions are fulfilled. Such applications may have many different names and involve alternative radiation sources. SEP is one example of *optical–optical double resonance* (*OODR*) where the population of a quantum state is detected by one photon and modulated by a second (Ye, Pang and Cheung, 2007). Population transfer may, however, be achieved by the absorption of a microwave photon that produces either enhancement or reduction of a laser signal: *microwave-optical double resonance* (*MODR*) (Barnett, Ramsay and Zhu, 2005). Similarly, ion dip spectroscopy measures the influence of a second, usually laser, photon on the ion current usually produced by photoionization by a laser (Sakota, Kageura and Sekiya, 2008).

19.4.3
Stark Spectroscopy

Stark spectroscopy is the electric field analog to LMR spectroscopy but tends to be less limited in its range of application. The Stark splitting patterns of transitions may be used to assist in assignments. In combination with tunable lasers, the shift of a single transition may be measured as a function of electric field, which allows the dipole moment in both ground and excited states to be determined (Chen and Steimle, 2008).

17.1
Introduction

Photoacoustic (PA) spectroscopy is an indirect technique in the sense that an effect of light absorption is measured rather than light absorption itself. Light that is absorbed by a sample is, completely or partly, converted into heat, giving rise to pressure waves that can be detected. Using PA spectroscopy (PAs), regular absorption spectra can be obtained. PA spectroscopy is complementary to regular absorption/transmission spectroscopy, because only absorbed light contributes to the PA signal and drawbacks of regular spectroscopy (e.g., background absorption, scattered light, opaque media) do not play a role in PA spectroscopy. In general, when matter absorbs light the transmitted power follows Beer's law: $P = P_0 e^{-\alpha l}$ in which P_0 the incident laser power, P the transmitted laser power after distance l in centimeters through the sample, and α in cm^{-1} the absorption strength at that frequency. For low absorptions, this exponential expression can be linearized:

$$\Delta P = P_0 - P = P_0 \alpha l \tag{17.1}$$

It shows that the generated PA effect (i.e., decrease in power) is proportional to the incident power. On the other hand, other factors, such as the optical, thermal, and acoustical properties of the sample and media involved, are now more important and can even be the direct objective of study in many applications of PAs.

Like in all spectroscopy, the spectral dependence of absorption permits selectivity and identification of the absorbing components. The PA response itself can be fast, highly sensitive, and in principle, background-free. Thanks to these qualifications, no lengthy accumulation periods (e.g., in trace gas detection) or long absorption pathways are needed. Because transparency and scattering play no role, solids, whether crystalline, powdered, or amorphous, can be studied. Using the dependency of the PA signal on thermal and acoustic properties, surfaces and solids can be tested noninvasively for structural inhomogeneity. For these latter applications, the spectroscopical aspect plays a minor role. PA spectroscopy is especially suited to monitor local effects. Remote sensing, conversely, is alien to PAs.

A medium that absorbs electromagnetic radiation experiences a local temperature increase by relaxation processes that transfer electronic, vibrational, or rotational energy into translation energy (phonon energy in case of solids). This nonradiative relaxation process occurs if its relaxation time can compete with the radiative

Handbook of Metrology. Edited by Michael Gläser and Manfred Kochsiek

ISBN: 978-3-527-40666-1

lifetime of the excited energy levels. If the absorption is modulated, at an acoustic frequency, for example, by modulating the intensity of the radiation source, these temperature changes occur periodically and give rise to acoustic phenomena. Hence the name ''photoacoustic''; light absorption is detected through its accompanying acoustic effect.

A sensitive microphone can detect the effect, especially, when it occurs in the gas phase. In the case of solids or fluids, a piezoelectric transducer is often used. Thus, the minimum requirement is a suitable source of modulated electromagnetic radiation for which the wavelength can be selected, such that the absorption spectrum of the substance investigated can be accessed. In addition, a detection device such as the mentioned microphone or piezo transducer must indicate that absorption takes place (Figure 17.1). This short description already clarifies that PA spectroscopy is based on a two-step process; first, electromagnetic radiation energy must be absorbed, this being the spectroscopically selective step; second, the absorbed energy must be transferred to sound-producing degrees of freedom, by relaxation processes. If this relaxation is too slow with respect to the employed modulation times, PA spectroscopy will not work. Note that the relaxation rate depends on the properties of the participating molecules.

The instrumentation required for PA spectroscopy can be relatively inexpensive and simple; the powerful and tunable laser that may be used forms the cost-determining part, but for some applications a simple mercury lamp and an inexpensive microphone suffice. However, the instrumentation has to be well designed and cleverly chosen, and its operation requires skillful people. Especially, the PA cell has to be designed with care, fitting with the chosen application.

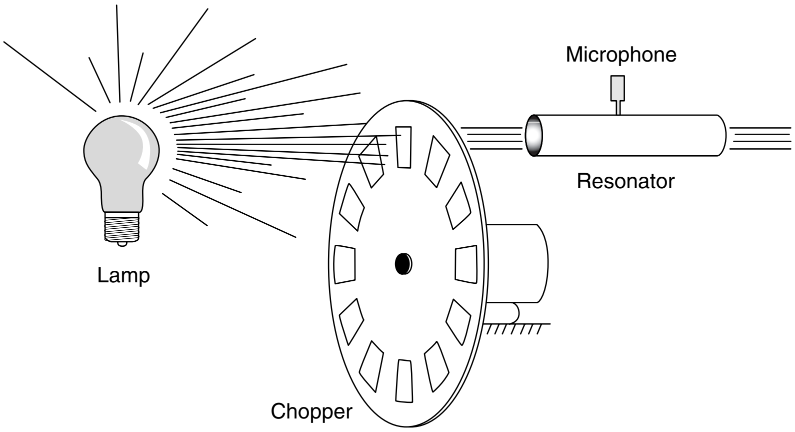

Fig. 17.1 A schematic representation of the photoacoustic setup. The lamp represents the light source, which was the sun in the original experiments by Bell. Nowadays lasers are used because of their tunability and brilliance. When, for example, a gas absorbs the light, the temperature of the gas increases, the gas expands adiabatically, generating a pressure increase. By switching off the light, temperature and pressure drop. The light is modulated, in this case mechanically chopped to generate an AC temperature and/or pressure wave (i.e., sound). If the modulation frequency corresponds to the resonance frequency of the acoustical resonator, the sound is amplified. A microphone is inserted into the resonator at the point where the resulting pressure standing wave has maximum amplitude.

The PA effect has been discovered and clarified almost simultaneously by Bell (1880), Röntgen (1881), and Tyndall (1881). In those days, neither laser sources (which are ideally suited for PA spectroscopy, owing to their brilliance) nor sensitive small microphones were available. Therefore, being well understood, but rather impractical, the effect remained slumbering in the cabinet of curiosities. In 1938, Veingerov refined the PA technique for the first spectroscopic gas analysis (Veingerov, 1938); and in 1943, Luft measured trace gas absorption spectra with an infrared broadband light source down to the part per million level (Luft, 1943). By the end of the 1960s, after the invention of the laser, the scientific interest expanded again. Kerr and Atwood (1968) utilized the laser PA detection to obtain the absorption spectra of small gaseous molecules. Owing to the high spectral brightness of lasers and improved phase-sensitive lock-in techniques to amplify the acoustic signal, they were able to determine low absorption strengths. Since then, a broad field of pure and applied spectroscopic methods has emerged using the PA effect. The last decades have seen an ever-increasing use of PA techniques in a very wide field of applications. These activities range from fundamental research (e.g., the investigation of vibrationally highly excited molecules) to applications (e.g., testing of solids, surfaces, biomedical applications). A number of useful reviews have appeared over this period (see Further Reading), covering most of these areas.

Firstly, the equipment is discussed. Various types of PA cells are introduced, which are resonant and nonresonant with respect to the modulation frequency of the light. In addition to the sound detection by microphones, related techniques such as thermal lensing and photothermal deflection are discussed, which are often applied if liquid- or solid-state samples are investigated. In Section 17.3, applications to solids, liquids, and surfaces and to gas spectroscopy are dealt with. As one of the more recent applications, trace gas detection is also considered with environmental and biological studies. Besides these key references, books and review articles are given for further reading.

17.2
Devices and Equipment

17.2.1
Light Sources

In principle, there is no need for lasers to operate a PA detection system. Light from lamps can be filtered by a monochromatic system to obtain radiation needed for spectroscopic discrimination to distinguish between components. Other highly sophisticated instruments use, for the selection of wavelength, the gaseous species under investigation itself (Figure 17.2); all wavelengths at which absorption takes place are simultaneously active. With the latter instrument (URAS, ABB Germany) detection limits in the sub-ppmv (1 ppmv = 1 part per million volume = $1 : 10^6$) range can be achieved for more than 25 gaseous compounds.

However, more often PA detection goes together with the application of laser light sources, ranging from the infrared to the visible and UV, including both continuous wave (CW) and pulsed lasers. Since the PA signal is proportional to the laser power, strong lasers are advantageously applied.

In the mid-infrared wavelength region, CW CO_2 (wavelength region from 9 to 11 μm) and CO lasers (4.6–8.2 μm) were

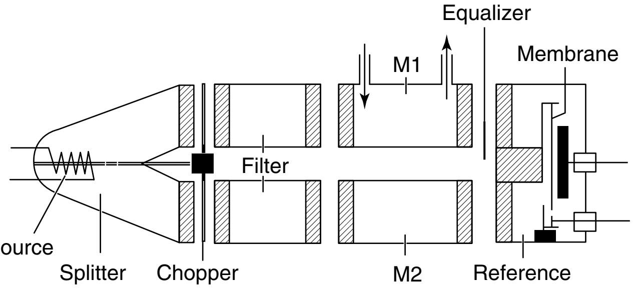

Fig. 17.2 The infrared absorption spectrometer setup (URAS). Light from the thermal IR source is divided into two paths. The chopper modulates the intensity for both paths. The filters serve to filter out light of wavelengths not needed for the detection process; they can be filled with gases whose absorption spectra do not overlap with those of the species under scrutiny. M1 represents the sampling cell through which the sampled gas is flowed. M2 serves as a reference cell with a calibrated gas mixture in which the traversing light is attenuated to equalize the light intensities at the entrance of the last cell at the far right. The light is equalized before the cells M1 and M2 are filled. The last cell consists of two compartments with a membrane in between. Both compartments are filled with the gas under scrutiny so that all wavelength characteristics for this gas contribute to the signal. If in M1 the attenuation differs from that in the reference cell, the membrane starts to oscillate with the frequency of the chopper. This oscillation (typically hertz) is detected capacitively.

among the most used. At present, developments in solid state physics and nonlinear optics have expanded the potential for PA spectroscopy to other wavelength regions. The recent availability of high power, pulsed, and CW quantum cascade lasers (QCL)s, operating at room temperature with power levels up to 1 W, has boosted PA spectroscopy in the mid-infrared wavelength region. Even more, single-mode tuning ranges, approaching 300 wavenumbers, are now achievable from commercially available external cavity QCL products. QCLs operate in the mid-infrared wavelength region from 3.5 to 24 μm (Kosterev and Tittel, 2002). For the 2.5–5 μm region CW periodically poled lithium niobate optical parametric oscillators (PPLN–OPOs) became available at high (several watts) power level and narrow linewidth. Nowadays, OPOs are pumped by high power, near-infrared lasers with excellent spectroscopic properties (narrow linewidth, Gaussian beam profile, fast wavelength scanning), which they can convert into the mid-infrared wavelength region due to their instantaneous nonlinear effects (Ebrahim-Zadeh and Sorokina, 2005).

In the near infrared wavelength region, CW titanium–sapphire ring lasers (650–1000 nm) are intensively used for high-resolution studies of weak overtone absorption spectra of molecular gases. High-overtone spectroscopy profits from sensitive PA detection, since one deals with high vibrational excitation, where fluorescence-based techniques do not work. Electronic spectroscopy with light sources in the visible or in the ultraviolet region does not immediately ask for PA detection because other techniques provide more powerful means (e.g., laser-induced fluorescence (LIF) or resonance-enhanced multiphoton ionization).

In addition to this, near-infrared “telecom” diode lasers have the advantage of small size, reliability, and low costs. Because of their low power the combination with PA spectroscopy is not always very favorable. However, the development of fiber amplifiers in this wavelength region could overcome this disadvantage. Telecom lasers are well suited to be used in gas sensing instruments in which the sensitivity is limited to the ppmv range. These lasers are tunable only over a limited wavelength region (1 cm^{-1}), but larger tuning ranges can be obtained by external cavity setups (external cavity diode laser). The near-infrared diode lasers have the main disadvantage that they operate at the weak overtone absorption bands instead of the strong fundamental vibrational absorption bands in the mid-infrared wavelength region.

By using pulsed lasers and gated detection, the pulse character of the signal allows suppression of a possible window signal by setting the boxcar delay such that the window signal has not yet arrived at the piezo transducer (or microphone) when the trace signal is detected. In general, however, the highest sensitivity of PA detection has been achieved for modulated CW lasers; if no other arguments prevail, the use of CW lasers is recommended.

17.2.2
Gas-Phase Photoacoustic Cells

The proper choice of the PA cell geometry depends on the intended application. For gas-phase measurements, mainly resonant cells are combined with frequency- or amplitude-modulated CW lasers. For condensed-phase spectroscopy (e.g., surfaces, thin surface layers, or depth profiling) with CW lasers, gas-coupled microphones are used within a small nonresonant cell. Utilizing pulsed lasers, the response is monitored with a piezoelectrical crystal directly coupled to the material. In competition with this is the noncontact detection by the photothermal effect, in which a laser beam is deflected or dispersed by the heat gradient from the sample.

17.2.2.1 **Nonresonant Cells**

If the modulation frequency of the incident light is much smaller than the lowest resonance frequency of the cell, it is to be considered a nonresonant cell. The performance of a cell is related to its efficiency in converting absorbed photon energy into acoustic energy by a cell constant *F;* that is, $p_{\text{gas}} = F\Delta P$ with p_{gas} being the generated acoustic pressure in the gas and ΔP derived from Equation 17.1 The cell constant F in (Pa m W^{-1}) can be derived by

$$F_{\text{nonresonant}} = \frac{G(\gamma - 1)l_{\text{nr}}}{2\pi \nu V_{\text{nr}}} \tag{17.2}$$

with l_{nr} and V_{nr} being the length and the volume of the cell, respectively; γ the specific heat constant, ν the modulation frequency, and G a geometrical factor, typically of the order of 1. From the above formula, one can derive that the F is independent of the cell length. The diameter should be as small as possible to generate high signals, just large enough to allow proper alignment of the incident light beam. To minimize the detection of absorption by the cell windows, one has to maximize the cell length; the energy absorbed by the windows is then distributed over a larger volume. The PA signal decreases with higher modulation frequencies; therefore, it is advantageous to use low modulation frequencies.

For the investigation of solids, liquids, and surfaces, another type of nonresonant PA cell has to be designed. The sample has to be sealed in a gas cell having a window

and a microphone. In the extreme case of an open cell, the wall opposite the window can be the material under investigation. The gas buffer volume in this cell should be designed as small as possible; in some cases, the heat generated by the absorption of (modulated) light diffuses to the surface and into the buffer gas (e.g., helium). The probing depth into the surface is determined by the modulation frequency: at low frequencies deeper layers of the material are investigated as compared to high frequencies. This probing depth, the thermal diffusion length, μ_s is given by

$$\mu_\mathrm{s} = \left\{\frac{D}{\pi \nu}\right\}^{1/2} \tag{17.3}$$

where D is the thermal diffusivity of the sample and ν the modulation frequency of the light. To characterize the complete sample, the optical absorption length μ_α (the reciprocal of the optical absorption coefficient α) and the thickness of the sample L are also important (Figure 17.3). Because the values of all three properties (μ_s, μ_α, and L) can vary relative to each other and within orders of magnitude, six possible limiting cases can be distinguished, as elaborated by Tam (1983).

For pulsed operation, the bandwidth of the microphone is too small (typically 20 kHz) as compared to the fast nanosecond processes in materials. The microphone must then be replaced by a piezoelectric element, either ceramic or a polyvinylidene difluoride (PVDF) foil, which is directly attached to the material. These detectors can show an acoustic response up to tens of megahertz. High-output pulsed lasers combined with gated extraction of the acoustic signals yield a highly sensitive

($\alpha = 1 \times 10^{-7}\,\mathrm{cm}^{-1}$) technique that can discriminate against low-frequency noise and window absorption.

17.2.2.2 **Resonant Cells**

In a resonant cell setting, the modulation frequency is chosen to match one of the resonant frequencies of the cell. This produces a standing, amplified, sound wave in the resonator. For a gas-type resonant cell, two varieties of acoustical resonators have found widespread use: the Helmholtz resonator and the cylindrical resonator excited in a longitudinal, radial, and/or azimuthal mode (Figure 17.4).

A Helmholtz resonator consists of a closed volume (cavity) connected via a long narrow tube to the open air. It is the acoustic equivalent of a mechanical oscillator composed of a mass (long tube) and a spring (cavity). The oscillation frequency (ν_H) of the system depends on the length (l_H) and cross section (A_H) of the tube and the volume (V_H) of the cavity via the following relation:

$$\nu_\mathrm{H} = V_\mathrm{s} \left\{ \frac{A_\mathrm{H}}{V_\mathrm{H} l_\mathrm{H}} \right\}^{1/2} \tag{17.4}$$

with V_s being the velocity of sound (Kapitanov *et al.*, 2001). Although the acoustical response of such a resonator is somewhat lower as compared to the response of the cylindrical resonators described below, the type of resonator has some advantages when low or high temperatures are needed. Microphones have a limited operating temperature range, that is, around room temperature. When gases are investigated at low (e.g., 80 K) or high (350 K) temperatures, it is advantageous to have a homogeneous temperature distribution across the gas volume while the microphone operates at room temperature. The temperature gradient is over the long narrow tube of the resonator at the end of the microphone is placed.

For cylindrical resonant cells, one has to multiply the cell constant F (Equation 17.2) with the quality factor Q of the generated acoustic resonance:

$$F_\mathrm{resonant} = \frac{G(\gamma - 1) l_\mathrm{r} Q}{2\pi \nu V_\mathrm{r}} \tag{17.5}$$

with l_r and V_r being the length and the volume of the acoustic resonator, respectively; Q equals the ratio of the energy stored in the acoustical standing wave to the energy losses per cycle. For resonant cylindrical cells, one can derive for the cell constant: $F_\mathrm{resonant} \propto \sqrt{l_\mathrm{r}}/R$, with R being the radius of the resonator (Equation 17.5.) (Bijnen, Reuss, and Harren, 1996). Cell geometries with large diameter-to-length ratios, to excite the resonance in the radial or azimuthal acoustic mode, possess high Q-values and high resonance frequencies; they have, however, low F-values. PA cells with high Q-values are sensitive to long-term drifts, for example, owing to thermal expansion if the temperature is not carefully controlled. Such cells require active locking of the modulation frequency on the resonance frequency of the cell. In a longitudinally excited resonator, a smaller acoustic gain, as a consequence of a relatively low Q-value, is compensated for by the signal gain due to the smaller diameter.

The resonant acoustical amplification is limited by various dissipation processes, which can be divided into surface and volume effects. Main surface losses are viscous and thermal losses at the resonator surface; in addition there are microphone losses, and acoustic wave scattering losses at obstacles inside the cell. The less-important volumetric losses are radiation losses, free-space viscous and thermal losses, and dissipative relaxation losses within the absorbing gases. For a cylindrical resonator, the resonant frequencies are given by Hess (1983)

$$\nu_{\mathrm{nmp}} = V_{\mathrm{s}}\left[\left\{\frac{\alpha_{\mathrm{mn}}}{d}\right\}^2 + \left\{\frac{p}{2l}\right\}^2\right]^{1/2} \qquad (17.6)$$

with V_{s} being the velocity of sound of the gas inside the cavity, d the cell diameter, l the axial length, and $p = 0, 1, 2, 3 \ldots$ axial mode numbers; α_{mn} is the nth root of the derivative of the Bessel function, $dJ_m/dr = 0$ at $r = R$ (e.g., $\alpha_{00} = 0, \alpha_{01} = 1.2197$, $\alpha_{10} = 0.5861$, and $\alpha_{11} = 1.6970$).

To choose the proper frequency for an optimal signal-to-noise ratio, one has to take into account the noise spectrum. The theoretical minimum acoustical noise results from random pressure fluctuations and their frequency distribution due to Brownian motion. The total power of these pressure fluctuations is constant, but the noise spectrum depends on the Q-value of the acoustical resonance of the PA cell; a high Q-value will significantly amplify noise power at these resonances. However, often this Brownian noise level is below what is produced by other noise sources such as electronic amplifier noise and external acoustical noise from the surroundings; their power decreases with increasing frequency. It is then advantageous to utilize a resonant cell to improve the signal-to-noise ratio. The resonance frequency might be chosen such that contributions from Brownian noise and amplifier/external noise become comparable. At resonance, external acoustical noise within the cell will be amplified at a high Q-value. Here acoustical shielding helps, that is, a proper cell wall construction (massive), material choice (brass), and good design of in- and outlet ports are required. For the latter, $\lambda/4$ notch filters (λ the acoustical wavelength) are positioned in line with the gas in- and outlet (Figure 17.5). In practice, for the B&K 4179 condenser microphone mounted on a well-shielded resonant ($Q = 40$) PA cell, a noise level has been observed that is an order of magnitude above the noise of the complete system (microphone and pre-amplifier) quoted by the manufacturer (Bijnen, Reuss, and Harren, 1996).

By definition, noise components do not possess a fixed phase relation with the periodical modulation of the light intensity. External perturbing sources may have a fixed phase relation, for example, the directly generated acoustical sound caused by chopping the light beam. They must be minimized in the same way as the external acoustical noise. In the case of a mechanical chopper, a good choice of the chopper position and removal of objects in the neighborhood of the chopper wheel are advantageous. A more serious problem

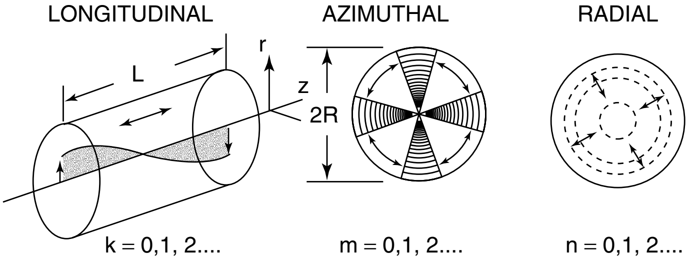

Fig. 17.4 Resonant acoustic modes of a cylindrical closed chamber, the fundamental longitudinal, azimuthal, and radial modes.

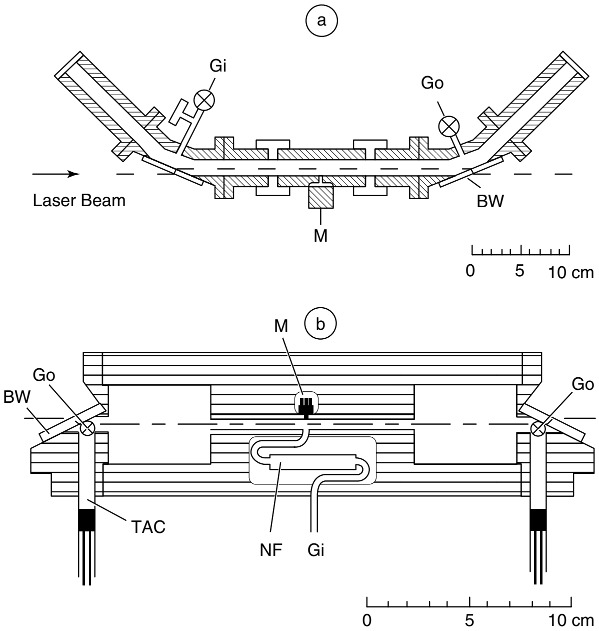

Fig. 17.5 Two photoacoustic cell types successfully used in trace gas detection. (a) The Zurich-banana cell, where the laser beam enters from the left through a Brewster window (BW) to leave the central part ($l = \lambda/2$) of the resonator at the right Brewster window. The position of the microphone M is indicated. The two pieces of length $\lambda/4$ before and after the bends serve to suppress the window signal. The total length of the banana cell amounts to λ. In the bends, the gas inlet (Gi) and gas outlet (Go) are shown. (b) The Harvard–Nijmegen open-organ-pipe cell; the main part is manufactured of a block of massive brass. The central organ pipe acts as an open resonator with length $\lambda/2$; the copper resonator tube has a highly polished, gold-coated inner surface to minimize wall heating by stray light. The central position of the gas inlet (Gi) is essential to obtain short measuring times; only the resonator volume of 2.8 ml must be replenished before an independent concentration measurement can be performed. TACs: $\lambda/4$ tunable air columns to suppress window signal. NF: $\lambda/4$ notch filter to suppress acoustic in coupling of noise via gas inlet.

is formed by the PA background signal; absorption of the light beam in the window material or light scattered/reflected from the resonator wall causes a signal at the frequency of the modulated light beam. In resonant cells, using $\lambda/4$-tubes next to the windows can diminish window signals. These tubes, placed perpendicular to the resonator axis close to the windows, are tuned to the resonator frequency and act as interference filters for the window signals (see Figure 17.5). Influence of scattered light on the PA background signal can be minimized by the use of highly reflecting polished material with a good thermal conductivity. In the case of infrared light a polished gold-coated copper wall of the acoustical resonator has been found to work satisfactorily.

We describe two successfully applied cells, the Zurich-banana-type cell and the Harvard–Nijmegen open-organ-pipe cell (Figure 17.5). In both cases, the modulation frequency ν is chosen in resonance with a longitudinal acoustic mode of the cell (typical length 150 mm and typical diameter

Tab. 17.1 Photoacoustic cell parameters; in the case of the open-organ-pipe cells in which the window signal is so far suppressed as to no longer limit the sensitivity, α_{min} is given for 1 W of laser power, that is, for 10 W of laser power α_{min} becomes smaller by a factor 10.

Cell type	Banana	Organ pipe
Microphone	Bruel and Kjaer	Knowless
Type number	4179	EK 3024

α_{min} (cm^{-1} W^{-1})	5×10^{-8}	2×10^{-8}

10 mm). The banana-type cell has as an important advantage its small volume; it forms an acoustically closed system with a moderately high Q ($Q = 53$ for its utilized second longitudinal mode); the "bent" geometry allows Brewster windows (BWs) to be positioned at pressure nodes, thereby minimizing the window signals (similarly, the gas in- and outlet with their external acoustical noise). The cell is operated at 555 Hz. The end pieces beyond the bends are optimized to suppress the window signal by interference. The open-organ-pipe cell may have a somewhat lower Q-value ($Q = 32$, inner radius $R = 3$ mm) but a higher F-value due to the smaller radius of the resonator tube ($F_{\text{resonant}} \propto \sqrt{l_r}/R$). Table 17.1 shows the properties of the cells.

17.2.2.3 Cantilever-Type Optical Microphone

Microphones, where the flexible membrane is strained over a frame or the pressure sensor is a thinner portion in a metal plate, are not very sensitive and the response is not linear because of the fact that the material has to stretch out radially under the pressure variations. A cantilever-type pressure sensor has been proposed as shown in Figures 17.6 and 17.7 (Uotila, Koskinen, and Kauppinen, 2005). The cantilever size is 2 mm × 4 mm and made out of silicon. Because of its extreme thinness (5 μm) the cantilever moves like a flexible door owing to the pressure variations in the surrounding gas. The frame around the silicon cantilever is thick (380 μm) and there is a narrow (30 μm) gap between the frame and the cantilever on three sides. As the pressure varies, the cantilever only bends but it does not stretch. Therefore, the movement of the free end of the cantilever can be about 2 orders of magnitude greater than the movement of the middle point of the tightened membrane under the same pressure variation. With this setup a detection limit of 0.9 ppmv for ethylene, 0.3 ppmv for methane, and 0.1 ppmv for carbon dioxide was achieved with a mechanically chopped blackbody radiator.

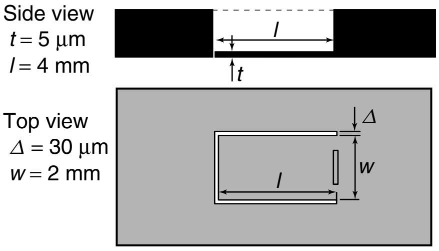

Fig. 17.6 The dimensions of the cantilever and the gap between the cantilever and the frame.

17.2.2.4 **Quartz Tuning Fork**

In the gas-phase spectroscopy, the common approach is to use a resonant PA cell and accumulate the absorbed energy in the gas. However, a recent developed approach is to store the absorbed energy in a sensitive element. A well-suited material for this is a high-*Q* crystal quartz element with piezoelectric properties. These elements are mass produced and inexpensive; every electronic watch or clock is built around a high-*Q* quartz crystal frequency standard. Usually, it is a quartz tuning fork (TF) with a resonant frequency close to 32 768 Hz. The mode at this frequency corresponds to a symmetric vibration (the prongs move in opposite directions). The antisymmetric vibration is piezoelectrically inactive. These quartz TFs have recently become widely used materials for atomic-force and optical near-field microscopy, and therefore their properties have been carefully analyzed (Kosterev *et al.*, 2005). A typical watch TF has a *Q* value of 20 000 in vacuum; at normal atmospheric pressure this is lower (~8000) because of the viscous properties of air. The typical energy accumulation time at atmospheric pressure is 250 ms, which is quite longer than any practical gas-filled resonator (Figure 17.8).

The special features of using a TF are as follows: (i) Ambient acoustic noise is very low above 10 kHz. (ii) External sound will always excite both prongs of the TF and, as a result, will not excite the piezoelectrically active mode, in which the two prongs move

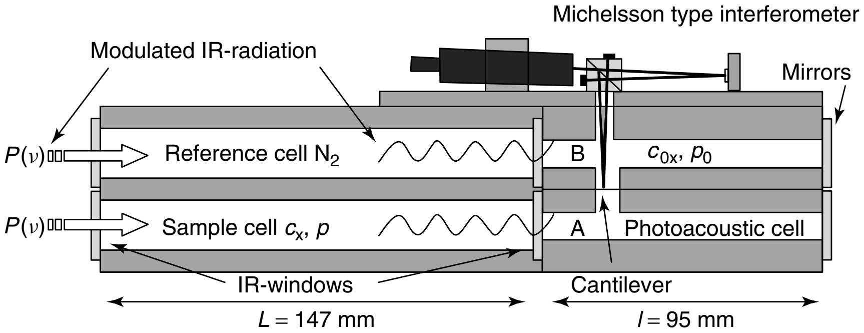

Fig. 17.7 The setup containing the cantilever is in principle the same setup as the nondispersive setup from Figure 17.2, but now with a cantilever detection setup. It consists of three cells: the reference cell, sample cell, and photoacoustic cell. The photoacoustic cell acts as a detector and includes high concentration of the gas to be detected. The cell is divided into two parts A and B which are separated by the cantilever and its frame. The position of the cantilever is proportional to the pressure difference between the cell parts A and B. The displacement of the cantilever end is measured continuously with a Michelson type interferometer.

in opposite directions. (iii) The width of the TF resonance at normal pressure is 4 Hz, and only frequency components in this narrow spectral band can produce efficient excitation of the TF vibration. (iv) The gas sampling volume is extremely small ($0.15\,\text{mm}^3$).

17.2.3
Condensed-Matter Photoacoustic Cells

Most spectroscopy on solid samples is done with gas-coupled microphones. Little sample preparation is needed and PA cells are commercially available. Modulation frequencies are generally low, 2–500 Hz, and coupling volumes are as small as possible. One increasingly popular design is the open photoacoustic cell (OPC) in which the sample makes up one wall of the cell.

The investigation of condensed matter using gas coupling becomes more complex when the sample absorption coefficient is small and the modulation frequency is high (e.g., pulsed lasers). The sample vibration itself will start to contribute in a significant way to the microphone signal. In addition, gas microphone detection of acoustic waves inside a condensed sample is not an efficient way of detection, because the acoustic impedance mismatch at the sample–surface interface causes a low transmission across the interface (Tam, 1983). A better, direct coupling, method involves the insertion or attachment of a transducer (piezoelectric) into or onto the sample.

When CW lasers are used in combination with condensed-matter PA cells, wavelength tuning allows a considerable reduction of the background signal generated by light scattering and window absorption. Factors that limit sensitive detection are as follows: besides light scattering and window absorption, mechanical noise at low frequencies, heating of the sample (self-defocusing), and convection currents in the case of liquid.

These limitations are avoided with pulsed lasers. Pulsed lasers allow time gating to discriminate against window absorption (arrives later) and light scattering (is instantaneous). Heating of the sample is minimized by the low average power (pulses are at nanosecond timescale) in combination with low repetition rates. Mechanical noise and the electrical pickup can be eliminated because the pulsed PA signals are at high acoustic frequencies ($>100\,\text{kHz}$).

Piezoelectric ceramics are (much more) suitable and many types are commercially available, for example, lead zirconate titanate (PZT), lead metaniobate, lithium niobate, crystalline quartz, and so on (Mason and Thurston, 1979). Thin, highly insulating polymeric films poled at elevated temperatures in strong electric fields also show a piezoelectric character: PVDF, Teflon, and Mylar are most commonly used. They combine a fast rise time (2 ns) with good flexibility and good acoustic impedance to liquids such as water (Tam, 1986).

17.2.4
Photothermal Detection

17.2.4.1 Photothermal Deflection Spectroscopy

Schemes different to PA detection are considered by Sigrist (1994). His conclusion is that for many applications, the PA technique utilizing a sensitive microphone appears to yield the simplest and the most sensitive solution. There are instances, however, in which PA fails. For the investigation of condensed matter using a microphone, a gas buffer is needed that results in low signals due to the acoustical mismatch between gas and solids. In addition, for fast (nanoseconds) experiments microphones are too limited due to their bandwidth. Piezoelectric transducers do have wider bandwidths but need to be attached to the condensed sample. When noncontact methods are preferred, techniques such as photothermal deflection and thermal lensing can be used. An additional advantage is that the bandwidth of detection is very wide and only limited by the bandwidth of the photodiodes.

In photothermal deflection spectroscopy, the basic principle rests on the change of refraction index n caused by a local temperature increase and a density decrease upon absorption of radiation. This change Δn results in deflection of a probe laser (in many cases a Helium–Neon laser with a good pointing stability), observed with the help of a position-sensitive detector. The basic idea can be implemented by two different geometries; the two lasers (absorption laser and probe laser) can either be aligned collinearly or perpendicularly (Figure 17.9). The advantages of the perpendicular arrangement are ease of reproducible adjustment and local probing since it defines a probing volume of some cubic millimeters. This small size is important in many applications such as local gas emission or local heating of the solid-state material for (sub)surface imaging. In the latter application, the excitation light is directed perpendicular to the surface, while the probe laser is parallel, and very close, to the surface.

17.2.4.2 **Thermal Lensing**

Like other photothermal phenomena, thermal lensing is based on the temperature increase after illumination of the sample and the nonradiative relaxation of the absorbed energy. In this case, a laser beam is needed because its radially symmetric Gaussian intensity distribution generates more heat at the center of the

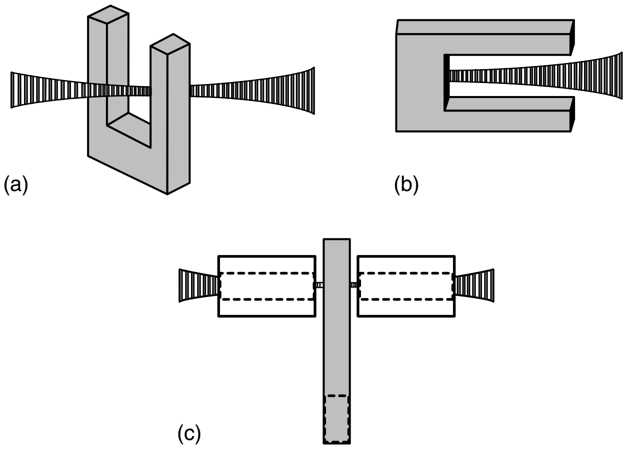

Fig. 17.8 Optical configurations for photoacoustic signal detection with a TF. (a) The laser beam is perpendicular to the TF plane. (b) The laser beam is in the TF plane. (c) An acoustic resonator (sound tube) is added to enhance the signal. The laser beam is directed through the tube. The pressure anti-node is at the center at the location of the tuning fork between the two pieces of the tube.

Fig. 17.9 Two schematic configurations of the photothermal beam deflection in which the sample absorbs the radiation of the pump laser and the probe laser (in many cases a He–Ne laser) is deflected by the refractive index gradient induced by the generated heat. (a) Parallel setup and (b) transverse setup.

beam than in the wings (Franko and Tran, 1996). Owing to this temperature gradient across the beam, a lens-like optical element is formed in the material. This thermal lens effect can be observed by a second laser beam or by the initial laser beam itself (single-beam thermal lensing). Single-beam instruments are relatively frequently used because of their simplicity and ease of operation compared to dual-beam instruments (see Figure 17.10). In such an instrument, the laser beam is focused with a lens and modulated by a chopper. After passing through the sample, the beam intensity is usually measured in the far field with a photodiode placed behind a pinhole. The thermal lens signal is linearly dependent on the energy of the pulsed laser or the power of the CW laser. The signal is also strongly dependent on the size of the pump beam; it is therefore necessary to focus the laser beam to obtain higher power densities and thus higher sensitivities. For a two-beam setup, a collinear configuration (two parallel laser beams) is more favorable as compared to a transverse configuration (beams crossing at a 90° angle) because of its higher sensitivity, although the second setup is sometimes preferable because of its small sample volume and independence of the sample length. Sampling volumes as small as a few microliters and absorbances as low as 10^{-7} have been detected and characterized by this technique.

17.2.5
Fourier-Transformed Infrared Photoacoustic Spectroscopy

Infrared lasers have mostly limited wavelength coverage. This restriction is circumvented if Fourier-transform techniques are combined with PA detection. As compared to dispersive techniques using filters or monochromators, Fourier-transformed infrared (FTIR) spectroscopy has the advantages of a relatively high spectral throughput (important since the PA signal is proportional to the light intensity), high spectral resolution, wide spectral range, and speed (Jiang, 2002).

The advantage of combining PA detection with a scanning FTIR derives from the signal being background-free; there is no contribution to the FTIR interferogram from IR frequencies where the sample does not absorb. In FTIR, the modulation frequency ν in Hz depends on the wavelength of the light λ and the velocity of the mirror V in the interferometer: $\nu = 2\,V/\lambda$. A drawback in using PAs is that now the generated PA signal depends on the wavelength of the light: it weakens at shorter wavelengths as the modulation frequency increases. An improvement is introduced by stepwise scanning of the interferometer. The PA signal is generated by an external intensity modulator (e.g., chopper) while the interferometer is scanned stepwise rather than continuously. The advantage of stepscan FTIR is that the strength of the PA signal only depends on the frequency of the external modulator. In addition, now relevant phase information can also be collected. In normal FTIR, short wavelengths will generate high Fourier frequencies and thus shorter penetration depth in solid-state material. Assuming equal thermal properties at both wavelengths, phase information will be different, with stepscan FTIR-PA proper phase information making spectral depth profiling possible for, for example, multilayer polymeric materials with a depth resolution of 1 μm. Initially, the stepscan interferometers were limited to only a few laboratories because they were very sensitive to environmental vibrations and had a poor mirror position control. Nowadays, they are commercially available, and use the computational power for interferometer function control, such as dynamic alignment, step and hold servo control, and modulation–demodulation signal generation.

17.3
Application

In general, PA spectroscopy can be an excellent spectroscopic tool, but more factors than just light absorption play a role. This might seem to complicate interpretation, but this makes it an ideal technique to monitor all kinds of other processes and to determine not only concentrations but also various material properties and local distributions of certain spectroscopically well-characterized compounds. In the following section, a number of typical studies will be shortly described with emphasis on those in which spectroscopic selectivity plays a role.

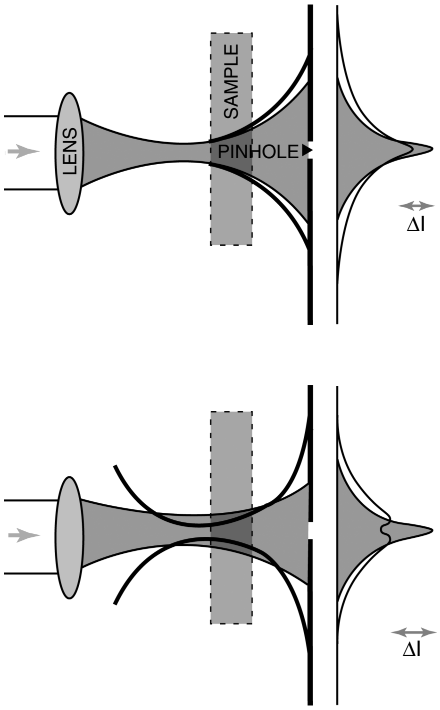

Fig. 17.10 Effect on the laser beam intensity behind a pinhole in a thermal lens effect. The upper panel shows a single-beam thermal lens effect. The lower panel shows a dual beam setup, with the effect of pump beam absorption on the probe beam intensity distribution.

17.3.1
Photoacoustic Spectroscopy in the Condensed Phase

The theory of PA spectroscopy in solids and semisolids was developed in the early seventies by Rosencwaig and Gersho at Bell labs (RG theory) not long after its revival in gaseous samples (Rosencwaig and Gersho, 1976). In those studies, chopped CW light and a gas-coupled microphone were used. In the late 1970s and early 1980s, Patel and Tam (1981) developed PA techniques on liquids and solids using pulsed laser light and a piezoelectric transducer as a contact device. Several aspects play an equally important role in the PA effect in the condensed phase: spectroscopic selectivity, optical, thermal, and acoustic properties of the sample, and the modulation frequency of the light, pulsed light being at the very high frequency end. This gives rise to a multitude of applications focusing on one or the other of these facets.

Despite their simple applicability, still, many of these have not found general use. This may very well be because of the sometimes complex nature of the PA signal in condensed samples. The amplitude and phase of the PA signal depend strongly on the modulation frequency, and both contain important information. There is a depth and absorption dependent phase lag in the signal, and if piezoelectric devices are used, the observed signal is a convolution of the PA signal and response properties of the detector itself.

For CW, light modulation frequencies between 1 and few 100 Hz are used. This can be by amplitude modulation (e.g., using a mechanical chopper), by frequency modulation, or by interferometry. Note that these frequencies are far lower than those applied in (resonance) gas spectroscopy. In

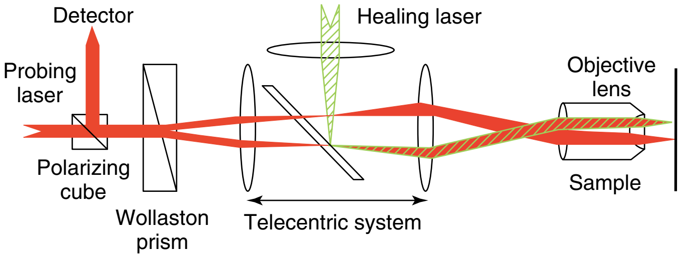

Fig. 17.11 The heating laser beam heats the sample containing the metallic nanoparticles behind the objective lens. The probing laser beam is modulated and split by a Wollaston prism into two probe interferometric arms, which are retro-reflected and again recombined by the Wollaston prism. After demodulation of the interferometer output, the modulated phase-shift induced by the heating can be detected when a nanoparticle is present. (Figure taken from Boyer *et al*., 2002.)

pulsed experiments, the short light pulses (microseconds, nanoseconds) correspond to modulation frequencies several orders of magnitude higher (megahertz, gigahertz) and are comparable to the time domain of absorption and relaxation processes. There, chemists and biologists find important applications, since PA provides a method that is complementary to flash photolysis techniques. All the more, since calorimetric information is also contained in the PA signal, it represents the part of the absorbed light energy that is not used in luminescence or in chemical processes.

The production of a PA signal in a solid (and to some degree also in a liquid) can be characterized by three parameters as follows: sample thickness, optical absorption length (depth), and thermal (heat) diffusion length. The relative values of these determine what kind of information (spectroscopy, depth profile, mechanical) can be obtained from the signal. The theoretical analysis of these cases also shows that there is an optimum coupling gas thickness (Tam, 1983). The thermal diffusion length, usually denoted as μ, depends on the chopping frequency of the incident light: $\mu = (D/\pi\nu)^{1/2}$, with D being the thermal diffusivity of the sample and ν the chopping frequency. It represents the distance traveled by the generated heat wave during one modulation period of the light. For slow modulation, this is longer than that for fast modulation, which shows in the signal phase lag, and the signal originates from deeper inside the sample.

17.3.1.1 **Solid-State Spectroscopy**

Although in gases the PA signal is inherently stronger, application of the technique to solids has important advantages over regular solid-state spectroscopy. Since only absorbed light contributes to the PA signal, spectroscopy on scattering and opaque samples is very well possible. Numerous spectroscopic studies on powders, gels, crystals, multilayer solids, nanomaterials, and surfaces have been done. Applications range from determining spectra of organic/inorganic compounds or complexes, soil samples, powders, surfaces, or thin-layer compositions (e.g., paint layers), catalysis research, nanomaterials, to monitoring living biological tissue. PA cells can be designed for each application but they are commercially available as well. Some commercial FTIR instruments have a PA cell as a standard option. In principle, a black reference material is necessary to correct for the change in spectral intensity over the wavelength range of a scan. Black rubber or carbon is normally used.

As an example, an important application is the spectroscopy of silica and semiconductor ceramics, whether in powdered form or as a crystal or a mixture of both. The band gap within the material is usually observed as an increase of the PA signal together with a change (up to 30°) in the PA phase angle at the band edge. In powdered samples several other bands may be observed, depending on the particle size and caused by quantum effects in small particles. Spectroscopy on powdered or porous samples requires some modifications in the RG theory, becaue of the presence of interstitial gas. There is some debate on the exact role that is played by this.

There is good agreement between spectra obtained with a gas-coupled microphone and with a piezoelectric transducer, but, since the detection with a transducer is directly connected to the sample, and usually at the backside, (thermo-)acoustic properties of the material can be more prominently present in the signal.

17.3.1.2 **Depth Profiling**

Many studies combine PA spectroscopy with depth profiling. As shown above, $\mu = (D/\pi\nu)^{1/2}$ is the depth from which the detected PA signal originates, as determined by the chopping frequency ν and the thermal diffusivity D in m^2 s^{-1} of the sample. A plot of the PA signal or phase versus the chopping frequency can be read as a scan through the layers of material. With thermal diffusivities in the range of $10^{-5}-10^{-9}$ m^2 s^{-1}, penetration depths can be obtained varying from a few micrometers (kHz modulation) to a few hundred micrometers (~2 Hz). It is important to realize that the depth accessible with this technique depends heavily on the absorption and thermal properties of the sample.

An objective can be to study the thermal/mechanical properties of a sample, looking at defects, or to find a distribution of (different) compounds at different depths in the sample. Likewise, the oxidation/etching depths of materials have been followed in many studies. Other examples include multilayer studies, thickness analysis, and material defects. A nonspectroscopic method is to monitor material defects by detecting the acoustic waves traveling through the material originating from surface heating by a modulated light beam.

Recent examples of this are studies in which the penetration of cosmetics or drugs into the skin (or model layers) is monitored. Using modulation frequencies between 13 and 122, or 418 Hz, the diffusion of compounds into depths between 8 and 26 μm was followed over a time course of several hours. Diffusion coefficients could be calculated from these data for different parts of the penetration layer (Hanh *et al.*, 2001).

17.3.1.3 **Thermal Diffusivity**

As a related subject, the thermal diffusivity: $D = \kappa/\rho C_p$ in m^2 s^{-1} with κ in W m^{-1} K^{-1}, the thermal conductivity, C_p in J kg^{-1} K^{-1}, the heat capacity, and ρ in kg m^{-3}, the density of the material, can be determined from the same relationship between the chopping frequency and the PA signal, using differential equations for heat flow and applying the RG theory.

For the study of thermal properties such as thermal diffusivity in solid samples, the OPC is a popular device. The sample is mounted directly on top of the (gas-coupled) microphone and is illuminated from the other side, resulting in a heat transmission configuration. Advantages of this OPC are the minimal gas volume (as small as 9 mm^3) between sample and microphone, and little sample preparation. Of course, the sample has to close off the PA cell gastight. The thermal diffusivity can be determined from the relation between the modulation frequency and the PA signal or the signal phase. A double-log plot or a plot of the PA signal versus the square root of the frequency can be used to derive the diffusivity. The technique usually does not rely on spectroscopic selectivity.

Similar schemes are possible in liquid samples as well, but then a PA cell is used in a transmission mode. Detection takes place using a piezoelectric transducer. The group of Mandelis has presented various treatises on these techniques, proposing improved modulation and referencing methods (Balderas-López and Mandelis, 2001).

Thermal diffusivities are important parameters in the thermal characterization of materials (dental resins, epoxy resins, wood, metals, alloys) and fluids (heat exchange), and the technique has been applied to this wide range of subjects.

17.3.1.4 **Phase Transitions**

Thermal (and acoustic) material properties, such as conductivity, heat capacity, and thus also diffusivity, change abruptly at phase transitions. This implies that it should be simple to determine the exact phase-transition temperatures from changes in the amplitude and phase of the PA signal. This has been used to study solid–liquid and solid–solid phase transitions in solid and liquid crystals. The transition range can vary from several degrees Kelvin to a few tens of milliKelvin.

More often, however, a pyroelectric detector is used as it proves to be more sensitive in this application than a PA sensor. The photo-pyroelectric effect detects the periodic temperature variation in a sample that is illuminated with modulated light, rather than the acoustic signal. In general, the study of phase transitions is mostly used for liquid crystals, but also for the determination of the properties of natural oils and waxes.

17.3.1.5 **Traces in Solution**

Just as in trace gas detection, traces of solutes can be detected photoacoustically with great sensitivity and by a variety of related techniques. And just as in PA spectroscopy on solids, detection in opaque samples is possible. The most straightforward way is to detect photothermal changes directly by a piezo transducer immersed in the solvent or acoustically coupled to the cell wall, or using a gas-coupled microphone. The latter option has the obvious disadvantage of acoustic mismatch between liquid and coupling gas. Another possibility is to use thermal lensing. This technique has been used to follow chemical reactions in solution in real time, and, for example, the disappearance of reactants or the formation of products can be monitored. It was proposed to use PA detection methods as detectors in high performance liquid chromatography (HPLC) systems, which has definite advantages, owing to their high sensitivity.

The sensitivity for weak absorption in liquids was compared for pulsed and CW laser excitation (Faubel *et al.*, 1994). In both cases, a piezoelectric detector has been employed. For pulsed dye lasers, the limiting sensitivity is estimated to be 1×10^{-7} cm^{-1} (the minimum detectable absorption). The corresponding value found for a CW dye laser of 55 mW, chopped at about 80 kHz, was $1 \times 10^{-5}\,\text{cm}^{-1}$ (Manzanares *et al.*, 1995). Note that applying PA to liquids has the distinct advantage of enhanced density of the investigated species, either traces in solution or pure liquids versus their vapors.

17.3.1.6 **Chemical Reactions**

Calorimetry If during light absorption processes the absorbed light energy is ‘‘used,’’ ‘‘stored,’’ or ‘‘lost,’’ PA techniques can be very helpful in resolving timescales and energy balances of processes. One excellent example is time-resolved PA calorimetry; it has developed a distinct use in (bio)-chemical research since the early 1980s. When light is absorbed in the UV–VIS range other de-excitation channels become more important, depending on the chemical structure of the compound under study and of its surroundings (solvent/reactants). Chemical reactions, luminescence, or intersystem crossing to a long-living (e.g., triplet) state take away energy from the direct thermal de-excitation that produces the PA signal. A simple calculation involving excitation energy and PA intensity then gives the amount of energy ‘‘stored’’ in products or ‘‘lost’’ in luminescence:

$$E_\text{a} = \varphi_\text{f} E_\text{f} + \alpha E_\text{a} + \varphi_{st} E_\text{st} \tag{17.7}$$

where E_a is the absorbed light energy ($h\nu$), ϕ_f and E_f are the quantum yield and energy of fluorescence, respectively, α is the fraction of absorbed energy immediately released as heat, and ϕ_st and E_st are the quantum yield and energy involved in energy-storing processes (reaction, intersystem crossing, all on a molar basis). By comparing the PA signals (over a range of concentrations) of the process under study with those of a standard that returns all absorbed light energy immediately as heat, calorimetric information is obtained. Over the years, knowledge on energy balance and PA response has become more detailed and it is now fairly well understood how reaction enthalpies, reaction volumes, and the timescales of processes are incorporated into the PA signal. It was also shown on many occasions that changes in chemical volume, solvent interactions, and enthalpy contributions of phenomena such as hydrogen bonding need to be taken into account (Laarhoven, Mulder, and Wayner, 1999).

Volume Effect The acoustical signal is not generated only by thermal expansion due to heating. Many chemical reactions are accompanied by changes in volume between reactants and products (reaction stoichiometry), or between ground state and transition state (e.g., protein folding). One of the reactants or products may be gaseous (photosynthesis), which produces a significant volume (decrease) increase. Also, differences in solvation between reactants and products can produce a volume effect (and also affect the reaction enthalpy) that can become incorporated in the observed PA signals.

Time Resolution Since most chemical reactions take place in the submicrosecond time domain, usually pulsed techniques are used in combination with piezoelectric transducers such as PZT (lead titanate zirconate crystal) or PVDF/polyvinyl difluoride (PVF_2). The first has a relatively slow time response and the signal obtained is a convolution of the PA response and the response/ringing of the piezo element. Deconvolution methods and a reference compound must be used to obtain time constants of the processes involved. The

PVDF film has a faster time response, and the PA trace obtained from this device is in the nanosecond–microsecond domain. If reaction rates are faster than the time response of the transducer, all energy used/produced in the reaction is integrated in the PA signal. If reactions are slower (factor sometimes used: 5τ, where τ is the instrument response time), the energy is stored. In the intermediate time domain, deconvolution methods must resolve reaction rates.

Because enthalpy, volume change, and time resolution are contained in one signal, a wealth of information can be obtained using PA techniques, but disentangling the signal can be cumbersome and requires an insight into the processes under study.

As a more recent development, the thermal grating method was proposed as a means to disentangle thermal and volume effects more easily (Terazima, Hara, and Hirota, 1995; Nishioku *et al.*, 2002). In this method, the interference of two light waves causes a transient grating in the solution. Photoexcitation of the sample by this light creates a (sinusoidal) modulation in the refractive index that contains contributions from the released reaction heat, the reaction volume change, and the change in absorption spectrum. The grating is probed by a second laser, similar to the thermal lensing system.

17.3.1.7 **Biological Processes in Solution**

Along the same line as the chemical investigations, important research on biologically relevant molecules and *in vivo* processes is in progress (Herbert, Han, and Vogelmann, 2000). For instance, inhibition of photosynthesis systems I and II has been studied photothermally in leaves and in cyanobacteria. Inhibited photosynthesis leads to an increase in heat produced under illumination. Various schemes to attach a PA cell to a leaf have been designed. The main complication is to assure gas exchange to keep the leaf functioning, while closing the cell tight enough to obtain a valid PA signal. The signal from an *in vivo* experiment has to be disentangled both for time resolution and for gas evolution (photobaric signal).

A great deal of research has been done on *in vitro* photosystems. Time resolution and volume changes associated with the different steps in the primary photochemistry of various rhodopsins have been studied by various laser-induced PA spectroscopy experiments (Losi *et al.*, 1999). Photothermal deflection measurements on bacteriorhodopsin have been shown useful to investigate conformational changes in photorefractive compounds (Schulenberg, Gaertner, and Braslavsky, 1994).

Laser-induced PA spectroscopy in biological tissue has developed itself toward three-dimensional tomography, to such an advanced state that animal brain structures can noninvasively be imaged, *in vivo* with skin and skull intact (Wang *et al.*, 2003). The imaging modality combines the advantages of optical contrast and ultrasonic resolution. The intrinsic optical contrast could not only reveal blood vessels but also other detailed brain structures.

Photothermal interference combined with high-frequency modulation and polarization interference provides an efficient, reproducible, and promising contrast method to visualize low amounts of proteins in cells (Boyer *et al.*, 2002). Membrane proteins in cells labeled with 10-nm gold nanoparticles could be visualized (Figure 17.11). The high sensitivity of the method and the stability of the signals allow 3D imaging of individual nanoparticles without the drawbacks of photobleaching and blinking of fluorescent dyes normally used for optically marking molecules. Furthermore, the photothermal image is immune to the effects of scattering background, which limits particle imaging through Rayleigh scattering to diameters larger than 40 nm.

17.3.2
Photoacoustic Spectroscopy in the Gas Phase

The full potential of molecular selectivity of the PA method becomes apparent when it is applied to the gas phase. It is not a high-resolution method (being limited by Doppler and/or pressure broadening); its successful application derives from high sensitivity, easy handling, and fast response.

17.3.2.1 **Overtone Studies**

Intracavity laser PA spectroscopy is one of the most sensitive techniques for studying (highly forbidden) vibrational overtone transitions. First used by Stella, Gelfand, and Smith (1976), this type of spectroscopy, utilizing tunable dye lasers or titanium–sapphire lasers, can determine weak overtone absorptions up to frequencies in the visible region because of its inherent high sensitivity. Overtone excitation deals with vibrational transitions. Since fluorescence lifetime of these energy levels in the infrared is much longer, as compared to collision-induced rotational–vibrational relaxation lifetimes, the sensitive LIF detection is not applicable. Information about highly excited vibrational levels is most useful to study molecular structure, anharmonicity constants, and (non-)localized bonds. Without these types of measurements, the local mode model for R–H bonds would be poorly developed. Typical spectra are obtained with Doppler-limited linewidths (<100 mbar) and at room temperature; the latter to ensure sufficient vapor pressure of larger organic molecules. A typical example is the high-resolution study of the 4 ν_1 band of monofluoracetylene with the Ar^+-pumped titanium–sapphire ring laser (laser bandwidth 20 MHz) (Vaittinen *et al.*, 1993). Within the tunability of this laser (9090–17 800 cm^{-1}), Doppler-limited rotational lines of 58 overtone bands in the wavelength region of 10 750–14 500 cm^{-1} have been observed with a very good signal-to-noise ratio. In this way, a study of Fermi resonance interactions at high overtone excitations has been performed. A resonant PA cell was used, excited in its first longitudinal mode (resonator length 180 mm, cross section 2.1 mm × 5.3 mm, overall length 200 mm) (Lehmann, Scherer, and Klemperer, 1982).

The group of Demtröder (Hornberger *et al.*, 1995) has utilized a 500-mW single-mode F–Center laser (6300–6400 cm^{-1}) and a radially excited resonant PA multipass cell (50 passes) to detect weak combination bands of acetylene. In spite of the relatively modest laser power, a minimum detectable absorption of $\alpha_{\min} = 10^{-9}\ \mathrm{cm}^{-1}$ has been achieved (Figure 17.12). Often, multiple passing is considered to be a nuisance with PA detection because each mirror reflection produces a mirror signal (analogous to the window signal discussed earlier). Here, however, a radial acoustic mode has been excited, to which the mirror signal barely contributes.

17.3.2.2 **Relaxation**

There have been many proposals and attempts to study gaseous relaxation processes by PAs. Phase and amplitude of the PA signal change in a characteristic way when the modulation frequency ν and the relaxation time τ obey $2\pi\nu\tau = 1$. However, before the group of Hess really started

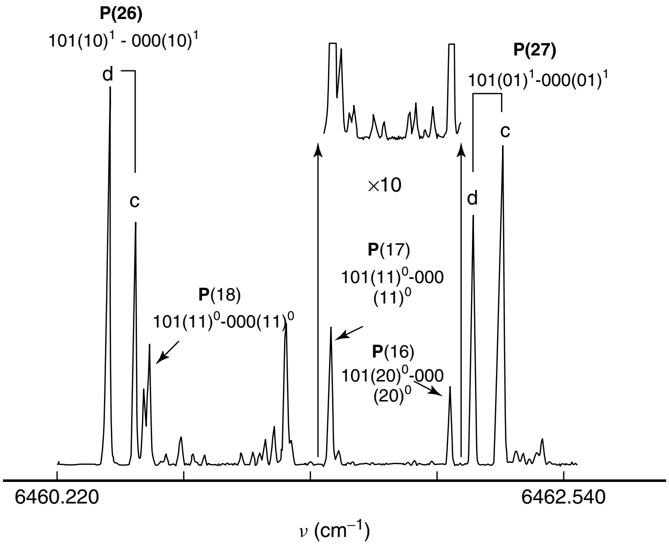

Fig. 17.12 Photoacoustic spectrum of C_2H_2 around 6461 cm^{-1}, the acetylene pressure is 16 mbar. The peaks belong to weak hotband transitions, that is, starting from vibrationally already excited levels with small populations at room temperature. The sensitivity of photoacoustic spectroscopy is illustrated by the inset, which has a 10-fold amplification (Hornberger *et al.*, 1995). (Reproduced with permission from Hornberger, C., Konig, M., Rai, S.B., and Demtroder, W. (1995) *Chem. Phys.*, **190**, 171–177).

an accurate analysis of laser excitation of acoustic modes in cylindrical and spherical high Q-resonators, the results suffered from ambiguities and systematic uncertainties (Karbach, Röper, and Hess, 1983). Essential in the treatment of Hess and coworkers was the theoretical and experimental study of the shift of the resonance frequency and the width of the acoustic resonance curve for various sample pressures. Consistent rate constants have been derived for several reactions, for example, $N_2O_4 \rightarrow 2NO_2$. Similarly, vibrational and rotational energy transfer has been studied for CH_4 excited to the (1,0,0) vibrational state at about 3000 cm^{-1}. At room temperature, rotational relaxation (equilibration) of 1.18 ns bar has been found to be very different from the value for vibrational relaxation (1.74 μs bar).

Vibrational relaxation occurring in the PA cell also has unintentional, practical consequences for other applications. Perhaps the most spectacular is the so-called kinetic cooling effect. PAs relies on (fast) relaxation into thermal heat. If the relaxation is too slow compared to the modulation frequency, the absorbed energy is not represented in the PA energy, that is, the energy is lost (the gas is kinetically cooled). The results are a lower signal and a phase shift. Well known for this is CO_2 in air; traces of CO_2 are excited by the CO_2 laser radiation (e.g., $(02^00) \rightarrow (001)$). Quasi-resonant, slightly endoergic vibrational energy transfer occurs to N_2 molecules: CO_2 (001) $\rightarrow$ N_2 ($v = 1$). Some translational energy from the CO_2 molecules is thus transferred and stalled as internal vibrational energy of the N_2 molecules and, temporarily, cooling occurs. Collisional relaxation of the excited N_2 ($v = 1$) molecules is too slow for PA

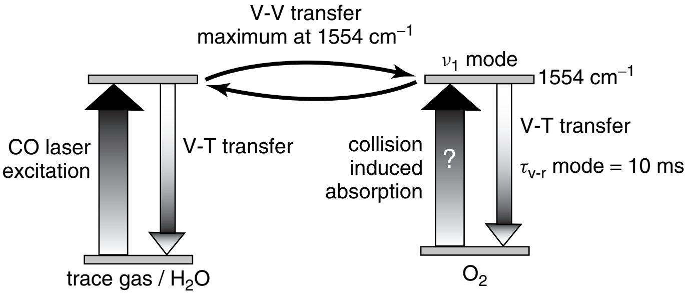

Fig. 17.13 Schematic overview of the excitation and energy transfer process in ethanol in the presence of O_2. Oxygen molecules can become vibrationally excited via vibrational energy transfer from a vibrationally excited trace gas, or directly via collision-induced absorption. Vibrational–translational transfer of H_2O and most trace gases takes place at a nanosecond timescale, while for O_2 this process takes about 10 ms.

measurements at high modulation frequencies and will therefore not contribute to the PA signal. A phase shift of the signal, however, can be observed at typical circumstances as a consequence of the temporary cooling. Addition of H_2O or SF_6 molecules (notorious relaxers) can reverse the situation.

An example is shown in Figure 17.13. Collisional relaxation allows observation of collision-induced absorption phenomena within oxygen. Oxygen molecules, whose ν_1 vibrational mode is centered at 1554 cm^{-1}, can be vibrationally excited via collisional energy transfer. Through collision-induced absorption, that is, a collision between oxygen and a trace molecule or a collision between two oxygen molecules, a dipole moment is induced, which creates an infrared absorption band. Because the induced dipole only exists for times that are on the order of the collision rate, the spectra exhibit a large bandwidth. The induced absorption strength of oxygen is relatively low but still significant due to the high abundance of O_2. The number of collisions required for a vibrationally excited O_2 molecule to relax to the ground state is 8.3×10^7 in pure O_2, while at standard temperature and pressure, 8×10^9 collisions per second take place (Lambert, 1977). Thus, relaxation of vibrationally excited O_2 to the ground state takes about 10 ms, which is long compared to a modulation period of 0.9 ms.

Figure 17.14 presents phase measurements in a mixture of water vapor and ethanol diluted in air and nitrogen. In addition, it shows the collision-induced absorption strength as taken from Thibault and coworkers (Thibault *et al.*, 1997). The observed phase has a pattern similar to the collision-induced absorption strength, however, with a long tail at higher frequencies. If collision-induced absorption would be the main mechanism, such a tail is not expected. Molecules excited at frequencies above 1554 cm^{-1} probably lose some of their energy via rotational–translational energy transfer because in polyatomic molecules the rotational–translational energy transfer is very rapid. As a result, they are closer in resonance to O_2 and vibrational energy transfer is likely to occur. A molecule excited at a frequency below 1554 cm^{-1} can lose some of its energy making vibrational energy transfer to O_2 less probable and hence no tail is expected.

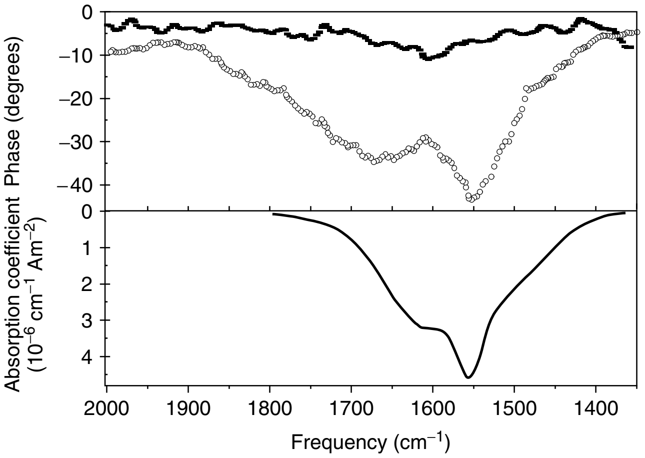

Fig. 17.14 The upper panel presents the phase angle for water vapor and ethanol, both at ppmv level recorded in air (○) or nitrogen (■). In nitrogen, the remaining structure in the phase angle is partly due to out-of-phase contributions of the background signal. The lower panel presents the O_2-air normalized absorption coefficients for collision-induced absorption as taken from Thibault *et al.* (1997)). The main mechanism responsible for the observed phase lag is vibrational energy transfer from excited water/trace gas molecules to the slowly relaxing O_2 molecules.

17.3.3
Trace Gas Detection

PA spectroscopy shows its full flavor in trace gas detection for three main reasons. Firstly, the spectral selectivity becomes exploited; many gases have a clear spectrum of identifiable absorptions in the infrared. Secondly, PA and related techniques are fast and thirdly, they are sensitive. Trace gas detection techniques are important in view of environmental applications, but also for their possibilities in basic science (biology, agriculture, human health) (Cristescu *et al.*, 2008). With their help, it is possible to discover and control mechanisms in plant physiology such as: germination, blossoming, water household, stress reaction, respiration, fermentation, senescence, ripening, injury, and so on. In the following sections, examples of these important applications will be discussed. In the context of human health, an example of analyses of exhaled air and its interpretation toward the physiological status of the human body is given. For PA trace gas detection, a few, usually less sensitive, instruments are commercially available.

Fast and sensitive trace gas detection is not exclusively reserved for PAs. In Table 17.2, various spectroscopic methods are compared, all utilizing modern laser equipment. The first one, direct absorption (DA) spectroscopy, relies on long effective absorption path lengths, since in general the minimum observable laser power difference $\Delta P/P$ is in the order of 10^{-4}. This, combined with Beers' law: $P = P_0 e^{-\alpha l}$, in which P_0 is the incident laser power, P the transmitted laser power after distance l in centimeters through the sample, and α in cm^{-1} the absorption strength at that frequency, shows that sensitivity increases with increasing path length. Even better detection limits can be obtained by combining the multipass cell with a modulation technique, such as wavelength

Tab. 17.2 Feature comparison of the different spectroscopic detection schemes.

	DA	WMS	CRDS	PAS	QEPAS
Calibration required	Yes	No	Yes	No	No
Detection time constant	ms	ms	ms	s	s
Low pressure response (∼10 mbar)	Good	Good	Good	Some loss	Good
Alignment, complexity	Average, multipass alignment	Average, multipass alignment	Difficult. Mode-matching	Easy	Average, tuning fork alignment
Spectral coverage, limiting factor	Wide, photodetector	Wide, photodetector	Limited, mirror coatings	Very wide, windows	Very wide, windows
Cell volume	300 ml	300 ml	500 ml	30 ml	1 μl
Ability to detect broad absorption features	Yes	No, only species till HWHM modulation amplitude	Yes	Yes	No, only species till HWHM modulation amplitude

[a] DA: Direct Absorption, WMS: Wavelength Modulation Spectroscopy, CRDS: Cavity Ring-Down Spectroscopy, PAS: Photoacoustic Spectroscopy, QEPAS: Quartz-Enhanced Photoacoustic Spectroscopy, Half-Width Half Maximum (HWHM) of the absorption profile.

modulation spectroscopy (WMS) (Bomse, Stanton, and Silver, 1992). Originally, WMS was designed for microwave spectroscopy where it is a standard method. However, now it is also commonly used in laser spectroscopy for fast and ultrasensitive trace gas detection applications. The cavity ring down (CRD) method combines accurate decay time measurements of light pulses in an optical cavity filled with weakly absorbing gas ($\Delta\tau/\tau = 10^{-4}$ is observable) with extremely long effective absorption lengths (Berden, Peeters, and Meijer, 2000). The last method, mainly advocated in this contribution, rests upon very sensitive detection of acoustical signals generated by infrared laser absorption in an intracavity-placed resonant PA cell and with quartz enhanced photoacoustic spectroscopy (QEPAS). Each of these spectroscopic detection methods can offer the sub-ppbv (1 ppbv = 1 part per billion volume = 1: 10^9, 1 pptv = part per trillion volume = 1 : 10^{12}) sensitivities required for trace gas detection (Kosterev and Tittel, 2002). However, they also have their own advantages and disadvantages, which should be considered carefully for each specific application. When the experiment, for example, requires determining absolute absorption values, cavity ring-down spectroscopy or DA with multipass enhancement is preferred. These two methods and WMS would also be good choices if highly dynamic processes are studied, since they require a short measurement time per point. However, the required gas volume of these methods is quite large (∼liter) which can be an obstruction for small gas samples. In that case it will be better to use normal PA- or quartz-enhanced PA spectroscopy, which have volumes of

30 ml and 1 μl, respectively. The PA detection schemes also have the advantage of having a very broad spectral usefulness, covering a wide wavelength range.

17.3.3.1 **Environmental Applications**

At low absorption signal levels uncertainties in the measurements are determined by the microphone noise and/or background signal fluctuations. For stronger absorption signals, uncertainties can be either limited by the used calibration mixture, presence of spectral interfering compounds, or uncertainties in the used absorption coefficients. Under good controlled conditions a 1% uncertainty has been achieved (Morgando, 2008).

Measurement of practical samples can pose a real challenge as besides the compound(s) of interest other absorbing gases are present in often much higher levels. For instance, exhaled human breath contains typically 4–5% of both water vapor and carbon dioxide, both of which absorb in large part of the infrared spectrum. When no special precautions are taken, the measurement uncertainties will be considerably higher than for the ideal case of measurement in pure nitrogen or clean air. In most of our measurements, we lower the level of compounds showing spectral interference by using a cold trap and/or chemical scrubbers such as $CaCl_2$ for H_2O removal or KOH for CO_2 removal. Consequently, uncertainties in the measurements are only slightly higher as compared to the ideal case. For molecules like ammonia or nitric oxide these tricks cannot be played since they readily adsorb to most scrubber materials. As these molecules have a permanent electric (ammonia) or magnetic dipole (nitric oxide) moment they can be selectively detected with Stark or Zeeman modulation PA spectroscopy.

Early attempts have been made to measure stack gas emissions from power plants with laser PAs. Owing to their high amounts in the emissions, nitrogen oxide (NO and NO_2) compounds contribute significantly to photochemical smog formation and acidification of the soil. To reduce the total amount of NO_x in the stack gas, NH_3 is added in the exhaust gas toward the chimney. Using a voluminous catalyst, NO_x reduction (within the stack gas) takes place. To check the performance and to avoid an excess of ammonia injection, the ammonia concentration in the chimney is monitored. For this, a CO_2 laser-based PA detection system was successfully applied for *in situ* monitoring of ammonia concentrations (Olafsson *et al.*, 1989). Owing to the difficult, hostile environment halfway up the chimney (vibrations, temperature fluctuations, etc.), concessions have to be made as to the sensitivity of the apparatus. With a nonresonant PA cell at 125 °C a detection limit of 1 ppmv NH_3 was achieved in a multicomponent gas mixture containing 10–15% CO_2.

Another example of a mobile system was developed and used in a field campaign by Sigrist and coworkers (Moeckli, Fierz, and Sigrist, 1996). Installed in a small trailer, the stress on the equipment is less severe. Thanks to this approach, the system has been operational for years and has been applied for several field campaigns in urban and rural environments. It can operate, for example, over a consecutive five-day period continuously to analyze multicomponent gas mixtures during sunny days in the summer, using 12 laser lines; three of them representative for ammonia absorption, three for water vapor, two for ethene, and the others for CO_2, benzene, and toluene. The spectrum of these 12 selected lines could be measured within about 10 minutes, thereby determining the time resolution of the derived pollutant concentrations (Moeckli, Fierz, and Sigrist, 1996). In literature, extremely low detection limits are mentioned on the basis of a signal-to-noise ratio of one, extrapolated from larger quantities of trace gases in a clean buffer gas. In reality, the detection limits are higher due to multicomponent gas mixtures, which induce cross sensitivities in the absorption coefficients. A mathematical analysis of the PA spectra of multicomponent mixtures is based on the weighted least squares fit of the measured spectra with additional iteration steps. By choosing the best set of laser lines with known absorption constants of all the relevant gases, the error in the calculated concentrations can be reduced.

A disadvantage of lab-based systems is that they are still rather bulky. Nowadays, complete PA systems are integrated into durable, man portable, computer size boxes, completely protected from dust, precipitation, and damage, making them applicable in field measurements. Two examples are given, one for measuring ambient ammonia concentration in the lower ppbv (1 ppbv = 1 part per billion volume = $1 : 10^9$) concentration range (Huszar *et al.*, 2008). Within the environment, ammonia is the third most abundant nitrogen compound in the atmosphere and plays an important role in cloud and rainwater chemistry. Typical ammonia sources include livestock, fertilizers, soils, forest fires, humans, animals, oceans, industry, and traffic. The main emission source is the use of animal manure and fertilizers for agricultural soils (responsible for more than 80% of the total ammonia emission). The PA instrument is based on a wavelength-modulated, near-infrared, room temperature-operated diode laser, and a PA cell in its longitudinal resonance mode, with compact electronics for fully automated, long-term operation. The PA cell was made of polyvinylidene fluoride to reduce ammonia adsorption effects. Cross sensitivities (from atmospheric water vapor) were suppressed by using a multiwavelength approach. The system featured highly reliable, automatic operation achieving a detection limit of 50 ppbv for ammonia.

Another laser-based PA instrument was developed and used for aircraft measurements of ethene from industrial sources near Houston. This instrument provided 20-second measurements with a detection limit of ~0.7 ppbv (de Gouw *et al.*, 2009). Data collected from this instrument in flight were compared with gas chromatographic measurements and they agreed within 15% on average. Ethene fluxes from a chemical complex near Houston could be quantified during 10 different flights. The average measured fluxes were an order of magnitude higher than the values regulatory emission inventories indicate.

17.3.3.2 **Plant Physiology**

It is a fortunate coincidence that the ubiquitously active plant hormone ethylene, C_2H_4, is especially easy to detect with CO_2 laser-based PAs. Ethylene is the only known gaseous plant hormone; it is involved in virtually all aspects of the plant life starting from seed germination through growth and flowering, until fruit ripening and plant senescence. The biosynthesis in plants is well understood, leading from the amino acid methionine over two intermediates, S-adenosyl-methionine and amino-cyclo-propane-carboxylic acid, to C_2H_4. Ethylene is produced by the plant tissue as a response to many external factors such as wounding, pathogen attack, light/temperature stress, chilling, drought, and so on. Modern gas chromatographic systems can be used in many instances but still lack the time resolution and extreme sensitivity of PA spectroscopy. With a detection limit of 10 pptv and a short time constant of about 10 seconds, PA detection is ideally suited to obtaining an insight into C_2H_4-triggered plant physiological properties. Examples of recent investigations are listed in Table 17.3 (Ramina *et al.*, 2007).

Numerous studies of the cellular and molecular biology of plants use *Arabidopsis thaliana* as model system. This is an organism about which much is already known, that is, easily manipulated, genetically tractable and offers the ability of fast and efficient testing of hypotheses. By using Arabidopsis as a reference system, we gain knowledge to move forward with molecular biological and genetic analyses on many physiological processes involving ethylene. With PA system dynamics of many processes in plants become easily visible. For example, ethylene released by Arabidopsis displays a circadian rhythm (high emission during the light and low emission during dark) with a peak in the mid-subjective day. When the plants were grown for six days in a succession of light (16 hours) and dark (8 hours) and afterwards were kept in continuous light for several days, they showed an ethylene pattern as would follow the light–dark periods (Figure 17.15).

17.3.3.3 **Oxidative Stress**

In humans, animals, and plants, many diseases are caused by the imbalance between the formation of oxygen radicals and other reactive oxygen species (ROS), which might ultimately result in cell injury. This is a condition of oxidative stress. These reactive molecules can start a chain of reactions known as lipid peroxidation, which leads to degradation of the outer and inner membranes of cells (Halliwell and Gutterridge, 1989).

Ethane (C_2H_6) is a product of lipid peroxidation as a result of oxidative stress and can serve as a marker for membrane degradation. Ethane is detected very sensitively using a laser operating around 3 μm, such as in the OPO-based system. As a practical example, one has investigated the damage of the chilled cucumber leaves under light and dark conditions by monitoring the ethane emission. Under light, the damage of leaf tissues was associated with the presence of free radicals. Additionally, low temperatures slow down the electron transport chains, and inhibit alternative energy dissipation paths. Both factors enhance the formation of free radicals at low temperatures. Furthermore, low temperatures also decrease the activity of antioxidants. In consequence, light-chilling leaves show elevated ethane levels in correlation with a damage leaf area (yellow coloring) of 15–30% of the total area after one-day chilling and up to 65% in a two-day treatment. The dark-chilling leaves did not produce measurable ethane and present no damage.

Plant recognition of pathogen infection leads to the so-called hypersensitive response (HR) indicated by a fast, localized cell death at the site of infection. Upon pathogen invasion an oxidative burst can be observed in plant; however, ROS alone cannot stop the pathogen invasion. A synergistic mechanism has been proposed between ROS and NO during HR in plants. Within the HR, the plant initiates a suicidal strategy, signaled by the production of NO that helps to kill the infected cells and activate the defense mechanism to isolate the infection (Figure 17.16). Using laser-based detection, the first in planta and direct measurements of NO emission from plants as response to *Pseudomonas syringae* challenge has been obtained (Mur *et al.*, 2005).

Tab. 17.3 Recent biological photoacoustic investigations monitoring ethylene emission (Ramina *et al*., 2007).

Studied process	Subject	Remarks
Germination	Pea, bean, rice seeds	Ethylene accompanies starting of germination, growth of shoots and roots
Root development	Arabidopsis seedlings	Ethylene emission during the root development
Flowering	Orchids, Carnations, tulips, Alstromeria, tobacco, transgenic tomatoes	Dynamics of ethylene emission during flower development and wilting
Pollination	Tobacco flower	Ethylene response to pollen tube growth in tobacco flower
Ripening	Fruit	Ethylene and CO_2 emission rates during ripening and post harvest of fruits
Cell death	Algae, tomato cells	Ethylene production during inducing cell death
Circadian rhythms	Arabidopsis plants	Circadian rhythms of ethylene emission in Arabidopsis
Wounding	Tomatoes, endive, cut fresh herbs	Wound-induced ethylene emission in tomatoes, endive, and cut fresh herbs
Water stress	Rumex plants	Ethylene production in relation with shoot elongation during submergence
Drought stress	Wheat, sun flowers	Ethylene rate in sensitive vs. tolerant wheat species and in sunflowers grown under potassium starvation and subjected to drought
Heavy metal stress	Aquatic plants	Ethylene from aquatic plants under heavy metals stress
Plant–insect interaction	Pine-sawfly *Diprion pini*	Plant responses induced by insect egg deposition
Plant–pathogen interaction	Tomato, Arabidopsis – *B. cinerea;* barley-powdery mildew; apples-bacteria	Ethylene production by *B. cinerea in vitro* and in tomato fruit; ethylene response from Powdery mildew infected barley plants; apples infected with *Erwinia amylovora*
Nitrogenase activity	Cyanobacteria	By adding acetylene, ethylene is produced functioning as a sensitive and fast indicator for nitrogen fixation
Hormone interaction	Mutated Arabidopsis plants, transgenic tomato	Cross talk between ethylene, abscisic acid, and auxin in mutated Arabidopsis and transgenic tomatoes

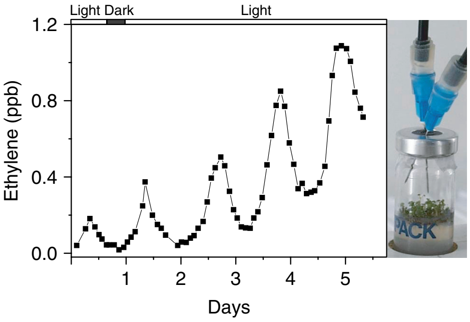

Fig. 17.15 Influence of day length on ethylene production in Arabidopsis. Seedlings were grown for six days in 16 hours light and 8 hours dark and then tested for ethylene emission during one light–dark cycle followed by constant light. Ethylene released by Arabidopsis displays a circadian rhythm with a peak in the mid-subjective day.

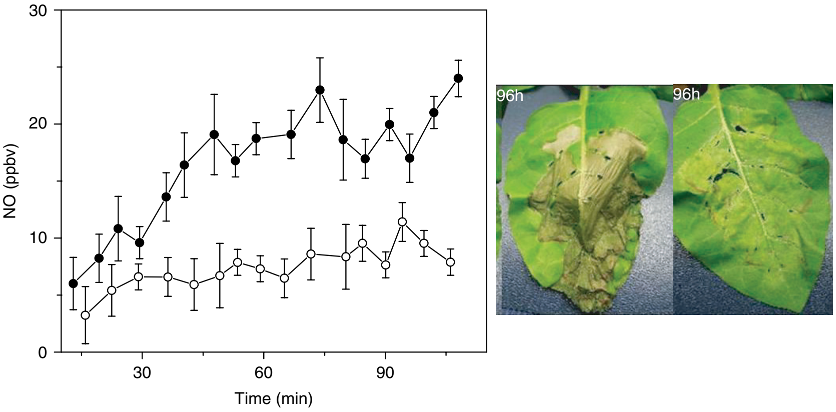

Fig. 17.16 NO formation after infection in tobacco leaves by virulent *P.Syringe pv. tabaci* (dark circles) and avirulent *P.Syringe pv. phaseolicola* (open circles). A suicidal strategy is applied by plant during the avirulent bacteria infection; plant localized fast the lesion due to the HR mechanism (a) compared to the one that did not recognize the bacteria and develops a typical disease response (b).

The quality of agricultural products at the time they arrive at the consumers strongly depends on the developmental stage at harvest, shipping, and storage conditions. Therefore it is commercially advantageous that fruits and vegetables have a long shelf life and do not deteriorate immediately after harvest. Fungal pathogens are known to be responsible for many post-harvest deteriorative processes. Enhanced production of the plant hormone ethylene is one of the earliest responses of plants to the perception of a pathogen.

Using a CO_2 laser-based PA detector the ethylene production by fungi was studied under *in vitro* conditions and then correlated with the ethylene emission from the infected host.

Infection of tomato fruits with *Botrytis cinerea*, a worldwide abundant fungus that attacks more than 200 plant species, resulted in enhanced ethylene release which started to rise before visible decay development (Figure 17.17). This demonstrates that ethylene can be considered a sensitive marker for early infection in harvested fresh products.

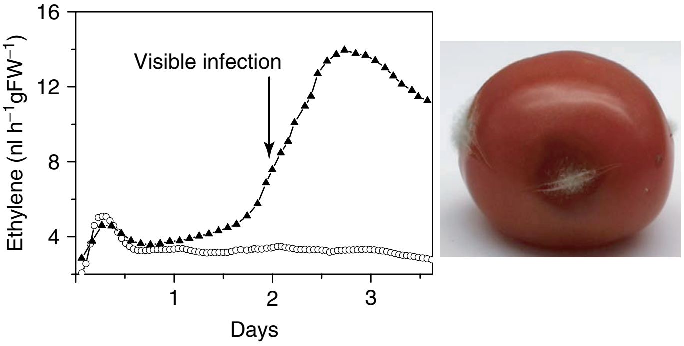

Fig. 17.17 Early detection of *B. cinerea* infection in tomato fruits. Ethylene production from artificially inoculated tomato fruits (triangles) starts to increase one day before visible infection. Production rate is given in nanoliter per hour per gram Fresh Weight (nl h^{-1} gFW^{-1}). For comparison ethylene emission of the uninfected fruit (circles) is shown (Cristescu *et al.*, 2002).

Besides ethylene, other compounds related to the quality control especially during storage can be monitored in real-time with the laser-based PA detectors. Currently, a trend in fruit storage is to reduce the oxygen level in order to slow down ripening and senescence. By lowering the oxygen level, aerobic respiration is gradually replaced by alcoholic fermentation that produces acetaldehyde and ethanol. These two compounds can thus serve as markers for suboptimal storage conditions; a timely observation is required in order to extend the storage period. Since in the storage room the concentration of these (and other trace gases) is normally below the detection limit of conventional gas analyzers, long accumulation periods are needed to obtain detectable concentrations. By avoiding the necessity of accumulation, online detectors such as laser-based PA trace gas detectors have proven to be capable of sensitive detection of ethanol and acetaldehyde at and below the part per billion levels.

Methane is an important greenhouse gas that originates both from anthropogenic and natural sources. In 2006 it has been reported that terrestrial plants may also emit methane under aerobic conditions by an unknown physiological process, and in this way may substantially contribute to the annual global methane budget with 10 Tg up to 260 Tg per year (Keppler *et al.*, 2006). The reported data have generated debates among the scientific community and also the general public. So far these findings were obtained in one single laboratory which was criticized for the experimental setup. Using an OPO-based system we have re-examined whether plants are producing methane in aerobic conditions by monitoring the $^{12}CH_4$ and $^{13}CH_4$ emissions of plants. Toward this aim ^{13}C-labeled plants grown under controlled conditions were used. Since about 99% of the carbon found in these plants was in the form of ^{13}C, one can expect that nearly 99% of the methane emitted by these plants is in the form of ^{13}C-methane. It is preferable to use these ^{13}C-labeled plants since the natural background concentration of ^{13}C-methane is 20 ppbv compared to 1.7 ppmv of ^{12}C-methane. An overall average production of 21 ng g^{-1} h^{-1} ^{13}C-methane was measured online which is 6–18 times lower than the average methane emission rates reported for the same plant species under ''sunlight'' and ''no sun'' conditions, respectively (Dueck *et al.*, 2007). Furthermore, less than 1 ppbv ^{13}C-methane was produced over a six-day period by the ^{13}C-labeled plants while the total plant biomass increased by 30%.

These tests indicated that plants produce insignificant amounts of methane in aerobic conditions, and the overestimated methane previously reported can be partly due to the diffusion of atmospheric methane from the plant tissue. Our results have been later confirmed by several other groups (Nisbet *et al.*, 2009; Beerling *et al.*, 2008).

17.3.3.4 **Microbiology**

The growth of all organisms depends on the availability of mineral nutrients, and nitrogen is one the most required nutrients in many biological reactions. Although the earth's atmosphere contains nearly 80% of nitrogen gas, this is unavailable for use by most organisms, being an inert molecule. In order for nitrogen to be used for growth it must be ''fixed'' (combined) in the form of ammonium or nitrate ions. This conversion process is known as nitrogen fixation and is exclusively performed by prokaryotes (bacteria) using an enzyme complex called nitrogenase. The acetylene reduction is the most widely used method for measuring the nitrogenase activity. It is based on the nitrogenase property to reduce compounds with a triple bond. Thus, by reducing nitrogen to ammonia, the nitrogenase reduces acetylene to ethylene. Both of these gases can be measured with high sensitivity by gas chromatography with flame ionization detection. However, due to its higher sensitivity and fast time response (about 20 seconds), laser PA spectroscopy offers the advantage of monitoring in real time small changes in the nitrogenase activity of low amounts of biomass.

The PA technique was applied for the first time to investigate the nitrogenase activity in a sample of the heterocystous cyanobacterium *Nodularia spumigena*. The

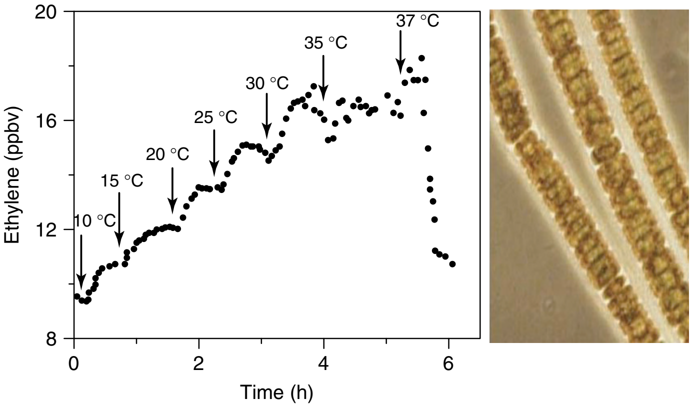

Fig. 17.18 Response of cyanobacteria *N. spumigena* to change in the temperature from 10 to 37 °C under light conditions. Significant instability in the nitrogenase activity is observed at 35 °C, leading to a short inhibition tendency at 37 °C, followed by a drastic decrease.

online monitoring allows measurements under constant conditions, which eliminates artifacts caused by changes in concentrations of oxygen or carbon dioxide due to respiration or photosynthesis during the incubations. Changes in light intensity and temperature, respectively, induce fast response in the nitrogenase activity. Knowing the level of saturation of the enzyme at different light intensities is important when rates of acetylene reduction are converted to rates of nitrogen fixation. At 35 °C and above this temperature, the nitrogenase activity is inhibited, most probably because nitrogenase, or because of the other substrate-generating enzyme systems (ATP and e^-) like the electron transport chain, are breaking down irreversibly (Figure 17.18).

17.3.3.5 **Entomology**

Laser PA trace gas detection is able to investigate the (respiration) behavior of the small insects like the Western Flower thrips, *Frankliniella occidentalis* (the smallest winged insects, size 1–2 mm, weight 50 μg) or single ant (weight of few milligrams) and *Drosophila melanogaster*, fruit fly (weight of 1–2 mg). In Figure 17.19 the respiration behavior of a single ant of 3.7 mg is shown. The ant is free moving in a 2-cm long tube with 4.5 mm internal diameter, and the CO_2 released is directed to the OPO-based system using air as the carrier gas. The respiration pattern periodically shows the release of CO_2 over several minutes that have been associated with the opening and closing, respectively, of the ant spiracles (the respiratory apertures that control the gas exchange of the insect).

Since the capability of the OPO-based system for monitoring CO_2 release of small insects has been demonstrated, one may think of investigating the metabolic changes in a single cell. In the future, this is in reach with the developments of more powerful lasers. For example, with a powerful pump laser which can supply more than 20 W of radiation between 1020 and 1050 nm, 10 times more power at the maximum of the CO_2 absorption can be

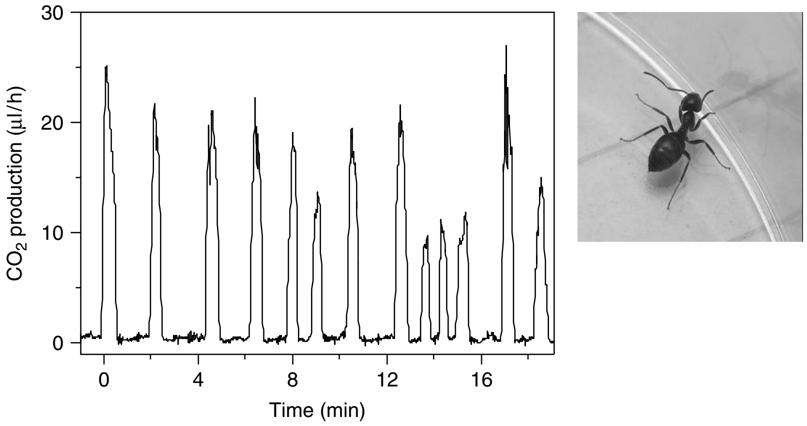

Fig. 17.19 Real-time CO_2 emission of a small ant. The respiration pattern displays periodic peaks of CO_2, which repeat on average once every 1.5 minutes. During the experiment the ant lives inside a small tube (diameter 4.5 mm) through which air is flowed.

Tab. 17.4 Molecules present in exhaled human breath with their physiological pathway and related health condition (Dueck *et al*., 2007; Nisbet *et al*., 2009; Beerling *et al*., 2008).

Compound	Concentration in breath	Physiological origin	Biological-pathology Indication
Acetaldehyde	ppb	Ethanol metabolism	Metabolism of lung cancer cells
Acetone	ppm	Decarboxylation of acetoacetate	Diabetes, fasting response, glucose metabolism
Ammonia	ppb	Protein metabolism	Liver and renal diseases, fasting response
Carbon dioxide	%	Respiration product	$13CO_2/12CO_2$ test for detection of ulcer bacteria *Helicobacter pylori*
Carbon monoxide	ppm	Degradation of hemoglobin by the heme oxigenase enzyme	Blood flow promotion
Carbonyl sulfide	ppb	Gut bacteria	Acute lung rejection in transplantations, liver and bile duct diseases
Ethane	ppb	Oxidative stress Lipid peroxidation	Chronic obstructive pulmonary disease, Rheumatoid arthritis, diabetes mellitus, lung cancer
Ethanol	ppb	Alcoholic fermentation of glucose by gut bacteria and yeast	Glucose metabolism
Ethylene	ppb	Oxidative stress Lipid peroxidation	Free radicals-mediated damage in the human body
Isoprene	ppb	Cholesterol biosynthesis	Hepatocellular injury
Methane	ppm	Gut methanogenic bacteria	Bacterial overgrowth in the small intestine
Methanol	ppb	the degradation of pectin by bacteria in the colon	Carbohydrate malabsorption, pancreatin insufficiency, renal failure
Nitric Oxide	ppb	Oxidative stress, endogenously produced by nitric oxide synthase enzyme	Lung diseases (asthma, COPD, cancer, airways inflammation, etc.), vascular smooth muscle response
Pentane	ppb	Oxidative stress Lipid peroxidation	Inflammatory diseases, transplant rejection, breast and lung cancer

generated. This will lead to an increase in the sensitivity by the same factor and pushes the CO_2 detection limit under 1 ppbv.

17.3.3.6 Human Health Research

Since ancient times, it has been known that the smell of exhaled air can be used as an indicator for several processes taking place in the human body; uncontrolled diabetes produces a sweet, fruity odor; advanced liver diseases entail a musty, fishy reek; failing kidneys bring about a urinelike smell and a lung abscess can be brought to light by its putrid stench. In the past, several attempts to use trace gas detection of exhaled air have been performed with varying success because of the insufficient detection limits of the detectors available. Gases produced in the body are transported to the lungs and are diluted (at rest, healthy persons exhale approximately 1000 l per h) before being exhaled. To measure them, it is usually necessary to accumulate the air samples by adsorbing the gases on a carrier column and releasing the concentrated gas at a certain moment, which decreases accuracy and time resolution.

Under stress conditions (e.g., ionizing radiation, toxic chemical substances, diseases, etc.), the production of free radical in the body is significantly increased. Subsequently, the capacity of the free radical scavengers in the body is overloaded and a chain of chemical reactions is activated. This leads ultimately to cell membrane damage that plays an important role in the aging processes and pathogenesis of some diseases such as cancer, Alzheimer, atherosclerosis, and so on. The cell damage is accompanied by the production of small hydrocarbons such as ethane, pentane, and ethylene that can be easily and quickly measured using PAs.

Other exhaled compounds were found to be by-products of endogenous biological processes. Ethanol, for example, is produced via alcoholic fermentation of glucose by intestinal bacteria and yeast. Acetone, a volatile ketone of fruity aroma, in breath results from the oxidation of free fatty acids.

Laser PA spectroscopy offers several advantages over the GC/MS analysis: (i) allows single breath collection since small sample volumes (few hundred milliliters) are required, (ii) no preconcentration steps are needed, (iii) excellent selectivity, and (iv) the detection and analysis procedure is fast (seconds–minutes) and computer-automated.

A summary of several compounds out of more than 300 present in the breath with their physiological origin and biological–pathological indication is given in Table 17.4 (McCurdy *et al.*, 2007; Kharitonov and Barnes, 2001; Risby and Solga, 2006). Many of these compounds have well-defined biochemical pathway and can be monitored in real time by PAs.

Acknowledgment

The authors wish to thank Frans Bijnen, Huug de Vries, Jos Oomens, Tim Groot, Edi Santosa, Iulia Boamfa, Bas Moeskops, Anthony Ngai, Sacco te Lintel Hekkert, Luc-Jan Laarhoven, Marc Staal and Jörg Reuss for their valuable contributions to this article.

Glossary

Absorption Coefficient: The absorption coefficient α in per centimeter is the attenuation coefficient of the light transmitting through a material. The transmitted light intensity I through a material with thickness l in meters is related to the incident intensity I_0 according to Beers law: $P = P_0 e^{-\alpha l}$, since for small absorptions this equation can be linearized: $\Delta P = P_0 - P = P_0 \alpha l$; the minimum detectable absorption from a device can be denoted as $\alpha_{min}/\text{cm}^{-1}\ \text{W}^{-1}$

Acoustic Resonator: Here, part of the photoacoustic cell allows a standing wave pattern to be formed (resonance). The modulation frequency of the exciting light beam should be tuned to the resonance frequency of the resonator.

Band Gap: Energy difference between the valence band and the conduction band in a semiconductor.

Boxcar Amplifier: Amplifier in which signals that occur within a preset (subsecond) time gate are selectively sampled.

Brewster(s) Angle: The angle of incidence on a window at which plane-polarized light suffers no reflection loss.

Brownian Motion: Random motion of small particles due to statistical variations in molecular pressure around the particles.

Cavity Ring Down (CRD): Sensitive direct absorption method. A laser pulse is stored in a high finesse optical cavity containing the sample. The decay time of the light intensity indicates the absorption strength.

Cell Constant: Parameter that describes the efficiency of conversion of absorbed modulated light energy into acoustical pressure amplitude, in Pa m W^{-1}.

Continuous Wave (CW): Constant, steady state delivery of laser power, as opposed to pulsed.

Depth Profile: Dependence of the photoacoustic signal (phase of amplitude) on sample depth as a consequence of a concentration gradient or changes in the thermal properties of the substrate.

Ethylene: Trivial name of ethene, C_2H_4, mostly used in biology; a gaseous plant hormone, involved in many processes. It can be detected very sensitively by photoacoustic spectroscopy.

HPLC: High performance liquid chromatography. A technique that is widely used to separate compounds in the liquid phase on a packed, (particulate) solid phase column. Often equipped with a UV-VIS detector.

Intracavity Photoacoustic (IPA) Detection: Sensitive method for trace gas detection; the photoacoustic cell is placed inside the laser cavity; due to the higher laser power better sensitivities can be achieved.

Laser-induced Fluorescence (LIF): Sensitive detection of fluorescence – radiative relaxation of electronically excited molecules – is used to detect specific laser-excited molecules. A technique used, for instance, for monitoring molecules in a flame.

Line Tunability: Indicates the restriction for gas lasers to emit light only for a discrete set of wavelengths.

Lock-in Technique: Only signals with a well-defined AC frequency are sampled. A lock-in amplifier locks to and measures the photoacoustic signal using the resonance frequency, ignoring all other signals (noise).

Multiple Pass Setup: A method to increase the absorption pathlength x-fold by reflecting a light beam many times between two mirrors.

Notch Filter: A simple acoustical interference filter that suppresses specific acoustical wavelengths, for example, perturbations from outside entering the acoustical resonator of a photoacoustic detector.

Open "Organ Pipe" Resonator: The central part of an often-employed resonant photoacoustic cell; it consists of an open-ended straight $\lambda/2$ tube, with the microphone mounted at its center where the pressure amplitude has its maximum.

OPC, Open Photoacoustic Cell: Simple photoacoustic cell, in which the sample serves as one wall, usually opposite the (gas-coupled) microphone.

Optical Parametric Oscillator (OPO): A nonlinear optical device where incoming laser radiation of frequency ν_0 is transformed into two light beams of frequencies ν_1 and ν_2 with $\nu_1 + \nu_2 = \nu_0$.

Overtone: Vibrational transitions (due to infrared light absorption) to a higher quantum level than the first excited level. Usually observed as weak absorption lines at shorter wavelengths.

Phase (angle): Position on a periodic wave (sinus) relative to a reference point on that wave (usually a node). In a photoacoustic signal the phase carries temporal information.

Piezo (electric) Element: A material, mostly a ceramic crystal or a polymer foil, that undergoes charge separation when experiencing pressure; piezo = pressure.

Quality Factor: Number that characterizes the quality of a cavity. It is given by the ratio between the stored energy and the energy loss during one cycle under stationary operation.

Quantum Cascade Laser: Laser action based on photon emission by a well-defined cascade of electrons through the layered semiconductor material.

Relaxation: De-excitation of a species after absorption of (light) energy. Relaxation can be radiative (fluorescence, phosphorescence) or nonradiative and within a wide time-window.

Rhodopsin: Protein that efficiently absorbs light in the middle of the visual spectrum with a maximum at 500 nm. Part of the light receptor in the eye and in, for example, halobacterial photoreceptors.

Spectral Coincidence: (Near) resonance between an employed laser transition and one or more transitions of the investigated molecule.

Spectral Selectivity, Spectroscopic Selection: The structural and vibrational properties of molecules allow selective excitation (and detection) of one component in a gas mixture while the other species do not respond to the chosen wavelength of the laser.

Thermal Diffusivity: Thermal diffusivity: $D = \kappa / \rho C_p$ in $m^2\ s^{-1}$, with κ in $W\ m^{-1}\ K^{-1}$, the thermal conductivity, C_p in $J\ kg^{-1}\ K^{-1}$, the heat capacity, and ρ in $kg\ m^{-3}$, the density of the material; the thermal diffusivity determines the response of the material to heat produced by, for example, absorption of electromagnetic radiation.

Thermal Lensing: Thermal nonequilibrium as a consequence of local heating changes the refractive index of a (transparent) material in such a way that light rays become deflected as by the action of a lens.

Trace Gas Detection: Techniques to determine concentrations of species present below about 1 ppmv in the atmosphere.

Window Absorption: Loss of energy of a light beam traversing an optical window, for example, at the entrance or exit of a photoacoustic cell; the resulting heating produces an unwanted photoacoustic signal that must be suppressed.

INTRODUCTION

Sputtering is an atom emission phenomenon from condensed matter. In other words, sputtering is an evaporation process or a gas-phase production from condensed matter using impact of high-speed particles such as accelerated ions without heating the condensed matter. A schematic illustration of the sputtering process is given in Fig. 1. The collision process, which is essentially a nonthermal process, suggests momentum transfer between the atoms of the condensed matter and the high-speed particles. Therefore, it should be possible that we can vaporize condensed matter even at 0 K if sputtering technology is applied to the matter because the momentum transfer is not affected by the temperature of the condensed matter.

In principle, any kind of high-energy (high-speed) particles such as electrons, neutrons, or photons can sputter matter. However, the production rate of the gas phase by use of those particles is extremely low, and their use is limited only for physical interests. As shown below, the momentum transfer between two particles is most efficiently performed by the collision between similar-mass particles. Hence, accelerated ions are usually used as the high-energy particles. The condensed matter (mostly solid) is called the *target* in sputtering technology.

As the gas phase is not in the state of thermal equilibrium with the surroundings, it condenses at the wall and other parts of the vessel in which the gas phase is produced. Many researchers often use the term "sputtering" for the combination of the emission of atoms from their condensed matter and their condensation or deposition on the surroundings. The special receiver of the depositing atoms for some applications is called the *substrate.*

The depositing atoms form thin films on the substrate. Nowadays, thin films produced

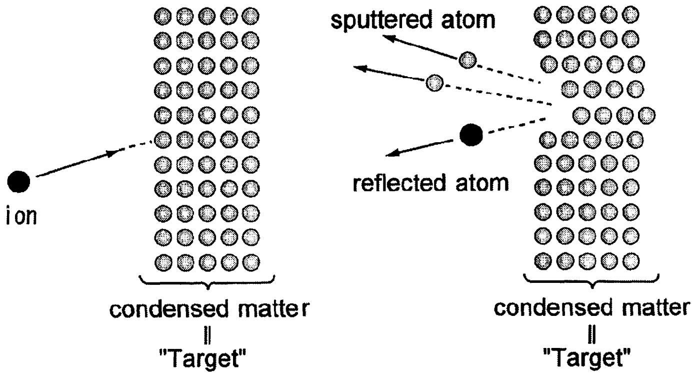

FIG. 1. Schematic illustration of the sputtering process (courtesy of Prof. Kusano, Kanazawa Institute of Technology).

by sputtering technology are applied in a variety of industries such as electronics, optics, mechanics, tribology, etc. There are a number of methods for thin-film production, but the sputtering technology has the highest flexibility for materials. Most materials including refractory metals, alloys, many inorganic compounds, and some polymers can be produced by sputtering technology.

Typical examples of the sputtered films are Al or Ti films for metal electrodes on Si integrated circuits (IC), indium tin oxide films as electrodes for liquid-crystal display (LCD) devices, TiC, TiN, and other hard coatings for machine tools, Pt films for gas sensors, etc.

The sputtering technology is very popular in advanced industries. A serious weak point has been pointed out by workers in these industries that the deposition rate of thin films by sputtering is lower than that by vacuum deposition. But this point has been overcome by introducing a magnetic field parallel to the target. This method is called magnetron sputtering (see Sec. 2.3), and is one of the most useful technologies in material science and industry. In addition, reactive sputtering, which uses reactive gas atoms as the sputtering particles, has produced good results in ceramics (refractory inorganic materials) coatings. Sputtering is no doubt one of the most important and valuable methods in advanced science and technology.

Sputtering is essentially an interaction between high-energy particles and a solid surface. Thus many phenomena in the target are related to sputtering. For example, secondary-electron emission, radiation damage of the target materials, ion implantation, modification of the target surface, etc. occur simultaneously with the sputtering. When we analyze the sputtering phenomenon in the target, we should take into account all phenomena. The sputtering theory should include a self-consistent interpretation for all of them. This makes it difficult to establish the theory and the modeling of the sputtering.

Here we consider a very primitive collision of two particles. Of course the particle–solid surface interaction is different from a particle–particle interaction, but the latter is closely related with the former. Let us consider the complete elastic collision of the two particles, of masses m_1 and m_2. At the initial stage, m_1 moves at the velocity v_1, and m_2 stands still. After the collision, the velocities of two particles change to v_1' and v_2', respectively. From the conservation of momentum and energy, we obtain

$$m_1v_1 = m_1v_1' + m_2v_2', \tag{1}$$

$$m_1v_1^2/2 = m_1v_1'^2/2 + m_2v_2'^2/2. \tag{2}$$

When we define the energy transfer coefficient Γ by

$$\Gamma = (m_2v_2'^2/2)/(m_1v_1^2/2), \tag{3}$$

we obtain from (1) and (2)

$$\Gamma = 4m_1m_2/(m_1 + m_2)^2, \tag{4}$$

$$= 4r/(1 + r)^2, \tag{5}$$

where $r = m_1/m_2$. Γ is plotted against r in Fig. 2.

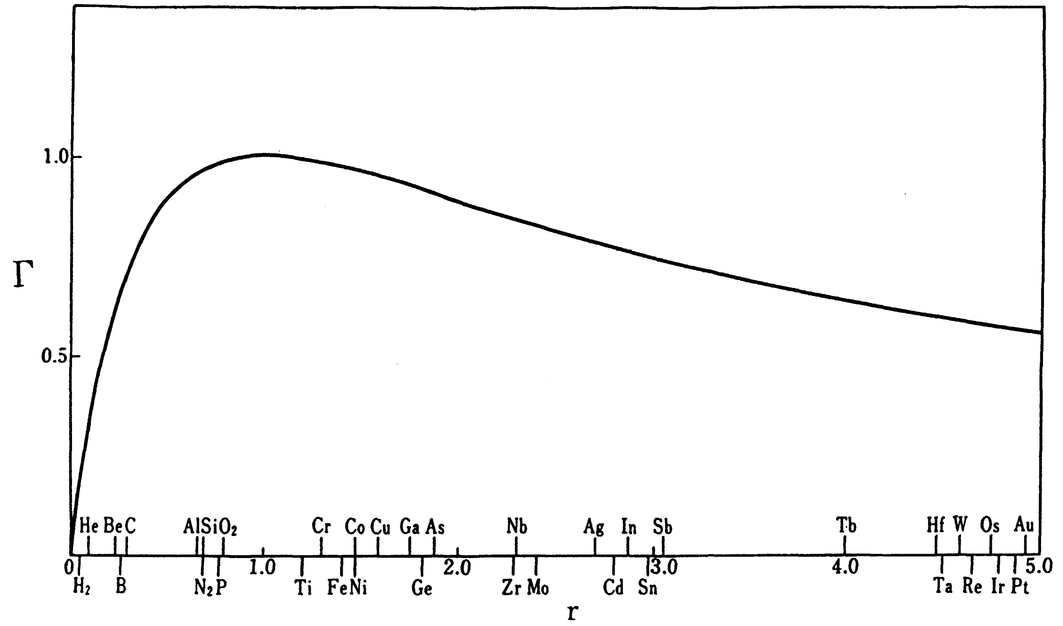

FIG. 2. Energy transfer coefficient Γ as a function of mass ratio r. The chemical symbols on the abscissa indicate the values of r for the respective substances when the bombarding gas is argon (m_1 = 39.948).

Γ is an indication of the energy transfer and often appears in the interpretation of sputtering mechanism. In actual sputtering, Ar ions are mainly used as colliding (sputtering) particles. The names of the elements shown on the horizontal axis in Fig. 2 correspond to m_2 when the mass of Ar is taken to be m_1. The dependence of Γ on r is rather dull, particularly in the range of $r > 1$. According to Fig. 2, we can qualitatively understand that Ar as a sputtering particle is excellent for the energy transfer to a variety of elements. However, electrons, neutrons, protons, and other low-mass atoms or ions are not appropriate as sputtering particles even if they have high energy.

During sputtering, the high-energy particles actually do not collide with isolated particles, but they do collide with a target consisting of many particles. This collision causes not only sputtering but also damage to the target. In addition, the cross section of the collision depends on the energy of the sputtering particles.

Therefore, the dependence of the sputtering phenomenon on energy and the related material, etc. is complicated, and the energy transfer in sputtering is, of course, not completely expressed in terms of (5), but a quantity named sputtering yield, which is one of the most important factors in the sputtering phenomenon and will be mentioned in the next section, is known to be strongly connected with Γ.

1. SPUTTERING YIELD

1.1 Definition

The sputtering yield of a target material is defined as the ratio of the number of sputtered (emitted) atoms of the target material to the number of sputtering (incident) particles in the particle impact process on the material. This quantity is denoted by Y hereafter. When we denote the number of sputtered atoms by N_s and the number of sputtering particles by N_i, Y is given by

$$Y = N_s/N_i \qquad (6)$$

Y is a fundamental quantity expressing the sputtering characteristics of a material. A large value of Y means that a small number of incident particles produces a large number of sputtered atoms. This characteristic is preferable for the production of thin films by sputtering but is not preferable when the material is used as a vessel that should be protected from the attack of fast particles such as nuclear fusion vessel.

It should be noted that *Y* is not inherent in the material, but it depends on many factors of both the sputtering particles and the target materials such as the energy, type, and incident angle of sputtering particles, the crystal surface structure, surface roughness of the target material, etc.

The direct measurement of *Y* is performed through the measurement of the weight loss of the target by sputtering (Kaminsky, 1965), even though a number of indirect methods have been developed (Krauss and Gruen, 1977). For this purpose, a constant and stable particle beam (generally, ion beam) of high energy should be produced. The energy and the intensity of the ion-beam current are varied by a controller.

The weight of the target before and after the ion-beam irradiation is measured by microbalance or another weight monitor. In a typical experimental condition, the irradiation period is an order of an hour or less and the weight loss is of the order of milligrams.

1.2 Experimental Results

Measurements of *Y* have been carried out by many workers. There is a wide variety of results. In Table 1, examples of elements sputtered by Ar ions accelerated in the energy range of 500–600 eV are shown (Maissel, 1970).

Table 1. Sputtering yield (Ar: 500–600 eV) and threshold energy of elements.

	Y	eV		Y	eV
Ag	3.4	4–15	Pb	2.7	
Al	1.05–1.2	13	Pd	2.4	20
Au	2.4	10–20	Pt	1.40–1.6	25
Be	0.51–0.8	15	Rb	1.15	
C	0.12–0.2	7–12	Re	0.9	35
Co	1.22–1.4	7–22	Rh	1.5	24
Cr	1.18–1.3	15–25	Ru	0.7	
Cu	2.3–2.55	12–17	Si	0.5	
Fe	0.84–1.3	14–20	Ta	0.6	13–26
Ge	1.1–1.2	25	Th	0.62–0.7	24
Hf	0.4		Ti	0.51–0.6	20
Ir	1.01–1.2	8	U	0.85–1.0	23
Mo	0.9	24	V	0.65–0.7	23
Nb	0.7	25	W	0.6	13–85
Ni	1.45–1.5	7–21	Y	0.68	
Os	1.0		Zr	0.65–0.8	7–22

One of the most noticeable features of *Y* is its ion-energy dependence. The particle-energy dependence of *Y* has been extensively researched. Ar-ion energy dependences of *Y* of several elements are shown in Fig. 3 as examples (Hosokawa, 1992). *Y* for Cu target has been well investigated and several data have been collected in Fig. 4 (Kinbara, 1985). The values and behavior of *Y* in most metal and semiconductor elements have been studied for a long period of time. The general features of the experimental results using noble-gas ions are as follows (*V* indicates the acceleration voltage of the ions):

1. The *V*-*Y* relation has a threshold voltage.
2. *Y* increases with *V* monotonically until a certain value of *V*.

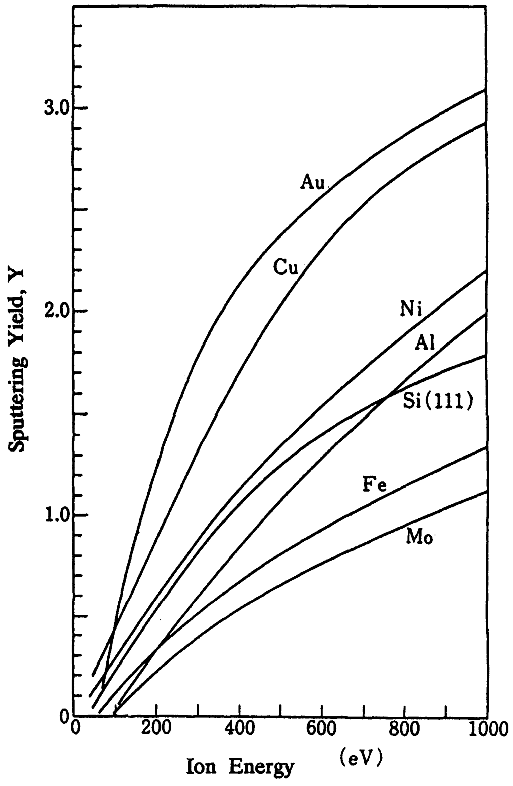

FIG. 3. Sputtering yield of various elements as functions of incident Ar-ion energy.

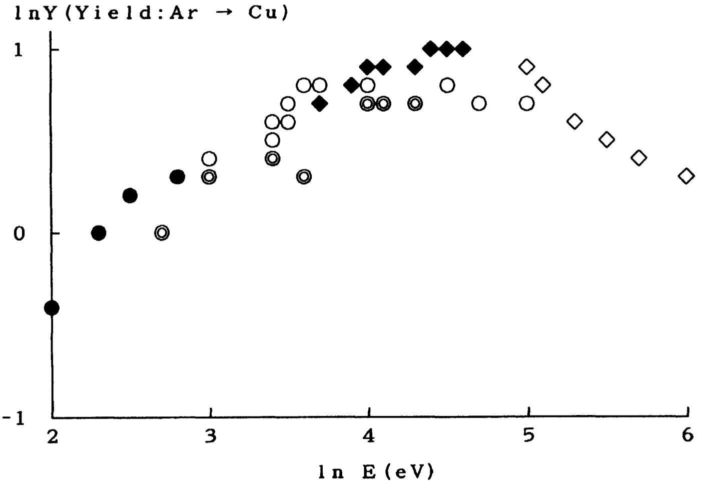

FIG. 4. Experimental results on the measurement of sputtering yield Y of a polycrystalline Cu target irradiated by Ar ions obtained by various workers: ○, Southern *et al.* (1963); ●, Laegreid and Wehner (1961); ◇, Dupp and Scharmann (1966); ◆, Yonts *et al.* (1960); ◎, Rol *et al.* (1960).

3. The *V-Y* relation reaches a maximum value of *Y* at around *V* = 10–100 keV.
4. The maximum value of *Y* does not exceed 100.

In general, there exists a threshold of energy in each target for the initiation of sputtering (Wehner, 1954; Harrison and Magnuson, 1961; Behrisch *et al.*, 1976). The determination of the threshold energy is complicated because it is difficult to generate ion beams of small energy and to observe the complete extinction of the sputtering. In addition, surface modification such as oxidation, contamination, etc. makes it difficult to obtain a precise determination of *Y* for a pure material. Many data have suggested, however, that the threshold energy ranges from a few to about 10 eV.

The measured values are not necessarily the same as the binding energies of the target materials themselves but are the same order, and it is suggested that a certain correlation exists between them. The experimental results on the sputtering threshold energy of elements are listed in Table 1.

There have been many data on polycrystalline copper target irradiated by argon ions, as shown in Fig. 4. *Y* is observed to increase with the ion energy in the low-energy region. The *V-Y* relation is affected by the surface crystal structure. Experiments on single-crystal copper targets have been done, and the dependence of *Y* on the particle energy is indicated in Fig. 5, where the Miller indices of the surface are taken as parameters (Naundorf and Macht, 1980). The curves in the figure are calculated results by Onder-

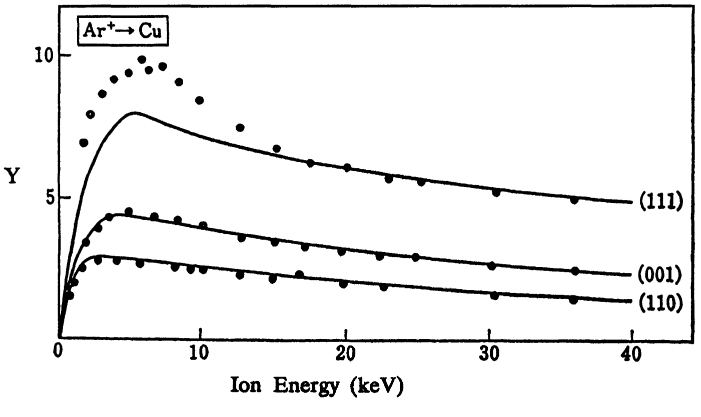

FIG. 5. Sputtering yield of three single-crystal faces of Cu vs Ar-ion energy.

delinden (1966). This figure shows that the larger surface number density of atoms causes the larger sputtering yield. The sputtering yield is related to the particle energy and the cross section for atom collisions at the target surface.

When the energy of the sputtering particles becomes very large—say, 10–100 keV or more—the value of Y is usually observed to decrease. This decrease is believed to be the effect of "channeling" (see ION-BEAM MODIFICATION OF MATERIALS). Namely, if the target is a single crystal, the incident particle can see channels from the front surface to the back surface in some directions, and the incident particles can go through without resistance. This is called the channeling effect. Of course, most targets are not completely single crystal, but the reduction of the cross section can probably cause the reduction of collision of incident particles with target surface atoms, and this is the origin of the decrease of Y.

1.3 Theory of Sputtering Yield

Modeling of sputtering phenomena has been performed by many authors in the process of the sputtering research. Among them, the theory of Sigmund (1968, 1969) is most well known. His model is based on the cascade knock-on atom generation in the target by the impact of the incident particles. Consider an infinite flat plane of finite homogeneous matter. An incident particle arrives at a point on the plane. From that point, a knock-on atom cascade starts, and atoms generated by the cascade diffuse in the target to form a dilute gas. The interaction among the atoms is ignored, and the linearity of the distribution function is considered to be preserved. The distribution function of the atoms is assumed to be determined by Boltzmann's transport equation. The incident atoms are supplied constantly, and a steady-state distribution is formed. Therefore, this theory may be called steady-state linear collision cascade theory. Final results of the calculation on the sputtering yield are related to the incident particle energy and the incident angle of the incident particles to the target surface. The sputtering in this model, in principle, is the diffusion of the gas atoms from the infinite plane to a certain direction.

An enormous amount of the calculation has been done in his model. They are so complicated that the process of the derivation is omitted here, and only the results are described. The main results are the relations of incident particle energy E and incident angle θ vs Y. As long as the elastic collision between the particles is assumed, Y is approximately expressed as follows in usual sputtering conditions:

$$Y(E) = 0.042bA/U_0, \tag{7}$$

where b is a correction factor of the energy transfer in the collision between a particle and a solid body, U_0 is the sublimation energy of the target material expressed in eV, having a value ~10 eV, and A is the nuclear stopping cross section expressed in Å^2. While the experiments showed that threshold energies for the sputtering exist, they have not been taken into account in the theory. In addition, it has been observed that a dependence of Y on the sputtered angle θ exists. These aspects have been considered by Shimizu *et al.* (1981). The relation for the modified sputtering yield Y' obtained by them is

$$Y' = [0.042bA/U_0]Y_n(E,\theta)[1 - (E_0/E)]^{1/2}, \tag{8}$$

where E_0 is the threshold energy and b is a function of θ, the angle of sputtering measured from the normal to the target surface. $Y_n(E,\theta)$ is expressed in an approximation,

$$Y_n(E,\theta)/Y(E,0) = \cos\theta - f; \tag{9}$$

here f is close to 1 in usual sputtering conditions.

Computer simulations of the sputtering process have been carried out in various ways (Ishitani and Shimizu, 1975; Helbig, 1976). These are useful to visualize what happens in the target. The collision process is repeated, a cascade is generated, and trajectories of recoil atoms and incident particles are drawn. As an example, the trajectories given by Ishitani and Shimizu (1975) are shown in Fig. 6. Two-body collision and Monte Carlo simulation are the main bases of the calculation. The Born–Mayer potential is assumed for the interaction between two

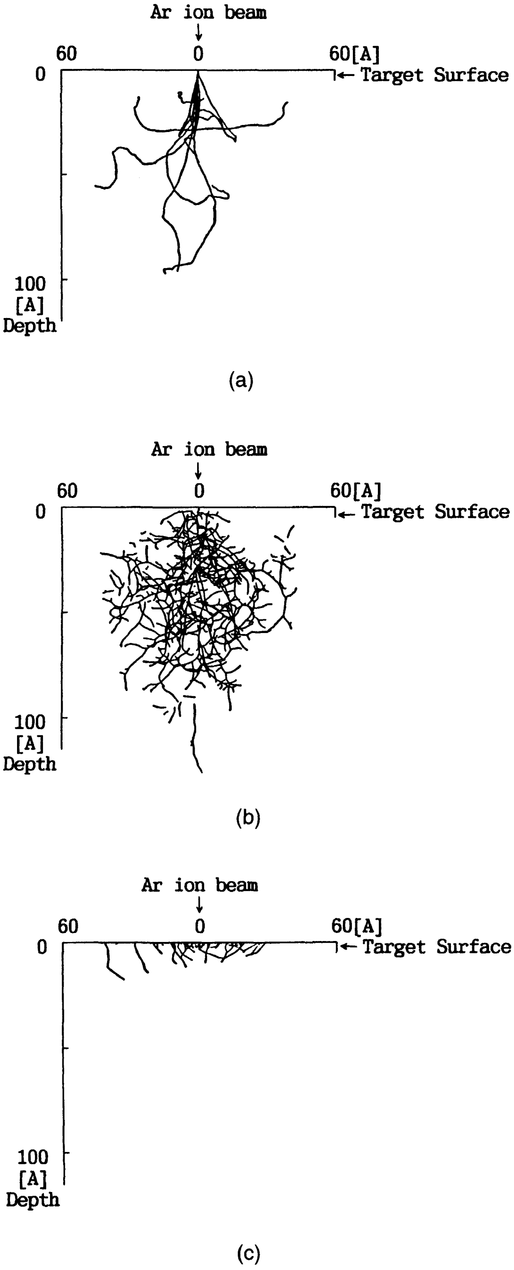

FIG. 6. Monte Carlo simulation on trajectories of (a) incident Ar ions, (b) knocked-on Cu atoms in target, and (c) sputtered Cu atoms (courtesy of Prof. Shimizu, Osaka University).

particles. Two well-known codes of the simulation, MARLOW (Robinson and Torrens, 1974; Hou and Robinson, 1979) and TRIM (Haggmark and Wilson, 1978), have been developed.

2. FUNDAMENTALS OF SPUTTERING APPARATUS

2.1 Ion-Beam Sputtering

Sputtering phenomena have been observed in various ways, but the most primitive method for the observation of sputtering is the ion-beam sputtering method. Ion beams are produced in ion sources. They are accelerated and collimated and arrive at the target. The beam current is directly measured by an ammeter to count the number of ions arriving at the target. For the measurement of sputtering yield, the secondary-electron emission from the target should be taken into account. Sometimes, a Faraday-cup–type structure is used for the target. Atoms emitted from the target move to substrates located around the target to condense and form thin films. The target is etched, and the target weight loss is measured. The number of atoms sputtered from the target is counted by the weight loss, and, hence, the sputtering yield is determined. In this method, the gas pressure around the substrate can be kept at a fairly low pressure. This method is frequently used except in the mass production of thin-film devices, because of the difficulty of manufacturing large-scale ion-beam sources.

2.2 Discharge Sputtering

A more prevailing method is discharge sputtering. A sputtering chamber is essentially almost equivalent to a discharge tube. Most of the discharge sputtering devices are composed of two facing electrodes in the vacuum chamber, and one of them, usually the anode, is grounded. On the anode, substrates are fixed, and high negative voltage is applied to the cathode. On this cathode, a target is tightly fixed.

Electrons emitted by the high voltage from the cathode are accelerated by the electric field between the two electrodes. Those electrons collide with the discharge-gas atoms and generate electrons and positive ions. The generated electrons also generate ions and electrons; thus a cascade is formed. The positive ions collide with the cathode (target) and emit secondary electrons. The cascade generation and the secondary-electron emission are essential to sustain the discharge. During the process of the positive-ion collision with the target, the target emits both electrons and neutral target atoms. This emission of neutral atoms is the sputtering by discharge.

It should be noted that the ratio of ions to discharge-gas atoms under usual glow-discharge conditions is not high. Plasma diagnostic shows that the fraction ranges between 10^{-3} and 10^{-4}.

When we use this sputtering method to produce thin-film devices in industries, a high production rate of the films is strongly required. This requires the production of a high density of ions. To satisfy this requirement, we should use high-pressure (100–10 Pa) discharge gas. The high-pressure gas increases the yield of ions, yet at the same time, it increases the scattering of the sputtered atoms and hinders the arrival of them at the substrate. Hence, the production rate of thin films by sputtering had been considered to have a limit. In addition, the rise in temperature of substrates caused by secondary electrons accelerated by the electric field during the sputtering becomes an important problem when the substrates are made of low melting point materials.

2.3 Magnetron Sputtering

In order to produce a high density of ions in the region close to the target in high vacuum (1–10^{-2} Pa), a magnetic field parallel to the target surface is applied. This field generates a cycloid motion of electrons in the space near the target surface, and the efficiency of the ion generation is drastically increased. This type of sputtering is called magnetron sputtering, and at present, most commercially available sputtering apparatus belongs to this category. Here, we interpret briefly the principle of the magnetron sputtering.

Consider an electron in the space in front of the target to which a magnetic field **B** parallel to the target surface is applied in addition to the electric field **E** perpendicular to the target surface. The equation of motion in this **E** × **B** field is

$$\frac{md^2\mathbf{r}}{dt^2} = -e[\mathbf{E} + (\mathbf{v} \times \mathbf{B})], \qquad (10)$$

where **r** is the position of the electron, t the time, and $-e$ the electron charge. This equation is simplified by taking an appropriate rectangular coordinate system and can be solved under proper boundary conditions. If **E** and **B** are constant and homogeneous, and the directions of **E** and **B** are taken as the z and y axes, the path of an electron is a cycloid and is restricted around the target surface. The trace of the electron motion in the **E** × **B** field is

$$x = x_0 + (v_0/\omega) - (v_0/\omega)\cos(\omega t + \beta), \qquad (11)$$

$$y = y_0 + (E/B)t + (v_0/\omega)\sin(\omega t + \beta), \qquad (12)$$

where $\omega = eB/m$ is called the cyclotron frequency and β is the initial phase angle. The maximum excursion of x is given by $r = v_0/\omega$. This is called the Larmor radius, and the motion of electrons on the target is limited to this radius.

This means that the ion generation occurs in a very limited space in front of the target. The restriction of the space of electron motion causes a high probability of ionization of discharge gas atoms in the restricted area, so that ions are generated even in the 10^{-2}-Pa range and sputtered atoms travel in the discharge space without being scattered by the discharge-gas atoms. The motion of an electron on the target under an **E** × **B** field is shown in Fig. 7.

Magnetron sputtering was one of the most innovative methods for the production of thin films in the 1960s. By this method, high-speed and low-temperature deposition of refractory metals could be realized. Magnetron sputtering is, as it were, an ultimate method, and no methods superior to this based on other principles have appeared yet.

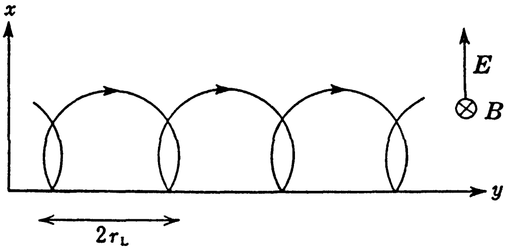

FIG. 7. Trajectory of an electron under an E × B field.

2.4 Modulation of Discharge Sputtering

2.4.1 rf Sputtering When the target (cathode) consists of an insulating material such as SiO_2, dc voltage cannot sustain the discharge because of positive charging of the target surface. Radio-frequency (rf: mainly 13.56 MHz) voltages are applied to the insulating target to maintain the sputtering. This is called rf sputtering. In rf sputtering, both electrodes (target and substrate) are sputtered. But because of a self-bias voltage appearing on the target surface, which is caused by the difference between ion temperature and electron temperature in the discharge plasma, the target is charged negatively, irradiated more heavily by positive ions, and sputtered more preferably.

2.4.2 Collimated Sputtering The direction of the atoms sputtered from the target seems to have some preference, as described in Eq. (9), but it is rather ambiguous, and on a practical level, the direction is nearly random except for a decrease at large sputtering angles. In the case of a single-crystal target, the direction of the sputtering is restricted, and what are called spot patterns appear (Wehner, 1955; Musket and Smith, 1968). They are interesting from the physical viewpoint but have little practical significance because single-crystal targets are never used in thin-film production systems.

In order to arrange the direction of the sputtered atoms, a mesh of a collimator made of stainless steel is placed in front of the target, as shown in Fig. 8. If the mesh is deep enough, the collimation is better but the loss of the film material becomes larger. This method is called "collimated sputtering" and is used for the case where the normal incidence or a certain angle of incidence of sputtered atoms is required in the deposition of the film.

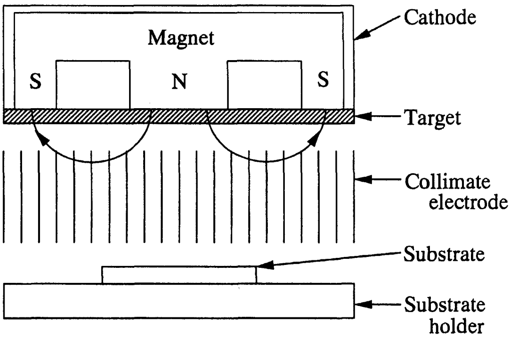

FIG. 8. Schematic illustration of collimated sputtering apparatus (courtesy of Prof. Hata, Kanazawa University).

2.4.3 Unbalanced Sputtering The magnetic field in the magnetron sputtering apparatus limits the discharge space, and the electrons emitted from the cathode cannot collide with the target. Therefore, heating of the substrate and the film by electron irradiation is prevented. The heating changes the film properties, and depending on circumstances, it gives rise to a positive effect such as removal of surface contamination. In order to make the best use of its decontamination effect, the magnetic field is intentionally distorted by adding extra magnets around the regular magnets. This type is called "unbalanced magnetron sputtering." In actual processes, the substrate seems to be immersed in the discharge space. The electrons and neutral reflected atoms from the target, and part of the ions in the discharge space, may collide with the substrate, provided the self-bias potential of the substrate is adequate.

2.5 Atom Motion in the Discharge Space

2.5.1 Sputtered Atoms The sputtered atoms emitted from the target come into the discharge space and move to the substrate. During this movement, sputtered atoms are scattered by discharge-gas atoms. This scattering impedes the direct arrival of the sputtered atoms on the substrate. Hence, some of the sputtered atoms cannot reach the substrate but are evacuated from the discharge chamber. Traces of the scattered atoms are estimated by Monte Carlo simulation (Nakano *et al.*, 1991; Kinbara *et al.*, 1993). Figure 9 shows the relative rate of sputtered atoms of La and B returned on the target. It is clear that heavy atoms such as La do not scatter much, while light atoms such as B scatter abundantly. This should cause a lack of B atoms in sputtered films produced by the direct sputtering of LaB_6, and experiments show the validity of the simulation. Figure 10 shows the composition of sputter-deposited films measured by Auger-electron

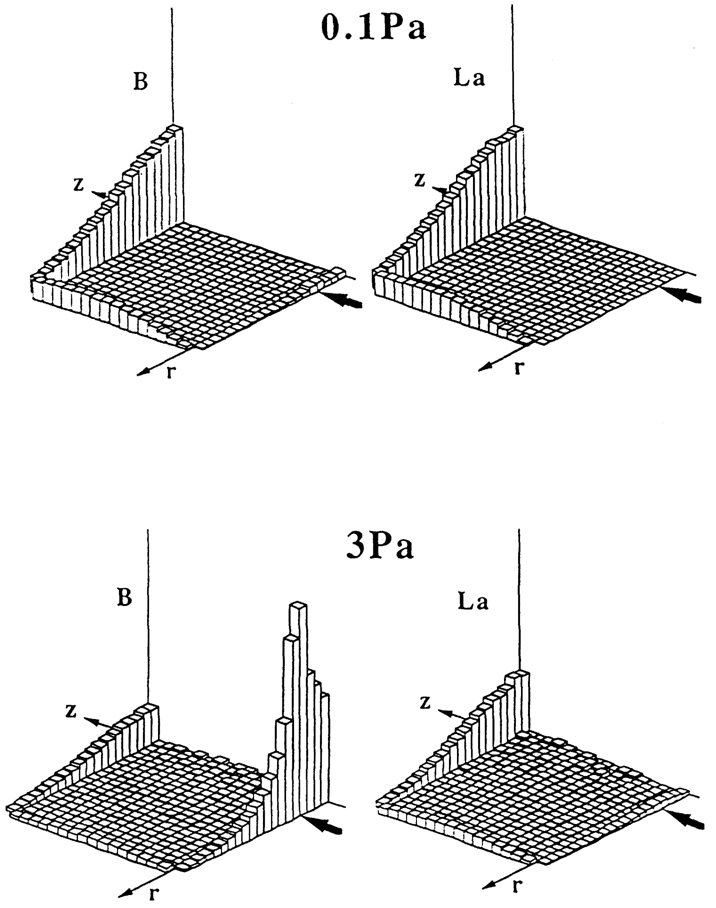

FIG. 9. Computer simulation of arriving rate of La and B atoms on a substrate under different discharge-gas pressures. Thick arrows show the starting point of both atoms at the substrate. It is clear that most La and B atoms arrive at the substrate under a pressure of 0.1 Pa, while most B atoms return to the target under a pressure of 3 Pa.

spectroscopy as a function of Ar discharge-gas pressure during deposition. At higher gas pressures, the rate of B atoms included in the film is observed to be reduced. Hence, we can conclude that the loss of B atoms is larger in thin films. It is considered that sputtering of a composite target causes a lack of the lighter component in deposited

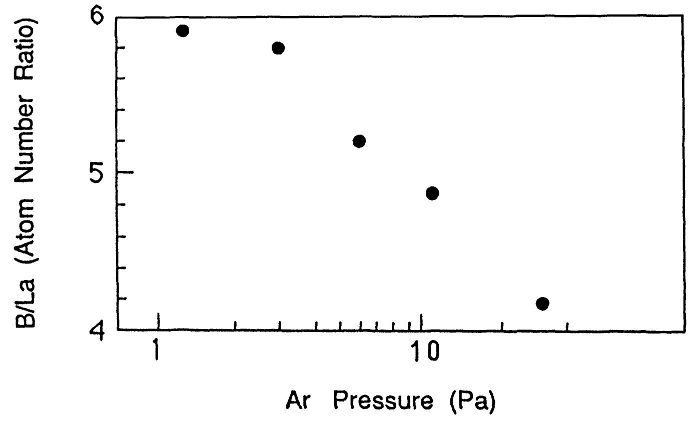

FIG. 10. Atom-number ratio of sputter-deposited La-B thin films measured by Auger-electron spectroscopy at various discharge-gas pressures.

films, and this is confirmed by the experiment.

2.5.2 Reflected Discharge-Gas Atoms

In the process of sputter deposition using a glow discharge, including magnetron sputtering, ions colliding with the target are then partially implanted in the target but mostly are reflected as their charge is lost. The reflected discharge-gas species are believed to be neutral atoms. Part of the energy of the incident ions is given to the target, and the rest remains in the reflected neutral atoms. For example, if the incident ion energy is 1 keV, the energy of reflected atoms is considered to range between several tens and a few hundreds of electron volts. These high-energy atoms cannot be controlled by electromagnetic field; therefore, part of the reflected atoms collide with the growing thin films. This effect hinders the adsorption of residual gas atoms on the film surfaces. Consequently, similar to electron irradiation, the reflected atoms "clean" the films on one hand but on the other hand, they destroy the crystal structure of the film. Some of the reflected atoms hit the atoms of the growing film and hammer them into the film inside. This effect is called peening effect and will be mentioned in Sec. 5.5.

2.5.3 Energy of the Sputtered Atoms

The energy of the sputtered atoms has been measured. There are several methods for its determination, but all the methods reveal that the energy of the emitted atoms sputtered by Ar ions of 10^2–10^3 eV ranges between 1 and 100 eV (Kruger and Scharmann, 1970; Oechsner, 1975; Elbern *et al.*, 1978).

3. SPUTTERING APPARATUS FOR THIN-FILM PRODUCTION

An ion-beam sputtering apparatus consists, in principle, of an ion-beam source and a target. Such a system is shown in Fig. 11. This system works in a high vacuum, but in the operating condition of the ion source, the vacuum is usually 10^{-1}–10^{-2} Pa.

The sputtering apparatus using a discharge is essentially equivalent to a discharge tube. But some ideas are naturally taken into account to generate effective sputtering and a high productivity of thin films.

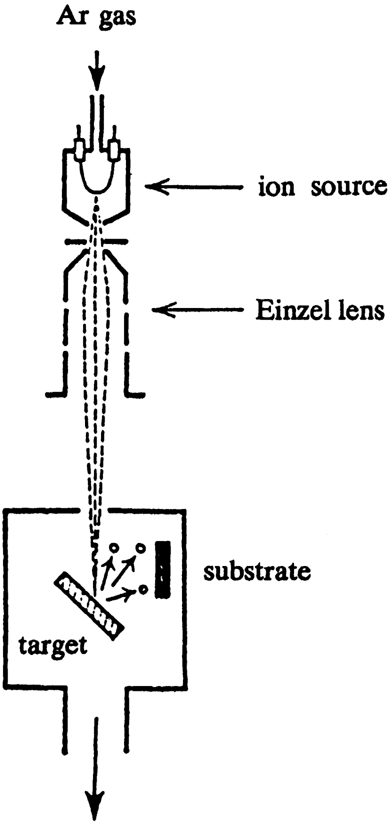

FIG. 11. An example of ion-beam sputtering apparatus.

Most sputtering devices are composed of two facing electrodes in the vacuum chamber, and generally, the anode is grounded, with the substrates fixed on it. High negative voltage is applied to the cathode. A target is tightly fixed on this cathode. In order to produce a high density of ions in the region close to the target, a magnetic field parallel to the target surface is applied as mentioned before. However, in a practical magnetron sputtering apparatus, it is not easy to produce a high parallel magnetic flux (0.1T or more) at the target surface. In reality, permanent magnets are placed on the back side of the target. The actual form of the magnetic flux used in practical equipment is schematically shown in Fig. 12. The top of the arc-shaped flux is parallel to the target, and many ions are produced at the tops.

The cathode/target is cooled by running water on its back side in order to prevent a

temperature rise during sputtering. As long as we use tap water, its electric conductivity is small enough and the electric loss through the water is ignored even if direct contact of water with a conductive cathode exists. The discharge from the cathode occurs in every direction. Namely, the discharge occurs not only between the cathode and the anode but also between the cathode and a chamber wall if the chamber is made of metal. To prevent a discharge in the unnecessary direction, the back side of the cathode is shielded by a metal plate placed close to it. Electrons emitted from the cathode to the plate arrive at the plate without colliding with discharge-gas atoms. This means that the discharge cannot occur in the back direction, and the discharge is limited to the space between the anode and the cathode. Schematic illustrations of a magnetron sputtering apparatus and a cathode/target are shown in Figs. 13 and 14.

4. SPECIAL PHENOMENA

4.1 Reactive Sputtering

4.1.1 Definition and General View Reactive sputtering is a process that forms compound thin films using a conductive (mainly metal) target and reactive gases. Many compounds such as ceramic films produced by reactive sputtering are used in various kinds of industries.

When we use a compound such as a ceramic target in order to produce compound (mainly inorganic) thin films by regular sputtering technology, we often encounter several difficulties:

1. Production of the target is not simple. For example, ceramics are generally brittle and refractory and are not easy to manufacture or to form in an appropriate shape to fit in the sputtering apparatus.
2. Selective sputtering from compound target hinders keeping the stoichiometry of the deposited film composition. A certain component of the target is short in the deposited films.
3. In many cases, the bonding of atoms forming the compound is more tight than that of conductors. This implies that the sputtering yield is small, and, hence, the deposition rate is small.

In order to avoid these difficulties, a pure metal (occasionally semiconductor) target is sputtered in a discharge gas including reactive gases such as oxygen, nitrogen, methane, silane, hydrogen sulfide, etc. Examples of generated materials are listed in Table 2 (Thornton *et al.*, 1981; Ritchie and Harding, 1979). The metal atoms sputtered from the target arrive at the substrate, while reactive gas atoms in the discharge gas also diffuse in the space and arrive at the substrate. Both metal and reactive-gas atoms/molecules migrate on the substrate and collide with each other to form compound molecules (Berg *et al.*, 1987, 1989; Kusano and Goulart, 1990; Kinbara *et al.*, 1992). This process is known as reactive sputtering. Reaction to form compounds occurs on the substrate. The collision probability of metal atoms and reactive gas molecules in the space is small and is negligible under usual sputtering conditions (~1 Pa). The reaction also occurs on the target surface. The reaction at the target surface generates a compound, inorganic, insulating material on the target, and it changes the sputtering characteristics. In particular, it has been well known that by a change in the reactive-gas flow rate, the production rate of thin films will be changed. Reduction and increase of the flow rate are not reversible but cause well-known hysteresis characteristics of the production rate. A schematic plot of the hysteresis is shown in Fig. 15. This hysteresis is caused by compound formation on the target surface. On the target surface, sputtering and compound formation occur simultaneously. The abrupt change of the production rate is related with the compound formation and disappearance (Stirling and Westwood, 1971; Donaghey *et al.*, 1976).

4.1.2 Apparatus Reactive sputtering apparatus is not specially designed. All sputtering apparatus is applicable for this pur-

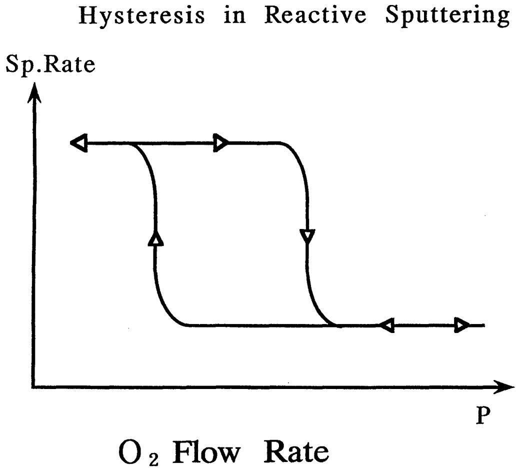

FIG. 15. Schematic form of hysteresis observed for sputtering rate with change of oxygen partial pressure in the reactive sputtering process.

pose. We only need a device to introduce the reactive gas. An accurate gas-flow controller is generally provided.

In some apparatus, the reactive gas is introduced into the chamber through a nozzle, which makes it possible for the gas to blow against the substrate (Vossen *et al.*, 1991; Niwa *et al.*, 1993). A gradient of the reactive-gas density is formed on the substrate. The degree of compound film formation is different from place to place on the substrate. We can clearly recognize and distinguish differences of compound formation on the substrate. The best amount of the reactive-gas supply is evaluated by this nozzle experiment.

4.1.3 Thin-Film Formation Many kinds of compound thin films have been produced by the reactive sputtering method. In general, sputtering is performed by use of Ar and reactive discharge-gas mixture. The most favorable ratio of Ar to reactive gas depends on the apparatus and cannot be precisely specified. However, generally the percentage of the reactive gas plays a rather small part in the total discharge-gas pressure. The role of the Ar is the sputtering of the target. This includes the cleaning of the target surface that is going to be contaminated or combined with the reactive gases.

The ratio of the number of reactive-gas atoms to the number of sputtered metal atoms should be carefully taken into account in order to produce stoichiometric materials. Sputtering and film deposition is not a thermal equilibrium process, and hence, nonstoichiometric compounds are likely to be formed. Therefore, the control of the ratio is very important in forming stoichiometric thin films.

4.2 Chemical Sputtering

Sputtering is essentially the emission process of atoms from a target. However, in the case of reactive sputtering, the reaction occurs on the substrate surface but not on the target. The name reactive sputtering has not been considered to be adequate because the reaction is not concerned with atom emission from the target.

Since nuclear fusion has been developed, the erosion of the reaction chamber wall has been widely investigated (Roth *et al.*, 1976; McCracken and Patridge, 1976; Webb *et al.*, 1980). The wall of the nuclear fusion reactor made of "low-*Z*" material such as carbon is exposed to the high-temperature hydrogen plasma. Chemical reaction of the hydrogen and the wall material (carbon) occurs at the wall and generates methane. This phenomenon has not fully been interpreted, but it is clear that accelerated H^+, D^+, or T^+ ions collide with the carbon on the wall and react to form CH_4 (Erents *et al.*, 1976). The wall is equivalent to the target in the sputtering apparatus, and this phenomenon is a genuine surface reaction on the target. This phenomenon is rather suitable for the name of reactive sputtering, but this name has already been used for the substrate surface reaction. For that reason this target reaction is called chemical sputtering. Of course, when carbon is exposed to H radicals, methane production appears. The efficiency of the methane production is much smaller than that produced by accelerated H^+ ions. The origin of chemical sputtering is still being investigated.

4.3 Selective Sputtering

When an alloy is heated and vaporized, the component of the alloy that has a higher vapor pressure at the alloy temperature evaporates more quickly than the others. The evaporation of an alloy is considered to obey Raoult's law. Hence, the composition of a vacuum-evaporated thin alloy film is not the same as that of the material in the evaporation source.

The sputtering process is close to milling or shaving, so that it is expected that the composition or the stoichiometry of the source (target) material is kept in the thin film during the sputtering process. However, actually, according to many experiments on alloys such as Ag–Cu, Cu–Ni (constantan), Ni–Cr, etc., the stoichiometry does not hold in sputtering, although the vaporization pressure of each component is not directly related with the sputtering. It has been reported, for example, that the ratio of the sputtering yield of Cu to Ni in Cu–Ni alloy ranges between 1.6 and 1.8 (Goto *et al.*, 1978; Coburn, 1979).

There exists a difference of sputtering yields among the components of the target material. The yield is not directly related to the yield of the single component state. In addition, atom diffusion of the component supplies the sputtered material onto the target surface (Pickering, 1976; Ho, 1978). Consequently, the composition of the surface of the target is kept almost constant at the initial stage of sputtering, and the larger-yield material in the alloy is constantly supplied to the target surface for a certain period. This process is called selective sputtering and makes it difficult to use alloy targets for the production of alloy films.

5. SPECIAL FEATURES OF SPUTTERED FILMS

5.1 General View

Sputtered films have characteristic features in structure and properties. They are mainly caused by the discharge-gas atoms in the sputtering chamber. During the sputtering process, the film surfaces are exposed to the discharge-gas atmosphere and adsorption of the gas atoms occurs. In addition, high-energy particles such as reflected sputtering particles at the target and, occasionally, ions irradiate the film surfaces. The adsorption and irradiation cause several effects on the structure and properties of the sputtered films.

5.2 Inclusion of Discharge Noble-Gas Atoms in the Films

In the case of the sputtering process using noble-gas glow discharge, the collision probability of the discharge-gas atoms with the growing thin-film surface is rather large. Most of those atoms desorb very quickly because the adsorption energy of the gas atoms on metal surfaces ranges from 0.05 to 0.35 eV. However, part of them remain on the film surface and are included in the film with the growth of the films. Sputtered films include more or less discharge-gas atoms. It is more probable that the reflected high-energy discharge gas atoms hit the film surface and intrude into the film (Winters and Kay, 1967; Hoffman and Thornton, 1980). The quantity of the atoms is evaluated by heating the film (Fagen *et al.*, 1974; Lee and Oblas, 1975) and x-ray fluorescence (Cuomo and Gambino, 1977; Bayne *et al.*, 1978). The total quantity of included Ar gas atoms are observed to amount to an order of 0.01–1 at. % under usual sputtering conditions. This quantity is affected by the bias voltages applied to the substrate during sputtering. When the bias voltage is −40 V, it was reported to increase to the order of 1–10 at. % (Lee and Oblas, 1970).

5.3 Columnar Structure

The structure of sputtered films is very characteristic. The structure is called "columnar structure." The columnar structure has been observed by a number of workers in the early stage of research on thin-film structure, and it has been investigated by many workers (Dahlgren *et al.*, 1970; Thornton, 1974; Dirks and Leamy, 1977).

TEM and SEM observations show that the cross section of sputtered films is observed to be thick with crystal columns grown perpendicular to the substrate surface. This structure is peculiar not only to sputtered films but to films prepared by CVD or other production methods that use gases rather than vacuum during film formation. An example of the columnar structure of sputtered Ti and Ni films prepared by magnetron sputtering is shown in Fig. 16. On top of the Ni film, a thin Au film is formed by vacuum evaporation.

Thornton (1974) accumulated and ar-

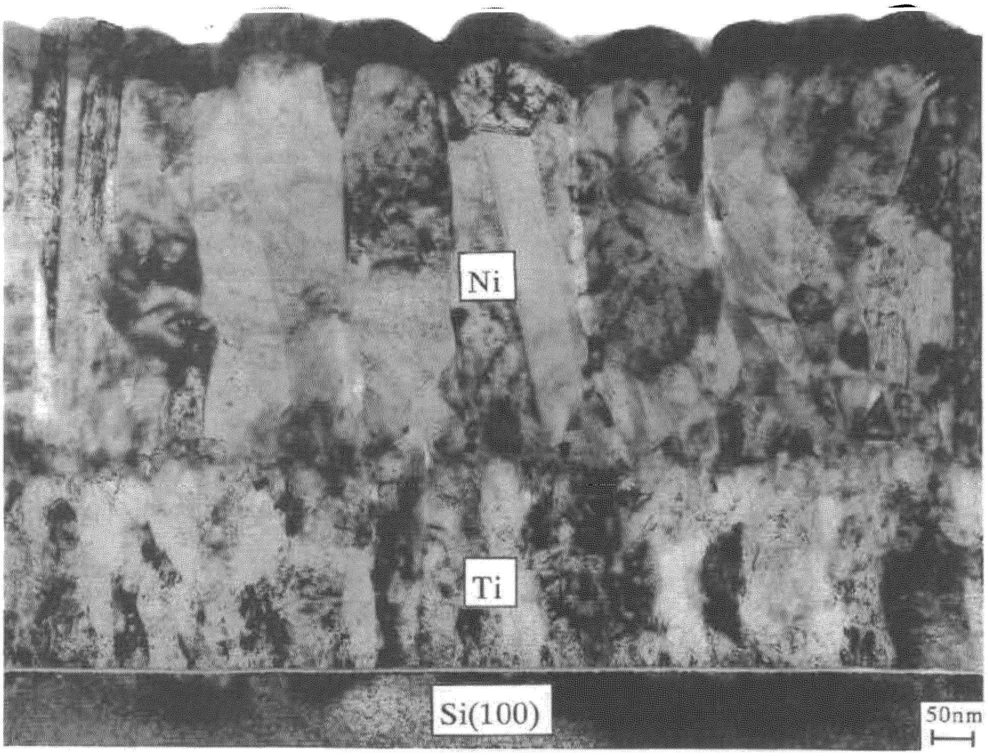

FIG. 16. Columnar structure of sputter-deposited Ti and Ni thin films (courtesy of Dr. I. Kondo, Nippondenso Co. Ltd.).

ranged the experimental data. He proposed a famous illustration of the columnar structure where sputtering-gas pressure and substrate temperature are taken as the parameters. This illustration is idealized more or less, and we occasionally observe discrepancies from this illustration in actual films, but in general, we can estimate the morphological situation of the sputtered films through this illustration. In short, the illustration shows that the columns become rough and thin at low deposition temperature and at high discharge pressure. With increasing temperature and decreasing pressure, the columns become more clear and thick and have better crystallinity. Also, the morphology of the film surface becomes flat and smooth.

One of the very peculiar features concerning the column formation is the effect of oblique incidence (Dirks and Leamy, 1977). Namely, when the incident film atoms arrive at the substrate obliquely to the normal to the substrate surface at an incident angle ϕ from the normal, then the growth direction of the axis of the column becomes ψ. It has been observed that there exists a relation between ϕ and ψ:

$$\tan\phi = 2\tan\psi. \qquad (13)$$

This relation is called the tangent rule and fits the experimental results fairly well.

In order to interpret the formation of the columnar structure and the oblique-incidence effect, computer simulations have been done by Dirks and Leamy (1977). The assumptions used in the simulation are as follows:

1. A self-shadowing effect occurs. Namely, sputtered atoms cannot arrive in the area of the shadows generated by nuclei, and islands of sputtered atoms formed on the substrate.
2. Arriving film atoms at a substrate collide with film atoms already arrived at the substrate to form nuclei. However, the movement of those atoms is hindered by

the adsorbed discharge-gas atoms on sites of the nuclei. Their movement is limited to one atomic interval.

3. The direction of arriving atom movement is random.

The simulation gives a kind of columns and, also, gives the oblique-incidence effect of the column growth, but the diameter of the columns obtained by the simulation seems to be too small. The simulation interprets the tangent rule fairly well.

5.4 Epitaxial Films by Reactive Sputtering

It is rather difficult to generate single-crystal films by the reactive sputtering method because during sputtering, growing films are always exposed to the reactive gas atoms that hinder the movement of film atoms during the film growth. The atom movement or crystallite motion is essential to form epitaxial films. However, recent studies have shown that single-crystal films are produced when the films are produced under a special condition. Horita *et al.* (1993) succeeded in producing oxide single-crystal thin films on Si substrates. They formed YSZ [yttria-stabilized zirconia, $(ZrO_2)_x(Y_2O_3)_{1-x}$] films by sputtering a Zr-Y alloy target. Before the deposition of the film, they formed an ultrathin (<1 nm) oxide layer by sputtering the target in O_2 discharge gas on the Si in order to prevent silicide formation. This metal deposition and oxidation process was repeated, and they observed the growth of fairly good single-crystal oxide thin films.

5.5 Internal Stress

Deposited thin films are well known to be in a stressed state. We call the state that the film has an internal stress. The stress is classified into two categories, namely, tensile and compressive. The internal stress of vacuum-evaporated thin films has been investigated by many workers, and common tendencies and behaviors of the stress have been understood. Most of the metal films prepared by vacuum deposition are in the tensile stress state. The stress values of many metals lie in the 10^6–10^8-Pa region. However, the stress of sputtered films depends strongly on the sputtering conditions. The stress of a given material is changed from tensile to compressive according to the conditions. Several workers investigated the internal stress as a function of the pressure of discharge gases (Thornton *et al.*, 1979; Wu, 1979). They found that the stress was tensile when the pressure of the discharge gas was high, but it changed to compressive at lower pressures. The compressive stress is ascribed to a so-called "peening" effect. This effect is essentially the irradiation of growing films by the reflected atoms at the target. When the pressure is low, the reflected high-energy atoms arrive at the film surface without being scattered by discharge-gas atoms; thus the reflected atoms maintain high energy. Hence, some atoms on the film surface are jammed into the interior of the film. They act as interstitials in the crystal lattice to expand it. The lattice expansion causes the compressive stress. This is the peening effect, and, at present, this model of the stress generation mechanism is accepted by many workers as the origin of the compressive stress of sputtered films.

6. CONCLUSIONS

The fundamentals of sputtering and its application to thin-film formation have been surveyed. Notable matters are indicated below.

Sputtering is regarded as a phenomenon connected with two-body collision. However, other effects peculiar to condensed matter such as cohesion, diffusion, radiation damage, etc. influence the sputtering. At present, simplified models have been proposed, and a formulation for dependence of sputtering yield on the energy of incident ions has been given.

One of the most effective applications of sputtering is thin-film production. In order to form thin films efficiently, a variety of sputtering methods have been developed. Ion-beam sputtering, dc-discharge sputtering, etc. have been well known. Above all, the magnetron sputtering method is now known to be one of the most excellent methods to produce thin-film devices and is widespread in industries, although other methods have their own advantages. No other method superior to this method on the whole has yet been developed in these 30 years.

Recently, reactive sputtering has been used in a wide range of industries. The apparatus is the same as the magnetron sputtering using a metal target, but the discharge gas used is a mixture of Ar and reactive gas such as oxygen, nitrogen, methane, etc. It makes it possible to produce high–melting-point inorganic compounds, ceramics, etc. This method is very useful for the production of oxides, nitrides, carbides, etc., but the process control should be drastically improved because of the instability of the discharge. For that purpose, plasma diagnostics including electromagnetic and optical measurement should be carried out more precisely during the sputtering process.

Sputter-deposited thin films include discharge-gas atoms in them such as Ar. Most of the films have a special structure called columnar structure, and often, they are in highly stressed state, but those features are complicatedly related to the sputtering conditions. These characteristics of thin films are interesting to many workers and are still in the stage of investigation.

Relatively novel technologies such as arc sputtering for high deposition rate, self-sputtering for less contamination, microsputtering for small areas, etc. have been tested. Some of them—for example, arc sputtering—have been already found practical, and some others are still in early stages of development.

In addition to the sputter deposition onto substrates of usual size, large-area sputter deposition such as the coating of window glasses of buildings has gradually been performed in industry. The homogeneity of the film thickness and the cost to produce the film by sputtering are the present points at issue. As future materials, so-called graded materials, quasi-equilibrium materials will possibly be produced by sputtering. The present sputtering technology rather depends on the know-how in individual cases. A more general and physically significant basis of sputtering technology is required.

GLOSSARY

Auger Electron Spectroscopy: An energy analysis of emitted electrons to identify species in matter by an electron bombardment. When an electron in an inner shell (K shell) of an atom is ejected by the bombardment, one electron in the upper shell (e.g., L shell) fills up the electron hole. During this process, another electron in the atom may be emitted from the atom (Auger process). The emitted electron has an energy peculiar to the atom. Hence, we can identify the material by the energy analysis of the electron.

Boltzmann's Transport Equation: A statistical equation to describe the general behavior of a distribution function of particles in phase space assuming the conservation of particle number.

Born–Mayer Potential: An exponentially decreasing potential between two particles.

Cyclotron Frequency: An electron moving perpendicularly to a homogeneous magnetic flux at a constant velocity moves on a circle of constant radius by the Lorentz force. The frequency of the circular motion is the cyclotron frequency.

Ion Implantation: The inclusion of accelerated ions in a solid by the ion bombardment of the solid.

Larmor Radius: The radius of circular electron motion in a homogeneous magnetic flux (see **Cyclotron Frequency**).

Low-Z Material: Material of low atomic number. Radiation loss of these materials in fusion plasma is smaller than that of high–atomic-number materials.

Radical: An atom or molecule that has unpaired electrons.

Raoult's Law: A law stating that the rate of the vapor pressure decrease of a solute in a dilute solution is equal to the mole fraction of the solute.

Secondary Electron Emission: Electron emission from the surface of matter or a particle by particle bombardment of the matter.

INTRODUCTION

Superconductors are best known for their ability to conduct current without developing a corresponding voltage. Perhaps a more fundamental property is the pairing of conduction electrons (see Superconductivity, Low-Temperature). This property of the microscopic charge carriers leads to the macroscopic phenomena associated with superconductivity. It also led to the invention of the most sensitive detector of magnetic flux known, the superconducting quantum interference device, or SQUID. The SQUID is, to the engineer, a magnetic flux-to-voltage transducer of unparalleled sensitivity. It is arguably the most sensitive detector of any kind, with an equivalent energy sensitivity that approaches the quantum limit. This article should serve as a starting point to any engineer or physicist who wishes to understand SQUIDs. The principles of operation, the methods of manufacture, and the applications of SQUIDs are each discussed in turn.

1. THE PRINCIPLES OF OPERATION

1.1 The Josephson Junction

The Josephson junction (Josephson, 1962) is the heart of SQUID technology. A SQUID is in essence a superconducting loop interrupted by one (rf SQUID) or two (dc SQUID) Josephson junctions. Figure 1 shows a typical junction and the Josephson equations, which govern its electrical properties. While several physical configurations are possible, the essential feature is a thin insulating layer, or a narrow constriction, between two superconductors. The Josephson equations may be derived from Ginzburg–Landau theory (1950). The essential feature of the theory is that in any particular superconductor, an order parameter ψ exists and has associated with it an arbitrary phase θ. In two *weakly connected* superconductors, the relative phase, $\delta = \theta_1 - \theta_2$, affects the electrical properties of the junction. The dc Josephson equation relates the applied current passing through the junction to the relative phase and the critical current of the junction, I_0. Notice that if $I = 0$, then $\delta = 2\pi n$; thus a bias current must flow through the junction for a physically meaningful phase difference to exist. The ac Josephson equation relates the voltage across the junction (once $I > I_0$) to the temporal derivative of δ.

To build a SQUID, the superconductors on either side of the junction must be joined, either by a loop with a second junction (dc SQUID, shown in Fig. 2a) or by a continuous superconducting loop (rf SQUID, shown in

FIG. 1. The Josephson junction and Josephson equations. A superconductor is interrupted by a thin insulating layer (cross-hatching). The phase of the superconducting order parameter ψ becomes a function of the current flow through the junction, which leads to the unique electrical properties of the junction.

Fig. 2b). A weakly connected superconducting loop is thus formed. The loop will contain flux only in multiples of the flux quantum $n\Phi_0$, where n is any integer and $\Phi_0 = 2.07 \times 10^{-15}$ Wb (see DIAMAGNETISM). Typically, the SQUID incorporates a resistor in parallel with the Josephson junction(s) to prevent hysteresis in the I-V characteristic. The equivalent circuit of the ideal, noise-free, resistively shunted junction (RSJ) consists of the Josephson junction, its physical capacitance, and the resistor, all joined in parallel, as shown in Fig. 2. Standard circuit analysis may be applied to the SQUID equivalent circuit, using Josephson's equations for the junction, and the resulting differential "equations of motion" can be solved numerically. This approach leads to the so-called washboard-potential model.

1.2 The dc SQUID

In the dc SQUID, a change in applied flux, Φ_A, leads to a phase difference across the junctions, giving rise to a voltage across the loop that we may detect. The characteristic I-V curves of the dc SQUID are shown in Fig. 3(a) for $\Phi_A = n\Phi_0$ and $\Phi_A = (n + \frac{1}{2})\Phi_0$, where n is any integer. If the bias current is held constant, the SQUID voltage will vary between two values, $V_{\min}$ and $V_{\max}$, as the flux applied to the SQUID varies between $n\Phi_0$ and $(n + \frac{1}{2})\Phi_0$. The V-Φ_A curve is thus roughly sinusoidal, as shown in Fig. 3(b), with period Φ_0. Figure 3(c) shows that a small flux modulation, $\Phi_m \sin(\omega t)$, where $\Phi_m \leq \Phi_0/2$, applied to the SQUID operating at three different points, A, B, and C, on the V-Φ_A curve will elicit three different voltage responses, V_s. At points A and C, V_s is at the same frequency as Φ_m, while at point B, where $\Phi_A = (n/2)\Phi_0$, V_s is at a frequency of 2ω. Thus the SQUID acts as a nonlinear flux-to-voltage transducer.

To linearize the V-Φ_A curve, we introduce the flux-locked loop (FLL) in Fig. 4. The FLL maintains lock by keeping the system at $\Phi = (n/2)\Phi_0$, one of the extrema in the V-Φ curve. A modulating flux $\Phi_m(\omega)$, where $\Phi_m \leq \Phi_0/2$, is applied to the SQUID, at frequency ω, by the oscillator. The response of the SQUID is fed into a lock-in amplifier, referenced to the oscillator. If the dc flux in the SQUID is a multiple of $(n/2)\Phi_0$, then the output of the SQUID is a periodic function of 2ω and the lock-in amplifier will put out 0 V dc. If the dc flux strays from an extremum by $\Delta\Phi$, then the SQUID output will contain a component at ω and the lock-in will put out a dc voltage, V_L, proportional to the amplitude of the signal at ω, as shown in the third line of Fig. 3(c). This dc signal is essentially an error signal; it is integrated and fed back into the modulation coil as $-\Delta\Phi$, returning the SQUID flux to $(n/2)\Phi_0$. The output of the loop, V_0, is a voltage proportional to the feedback current, controlled by V_L (which is proportional to $\Delta\Phi$.) The user records V_0 and relates that to the magnetic field through a prior calibration with a known field. The reader should note that many FLL oscillators put out a square-wave flux modulation with amplitude $\Phi_0/4$ and frequency ω. The system then shifts between $\Phi = (n/2 + \frac{1}{4})\Phi_0$ and $\Phi = (n/2 - \frac{1}{4})\Phi_0$, still centered on an extre-

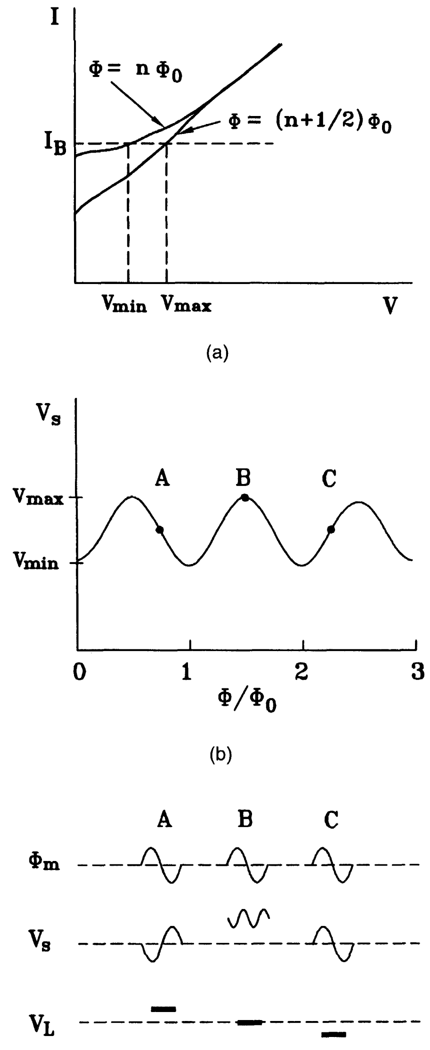
FIG. 2. (a) Schematic of a dc SQUID loop. The superconducting loop is interrupted by two Josephson junctions, marked by x. The dc SQUID is biased with a dc current. (b) Schematic of an rf SQUID loop. The rf SQUID has one Josephson junction. The rf SQUID is coupled to an rf tank circuit. The Josephson junctions are each shunted by a resistor. The physical capacitance of the junction is shown as well, because it must be considered in an accurate model of the electrical properties of the SQUID.

mum but spending very little time at the extremum.

The flux-locked SQUID has a bandwidth that is some fraction of the modulation frequency, typically 100-kHz modulation and 10-kHz bandwidth. If the applied flux changes too rapidly for the feedback electronics to track, then the SQUID jumps from one extremum to another, and the SQUID is said to have lost lock. The maximum change in flux per unit time that the system can tolerate while maintaining lock is the slew rate, typically $\approx 10^6 \Phi_0$/s.



(a)

(b)

(c)

FIG. 3. (a) The *I-V* characteristics of a dc SQUID. The amount of applied flux, Φ_A, determines the voltage output V_s for a particular value of bias current I_B. As the applied flux varies between $\Phi_A = n\Phi_0$ and $\Phi_A = (n + 1/2)\Phi_0$, the output voltage changes between V_{min} and V_{max}. (Adapted from Clarke, 1989.) (b) The *V-Φ* curve of a dc SQUID, with constant bias current. (c) The voltage response of the SQUID to a modulating flux, Φ_m. The response varies greatly depending on the value of Φ_A. Three possible points are highlighted to illustrate the response of a SQUID and the feedback needed to "lock" the SQUID to operation at an extreme value. From top to bottom we see one cycle of the flux modulation, Φ_m, applied to the SQUID operating at three different locations on the *V-Φ* curve; the voltage response of the SQUID, V_s; and the necessary feedback of the flux-locked loop, V_L, which applies a counter flux to the SQUID loop (see text), returning the system to an extreme position on the V-Φ_A curve.

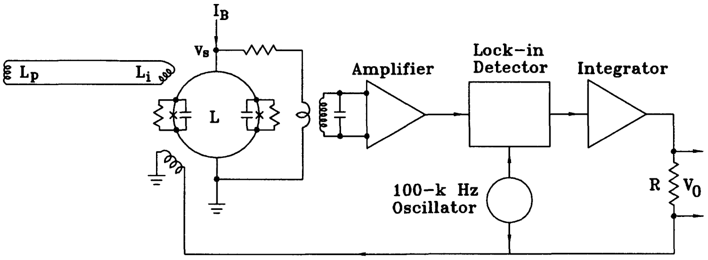


FIG. 4. Schematic of the pickup coil, input coil, SQUID and flux-locked loop (adapted from Clarke, 1989). A change in magnetic field at the pickup coil, with inductance L_p, induces a change in field at the input coil, with inductance L_i; the SQUID is inductively coupled to the input coil, and it detects a change in magnetic flux. The voltage response of the SQUID, V_s, is then fed into the flux-locked loop. The loop uses a modulating flux scheme, explained in the text, to maintain the SQUID at an extremum on the V-Φ curve. The user measures a change in V_0, which is proportional to the feedback from the loop and to the change in magnetic field at the pickup coil.

1.3 The rf SQUID

Conceptually, the operation of the rf SQUID is very similar to that of its dc counterpart. The rf SQUID is inductively coupled to a tank circuit, as shown in Fig. 2b, being driven at a frequency $f_{\mathrm{rf}} \approx$ 20–30 MHz. If the magnitude of the radio-frequency current in the tank circuit, I_{rf}, is kept constant, then the voltage across the circuit, V_{rf}, will be periodic with any flux applied to the SQUID. This holds true because of the hysteretic nature of flux in the SQUID loop. The V_{rf}-Φ curve is then linearized with a FLL in a manner similar to the dc SQUID. In this case, the modulating flux is applied through the inductor in the tank circuit.

1.4 The Pickup Coil

The SQUID is an excellent sensor of magnetic flux. To enhance its capabilities, most SQUID systems do not expose the bare SQUID to the magnetic field of interest; rather they typically employ a multiple-turn pickup coil inductively linked to the SQUID, as shown in Fig. 4. The pickup coil, with inductance L_p, is exposed to the environment, while the input coil, with inductance L_i, and the SQUID, with inductance L, are shielded from the ambient field by a superconducting niobium canister. Typical values for the inductances are $L_p = L_i = 1$ μH and $L = 0.1$ nH. Historically, all pickup coils were hand wound of superconducting wire, but in some thin-film configurations, the pickup coils are fabricated on the same chip as the SQUID or an adjacent "flip chip" using integrated circuit technology.

1.5 Noise in the SQUID

SQUID noise is quoted in different units by different members of the SQUID community. The given noise figure is generally a power spectral density in terms of energy (J/Hz), magnetic flux (Φ_0/Hz$^{1/2}$), field (fT/Hz$^{1/2}$) or field gradient [fT/(cm Hz$^{1/2}$)]. The distinction is important as one system (of special design) can have poor field sensitivity, despite superior energy sensitivity in the SQUIDs it contains. The energy and flux noise are figures of merit (FOM) for the bare SQUID, while the field and field-gradient noise are FOMs for the complete SQUID system. As a rule of thumb, the SQUID researcher quotes energy or flux noise, while the SQUID system builder begins with the flux figure and designs for the best possible field or field-gradient noise, which is of paramount interest to the end user. Typical orders of magnitude for commercial dc SQUIDs are noise energy $\epsilon = 10^{-31}$ J/Hz; magnetic flux noise $S_{\Phi}^{1/2} \sim 10^{-6}$ Φ_0/Hz$^{1/2}$; and magnetic field noise $B_N = 10$ fT/Hz$^{1/2}$.

Approximate formulas for the dc SQUID noise parameters are

$$S_{\Phi} = \frac{(4k_{\mathrm{B}}TR_D^2/R)[1 + \frac{1}{2}(I_0/I)^2]}{(R/L)^2}, \qquad (1)$$

$$\epsilon = \frac{S_\Phi}{2L}, \quad B_N = \frac{L_p + L_i}{\alpha\sqrt{L_i L}} \frac{S_\Phi^{1/2}}{A_e}, \tag{2}$$

where R_D is the dynamical resistance ($\partial V/\partial I$) of the junctions, A_e is the effective area of the pickup coil, and α is the coupling coefficient between the input coil and the SQUID. In discussing SQUID systems, the coupled energy sensitivity, ϵ/α^2, is often quoted rather than ϵ.

In the case of the rf SQUID, things are a bit more complex. The flux noise spectral density is given by

$$S_\Phi \approx \frac{(LI_0)^2}{\omega_{\mathrm{rf}}} \left(\frac{2\pi k_B T}{I_0 \Phi_0}\right)^{4/3}, \tag{3}$$

and the energy and field resolution have additional terms due to the room-temperature electronics.

Flicker or $1/f$ noise does exist in thin-film SQUIDs, but only below ~0.1 Hz does it begin to dominate in conventional niobium SQUIDs. At the current time, low-T_c dc SQUIDs are considerably less noisy than rf SQUIDS, except for rf SQUIDs operating at microwave frequencies. Thus most end users who need superior field resolution utilize dc SQUIDs. The rf SQUIDs dominated the market prior to the introduction of thin-film dc SQUIDs in the late 1970s; rf SQUIDs still command a substantial market share today.

1.6 The Digital SQUID

Digital SQUIDs attempt to replace the conventional room-temperature analog electronics of the FLL with either a room-temperature digital signal processor (DSP) or an on-chip (4.2 K) integrated Josephson-junction feedback circuit that involves flux counting. The DSP circuits are being used successfully by a growing number of research groups; the integrated digital SQUID is promising, but the technology is still immature and underperforms conventional systems. However, the interest in further development is spurred by the increasing number of channels being used in neuromagnetism. On-chip feedback would eliminate a great deal of the cost of electronics in systems of 100+ SQUIDs and allow for simpler cryogenic design as well, particularly by drastically reducing the number of wires between room temperature and the SQUIDs.

2. DESIGN AND MANUFACTURE OF SQUIDS

A single SQUID is not a particularly difficult item to manufacture. Consistently producing low-noise SQUIDs that integrate ideally into instrumentation is the technical challenge. Here we discuss the early SQUIDs, the modern thin-film SQUIDs, high-T_c SQUIDs, and the design considerations for manufacture.

2.1 Conventional SQUIDs

Some of the earliest SQUIDs were machined from blocks of niobium. Figure 5 shows two of these designs. Figure 5(a) depicts the simple "point-contact" dc SQUID (adapted from Zimmerman and Silver, 1966). The sharpened niobium screws could be adjusted, once the SQUID was immersed in liquid helium, until the proper I-V characteristic was obtained. Simple designs like this achieved flux resolution of $\sim 10^{-3}\Phi_0/\mathrm{Hz}^{1/2}$ in the late 1960s. Figure 5(b) shows a cross section of the very useful "toroidal" rf SQUID (Goodman *et al.*, 1973; Rifkin and Deaver, 1976). The smaller toroidal cavity contained the tank circuit, and the larger cavity contained the input coil, which is connected to the pickup coil. This self-screening design was a commercial success, and extensive work was done with this SQUID in biomagnetism during the late 1970s and early 1980s. The flux resolution was at least an order of magnitude better than contemporary dc SQUIDs, and the SQUID noise was white between 1 Hz and several kHz.

The modern thin-film SQUIDs are typically manufactured by sputtering of niobium thin films and patterning the films with photolithography or electron-beam lithography (see SPUTTERING; THIN-FILM DEPOSITION). In principle, any superconducting material can be used to manufacture SQUIDs, but in practice, niobium technology completely dominates the low-T_c commercial SQUID market. The junction itself may be a Nb/NbO$_x$/Pb or Nb/Al$_2$O$_3$/Nb trilayer, while the resistive shunts can be a thin film of copper, gold, or nearly any metal that does not be-

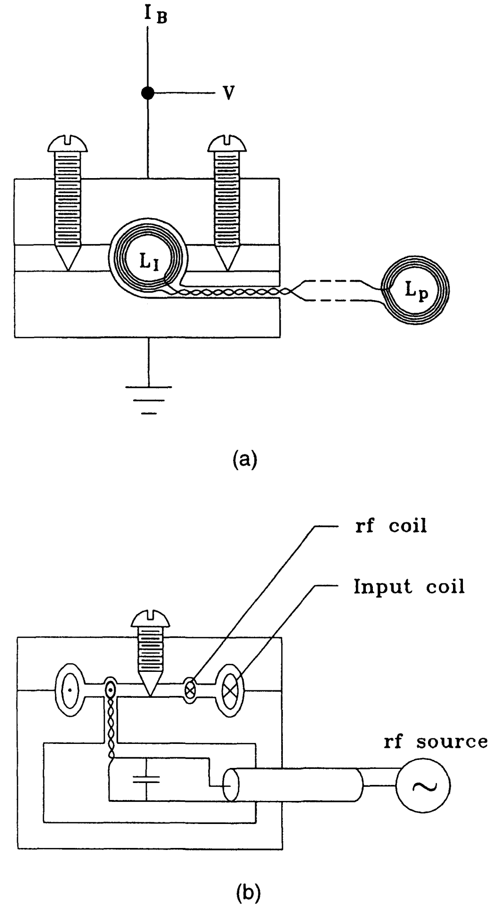

FIG. 5. Early SQUID designs machined from niobium. The Josephson junctions were made by adjusting the screws in liquid helium until the expected behavior was achieved. (a) The dc SQUID. The input coil, with inductance L_i, is linked to the pickup coil located near the magnetic sample. (b) The rf "toroidal" SQUID. The inner toroidal cavity contains the coil for the rf circuit, while a separate chamber houses the capacitor and the outer cavity holds L_i.

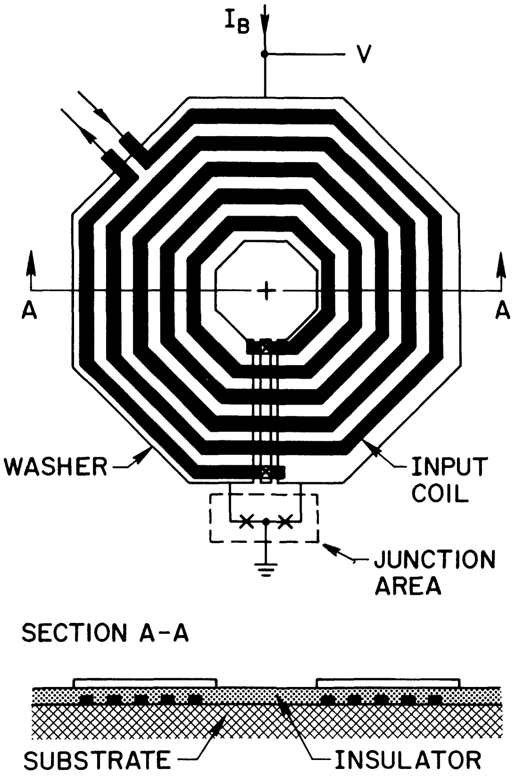

FIG. 6. A schematic drawing of a washer-type dc SQUID. The design has a very high mutual inductance between the input coil and the SQUID loop. The input coil, marked in black, is manufactured with the SQUID loop, which consists of the octagonal washer and the Josephson junctions, each marked by an x. Note that the washer is not a complete octagon; it is interrupted in two places, and the resulting bridge is used to complete the input coil. A cross section through the SQUID is shown at the bottom of the figure. The pickup coil, not shown, is connected to the input coil by the two leads in the upper left. In niobium, low-T_c technology, the entire structure is less than 1 mm across, while the junctions can be as small as 5 μm wide; the hole in the washer is typically 50–100 μm in diameter. (Courtesy of Mark Ketchen of IBM T.J. Watson Research Center.)

come superconducting at 4 K. Figure 6 shows an advanced design of the washer-type dc SQUID developed at IBM (Jaycox and Ketchen, 1981). This geometry provides SQUID loops with low inductance and hence high sensitivity, while allowing efficient coupling to an external flux transformer. Other dc SQUID designs have also been implemented for commercial SQUIDs.

The two characteristic physical parameters of a SQUID most often quoted in the literature are the reduced inductance β and the hysteresis parameter β_c, sometimes referred to as the Stewart–McCumber parameter:

$$\beta = \frac{2I_0L}{\Phi_0}, \quad \beta_c = \frac{2\pi I_0R^2C}{\Phi_0}, \qquad (4)$$

where R and C are the resistance and capacitance of the resistively shunted Josephson junction and L is the inductance of the SQUID loop. These parameters emerge quite naturally in an analysis of the differential "equations of motion" that govern operation of the dc SQUID. We see that these parameters are dimensionless, and that β is a function of the physical dimensions of the loop and the critical current of the junction, while β_c is a function of the resistively shunted junction alone. Numerical simulations of SQUIDs with various parameters have shown that for minimum noise energy β should approach unity. To avoid hysteresis β_c should be at or below 1. These conditions still give the manufacturer quite a bit of freedom, which may be used to design the SQUIDs for optimum *system* performance. To optimize the system performance, the manufacturer must achieve the highest possible signal-to-noise ratio for the signal of interest to the user in the environment of the user facility. Therefore, the system must be designed with foreknowledge of the signal of interest and the operating environment. The SQUID should be designed to couple as well as possible with the input coil, which should be impedance matched with the desired pickup coil (see below). The pickup coil must be designed to reject noise fields and to couple efficiently to the signal of interest. The designed SQUID noise should at all times be less than that of the amplifier used in the flux-locked loop. There is no single prescription for optimum performance, and SQUID design is still something of an art.

2.2 High-T_c SQUIDs

High-temperature superconductivity holds one great promise for SQUID builders and users: It will make the construction and operation of SQUID systems cheaper. The niobium SQUIDs described so far generally operate at liquid-helium temperature (4.2 K); the high-T_c systems being designed today operate at liquid-nitrogen temperature (77 K). The lower cost and greater cooling capacity of liquid nitrogen saves roughly a factor of 10^3 in the operating cost for systems in metropolitan areas and far more for remote systems. Construction costs will also be reduced as liquid-nitrogen systems are simpler and easier to build (see CRYOGENICS). The ultimate high-T_c SQUID performance will probably be inferior to the low-T_c counterpart. This is evident from the equations above for flux noise, since in dc and rf SQUIDs the flux noise scales with the temperature, i.e., by a factor of ~20.

Thin-film SQUIDs have been constructed from all the main families of high-T_c compounds: Y-Ba-Cu-O, Bi-Sr-Ca-Cu-O, and Tl-Ba-Ca-Cu-O. The material that has come to dominance is $YBa_2Cu_3O_{7-x}$. Josephson junctions have been manufactured in a number of ways using this material. The two main types of junction are grain-boundary and superconducting-normal-superconducting (SNS) junctions, i.e., $YBa_2Cu_3O_{7-x}$-N-$YBa_2Cu_3O_{7-x}$ junctions, where N represents a normal metal such as gold or silver. At the current state of the technology, the best grain-boundary SQUIDs have the lowest noise, but the best SNS junction SQUIDs are more rugged, reproducible, and manufacturable. The main difficulties with virtually all high-T_c SQUIDs fabricated to date are high $1/f$ noise below 1 Hz and poor performance when operated in weak environmental magnetic fields such as that of the Earth. The high $1/f$ noise precludes many applications in medicine and biophysics where the signals of interest have component frequencies as low as 0.05–1 Hz. Extreme sensitivity to environmental noise is a serious problem in the development of high-T_c SQUID systems, primarily because high-T_c magnetic shields and wire do not perform as well as the equivalent niobium components. This is likely to be a problem for some time, as all known high-T_c compounds are extreme type-II superconductors, which lose perfect diamagnetism at very low critical fields, H_{c1}. Electronic synthetic gradiometer systems, which incorporate multiple SQUIDs, are now being developed to allow high-T_c systems to function in noisy environments (Koch *et al.*, 1993). However, high-T_c SQUIDs already demonstrate lower noise than fluxgate magnetometers and may soon see commercial application in geophysics and nondestructive testing. The best high-T_c SQUIDs are getting better, and the optimum high-T_c SQUID is still to be made.

3. SQUID SYSTEMS

The vast majority of SQUID applications are concerned with the measurement of a magnetic field, in which the phenomenon of interest (usually a current, magnetization, or magnetic susceptibility distribution) generates a magnetic field or distorts an applied magnetic field. SQUID magnetometers, gradiometers, and susceptometers can be readily optimized for specific measurements. A typical SQUID instrument is depicted in Fig. 7. We see that the SQUIDs are located inside a small magnetic shield (e.g., superconducting niobium). Superconducting pickup coils are located at the bottom of the Dewar; the SQUID electronics are at room temperature, but close to the Dewar; and the magnetic object is placed beneath the instrument. If the experiment is conducted in an applied magnetic field, then the instrument is a susceptometer.

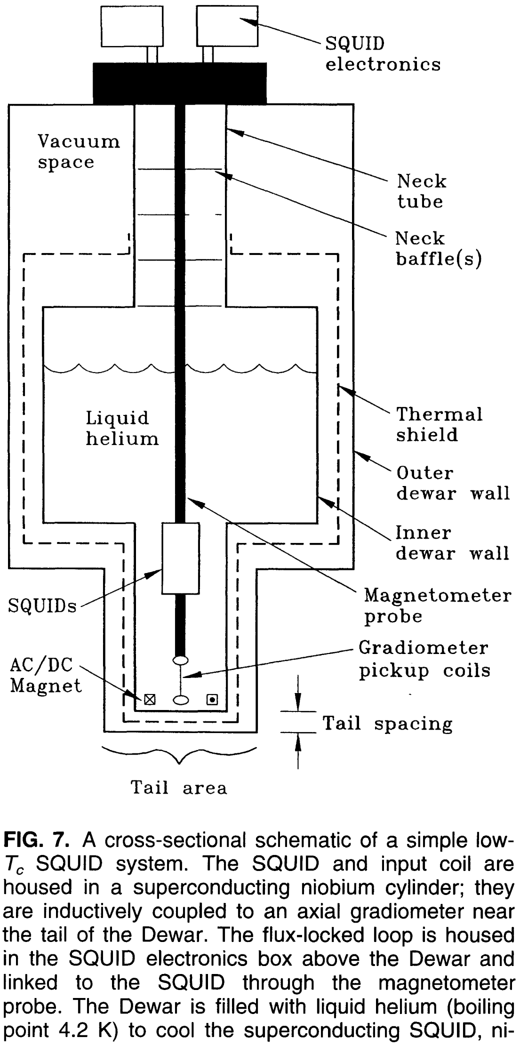

FIG. 7. A cross-sectional schematic of a simple low-T_c SQUID system. The SQUID and input coil are housed in a superconducting niobium cylinder; they are inductively coupled to an axial gradiometer near the tail of the Dewar. The flux-locked loop is housed in the SQUID electronics box above the Dewar and linked to the SQUID through the magnetometer probe. The Dewar is filled with liquid helium (boiling point 4.2 K) to cool the superconducting SQUID, niobium canister, and pickup coils. The Dewar is insulated by a vacuum space between the inner and outer walls. The instrument may be used to sense the intrinsic magnetic field of a sample or, with the magnet energized, it can measure the response of the sample to an ac or a dc magnetic field. (Adapted from Fagaly, 1990.)

3.1 Gradiometers

Although a simple single- or multiple-loop pickup coil (a magnetometer coil) can be used to measure one component of the magnetic field, such as B_z, there are a number of disadvantages to this approach, the most important of which are the contamination of the signal by environmental noise and extreme sensitivity to tilt in the Earth's magnetic field. Since the field of interest is generally orders of magnitude smaller than power-line noise, fields from passing vehicles, and radio-frequency interference, some means of background field rejection is required. This can be done either by shielding the entire experiment (as described in the next subsection), or with gradiometry. Gradiometers take advantage of the mathematical form of the falloff of magnetic fields with distance from the source. The local source of interest generates a much larger field gradient at the detector than does the more distant noise source, even though the absolute noise field is larger. Thus, by configuring coils to sense the magnetic field at two or more locations, it is possible to discriminate against the distant sources and in favor of the local one. The input coil is linked in series with two or more pickup coils, which are outside the SQUID's niobium shield. For example, we may sense $B_z(z_1)$ with one loop of the gradiometer coil and $B_z(z_2)$ with a second loop wound in the opposite sense, and the SQUID reports a voltage proportional to $\Delta B_z/\Delta z$. Commercial magnetometers are generally supplied with a hermetically sealed, shielded SQUID and two input terminals so that custom-designed gradiometers appropriate to the particular experiment and magnetic environment can be connected (see Fig. 8) (Wikswo, 1978).

3.2 Shielded Rooms

In hostile environments (such as hospitals and research facilities), the noise rejection achieved by a gradiometer may be insufficient. In these cases, the most reliable

FIG. 8. A variety of pickup coil designs and the physical quantity they measure. (a) Magnetometer. (b) First-order axial gradiometer. (c) Second-order axial gradiometer. (d) First-order planar gradiometer. (e) First-order radial gradiometer.

(though expensive) solution is to carry out measurements inside a magnetically shielded room. A closed shell (access ports can be designed that do not significantly compromise the shielding) consisting of welded aluminum plates can provide eddy-current shielding of about 100 dB above 1 Hz. At low frequencies, however, structures made from high-permeability, soft ferromagnetic materials such as Mumetal or Permalloy are required. Many practical shielded rooms employ both methods.

3.3 Cryogenic Dewar Design

Liquid helium is required to maintain conventional (low-T_c) SQUIDs and input circuits in the superconducting state. Although some continuous-flow cryostats have been used, the superconducting components are generally immersed in a helium reservoir, which is thermally insulated with a vacuum jacket containing carefully designed radiation shields. The expense of liquid helium makes the boiloff rate an important consideration. Dewars are constructed with fiberglass-reinforced epoxy, which has been found to have suitable structural and thermal properties without introducing Johnson noise, distorting uniform noise fields, or screening the magnetometer from low-frequency signals. Most magnetometer measurements can be improved by minimizing the separation between the pickup coils and the room-temperature environment, and this has led to Dewars in which the superconducting components are in the vacuum space, thermally coupled to the helium. For neuromagnetic measurements, helmet-shaped Dewars containing large numbers of SQUID channels are used, while tubular Dewars, which allow a sample to be passed through the plane of the pickup coil, are popular for low-temperature and geomagnetic research.

Dewar design (see CRYOGENICS) is critical to recently developed SQUID imaging systems (Wikswo *et al.*, 1990). These high-resolution SQUID systems are designed to measure the magnetic field very close to the surface of quasi-two-dimensional objects. The resolution of the images is determined by the size of the pickup coil and its distance from the magnetic source: For high-resolution SQUIDs, magnetic sources in living tissue that are separated by as little as a millimeter can be discriminated. Some SQUID imaging systems are designed for samples, notably superconducting thin films or integrated circuits, that can be located within the cryogenic space, so that resolution of 10 μm or better is possible.

4. APPLICATIONS

4.1 Magnetoencephalography

The human brain, consisting of some 10^9 electrically active neurons, has been at the focus of biomagnetism research ever since it became apparent that SQUID magnetometers had sufficient sensitivity to measure the tiny neuromagnetic fields (10–100 fT). The measurement, named magnetoencephalography (MEG), supplies information about the same physical process as its counterpart, the electroencephalogram (EEG). The widely cited advantage of MEG is that the magnetic field generated by cortical neurons is not distorted by the intervening bone and tissue, as are the electrical voltages recorded by the scalp EEG. The primary disadvantage is the capital and operational cost of the MEG instrumentation. Most researchers agree that a complementary approach, using both the MEG and EEG, is optimum. One of the earliest clinical MEG applications was to epilepsy. It was shown by Modena *et al.* (1982) and Barth *et al.* (1982) that interictal spikes, occurring between seizures, could sometimes be detected magnetically but not electrically. Furthermore, the magnetic signals obtained often allowed localization of the source, which could be confirmed intraoperatively. These measurements were carried out using single-channel magnetometers and were unable to characterize asynchronous events occurring simultaneously at multiple brain locations. It became clear that progress would be extremely slow until instruments were developed that could simultaneously measure the magnetic field at a large number of sites.

Commercial MEG multi-SQUID systems have evolved from 7- and 37-channel units introduced in the late 1980s and early 1990s to 128-, 122-, and 148-channel helmet systems being produced by companies in Canada, Finland, and the United States. Many of the recent MEG studies have involved an evoked response, in which a characteristic cortical response is stimulated by an external stimulus supplied to the subject. By measuring the magnetic field associated with the response, the functionality of the visual, auditory, and somatosensory areas of the cortex are mapped. Additionally, higher cortical function, such as recognition and attention, may be investigated. Another area of study is spontaneous brain activity, such as the alpha rhythm, during waking and sleeping. MEG is also used in the assessment of sensory pathways between the periphery and the brain, and in the study of stroke, multiple sclerosis, and migraine.

4.2 Magnetocardiography

The first measurement of the magnetic field of the human heart was made in 1963 using room-temperature induction coils of several million turns (Baule and McFee, 1963). Just a few years later, the SQUID sensor became available, enabling a huge improvement in signal-to-noise ratio and stimulating worldwide interest in magnetocardiography (MCG) research. As with MEG, it is felt that combined magnetic and electric measurements are more useful than a single technique alone (Stroink *et al.*, 1992). Clinical applications such as mapping the sources of arrhythmias, ventricular tachycardia, and Wolff-Parkinson-White syndrome may benefit from the development of multichannel instruments. High-resolution SQUIDs have also been used in experimental studies of cardiac tissue slices (Staton *et al.*, 1993), which have contributed to the development of mathematical models of cardiac electrophysiology, and in studies of cortical activity (Okada *et al.*, 1992).

4.3 Other Biomagnetic Studies

SQUID magnetometers have also been used in a number of other biomagnetic applications. By applying a magnetic field to the liver and scanning it with a magnetometer, a susceptibility signal is measured that may be used to estimate the level of stored iron. Unlike the alternative, needle biopsy, this technique is noninvasive and may prove useful in the assessment of hemochromatosis. Magnetic tracers can be used in conjunction with SQUID magnetometers to measure gastrointestinal transit times and in the study of the internal dynamics of cells.

4.4 Geomagnetism

The geomagnetic work done with SQUIDs is primarily divided into paleomagnetism and prospecting. Paleomagnetism is the study of the magnetization of ancient rock for the purpose of understanding the geological history of the region from which the rock was excavated. Prospecting is the search for valuable ore or oil beneath the earth. This may be done by applying a low-frequency electromagnetic field to the earth and measuring the magnetic and electric response. By probing at different frequencies, it is possible to determine for the region a profile of the conductivity as a function of depth. This profile is then correlated with geological data to determine the composition of the various strata. Geological mapping of the magnetization of the earth may prove very useful in other ways. In particular changes in the maps over time may be useful in the prediction of earthquakes. Increased stress at the junction of tectonic plates could produce a measurable change in the magnetization of the region.

4.5 Nondestructive Testing

One new field of SQUID research that has attracted considerable interest is nondestructive evaluation (NDE). The NDE SQUID magnetometry efforts of the past decade include flaw characterization, analysis of magnetic properties of materials, and corrosion study. In most of these areas, a measurement of the magnetic field is made at multiple locations in the vicinity of a test object, and a map or image of the field is recorded. Magnetic field sources can be intrinsic in the test object as in the case of galvanic currents flowing in a corroding pipe, or may be excited by an external source. The external field excitation can be done either magnetically or electrically. With magnetic excitation, the test object is placed within a relatively strong magnetic field, whereas a dc or an ac current is established in the sample for electrical excitation using the current injection or current induction method. In the injection method, the metal is directly connected to a current source; for current induction, eddy currents are generated within the inspected region by a coil, wire, or plate carrying an ac current.

The advantages of SQUID NDE are high sensitivity, wide bandwidth (from dc to 10 kHz), and a large dynamic range. The high sensitivity of the SQUID allows one to make engineering and design compromises to reduce cost, enhance signal strength for particular types of flaws, and still remain orders of magnitude more sensitive than other means of magnetic anomaly detection. The ability of SQUID detectors to function down to zero frequency allows them to sense much deeper flaws than traditional eddy-current sensors and to detect and monitor the flow of steady-state corrosion currents. Demonstration experiments have been performed on a wide range of samples, from tracing current in a printed circuit to detecting parasites in fish, but no clear market niche has yet been established.

4.6 Other Applications

It is often said that there are as many SQUID applications as there are SQUID researchers; this is most likely a conservative estimate. This section attempts to show something of the breadth of SQUID research.

There are a number of applications of SQUIDs that do not involve an entire SQUID magnetometer system. A SQUID can be configured to perform as a sensitive picovoltmeter (Clarke, 1966) for a variety of applications, including the measurement of thermoelectric voltages and the study of superconductor mechanisms. The sensitivity of these devices can be on the order of tens of $\mathrm{fV/Hz^{1/2}}$. SQUIDs are also used in gravity gradiometers (Paik, 1981) and gravitational-wave detectors (Michelson *et al.,* 1987), where they are configured to sense minute displacements. There has been some development of SQUIDs as radio-frequency amplifiers (Hilbert and Clarke, 1985) and as magnetic resonance detectors (Hilbert *et al.,* 1985). Finally, SQUIDs have been used for a number of fundamental physical measurements, including an investigation into the possible existence of fractional flux quantization (Cabrera *et al.,* 1989), measurement of the Cooper pair mass (Cabrera and Peskin, 1989), and the search for magnetic monopoles (Huber *et al.,* 1990).

GLOSSARY

Bare SQUID: A SQUID operated in the ambient magnetic field, with no magnetic shielding. Typical for the current high-T_c SQUIDs.

Critical Current: The maximum current a superconductor can carry without dissipating energy.

Flicker Noise: Also known as $1/f$ noise. Noise, present in nearly all electrical circuits, with a characteristic rise in amplitude with decreasing frequency.

Fluxoid: The quantum unit of flux, $\Phi_0 = 2.07 \times 10^{-15}$ Wb.

High-T_c Superconductor: Any of a family of ceramic superconductors, discovered in the 1980s, with transition temperatures as high as 133 K.

Magnetocardiography: The study of the magnetic field of the heart.

Magnetoencephalography: The study of the magnetic field of the brain.

Nondestructive Evaluation: The examination of materials or components, without impairing their future usefulness, in order to detect defects and determine serviceability.

SQUID Triangles: The roughly sinusoidal curve of voltage vs applied flux, V_s-Φ_A, of the current-biased bare SQUID.

Tank Circuit: A resonant *L-C* circuit.

Tuning the SQUID: Adjusting the bias current I_B to achieve the largest voltage response V_s for a small change in applied flux, $\Delta\Phi \leq \frac{1}{2}\Phi_0$.

INTRODUCTION: THE NATURE OF DATA ANALYSIS

The term *data analysis* admits no universally accepted or understood definition. It differs from applied statistics in that the usual restrictive assumptions, such as normality and independence, are not expected to hold. Here we think of data analysis as a collection of techniques, having their origins in a variety of disciplines, that are used in a coordinated fashion to elucidate the useful structure in a (possibly) complicated collection of recorded information. Many of the techniques used in data analysis were first developed by nonstatisticians to attack specific problems in their respective fields of interest. For example, the method of least squares (introduced by Legendre in 1805) was first used in astronomy and geodesy. Similarly, researchers in high-energy physics have created a number of novel techniques such as the *projection pursuit* algorithm (Friedman and Tukey, 1974) for looking at high-dimensional data. Unfortunately, we can discuss only a limited number of topics in this short survey article, but we hope that our selection will prove interesting and useful to professionals in the physical sciences who work with experimental or observational data. We strongly recommend that the reader seek out more detailed discussions of the topics presented here. The Works Cited and Further Reading lists should provide a good start in that direction.

We first give a brief treatment of measurement errors to motivate the need for statistical techniques in the physical sciences. Then we discuss three broad, but interconnected, topics: exploratory data analysis, classical and modern mathematical statistics, and statistical graphics. Finally, we briefly review the use of computers in data analysis and the resources available for doing data analysis in a modern computing environment.

1. MEASUREMENTS IN THE PHYSICAL SCIENCES

The scientific method requires that a proposed theory of nature be falsifiable. We usually test a theory by comparing its predictions with experimental or observational measurements. Ideally, we would like an experimental design that would produce unequivocal indications when the theory is false, but we rarely get that. Errors will inevitably accompany even our best experiments, and we must accept some uncertainty when we decide whether the measurements do or do not confirm the predictions of the theory. Therefore, it is important that we quantify the measurement uncertainty. An example of the importance of calculating and reporting measurement uncertainty was an early test of the general theory of relativity. Einstein predicted that starlight just grazing the rim of the sun would deflect by 1.75 s of arc (Einstein, 1915, p. 831; Misner *et al.*, 1971). A crucial test of his prediction came on 29 May 1919, during a total eclipse of the sun, observed by English scientific expeditions to Sobral in Brazil and to Principe Island off the west coast of Equatorial Guinea. On 6 November 1919, Sir Arthur Eddington reported that the measured deflection was $1''.98 \pm 0''.30$ at Sobral and $1''.61 \pm 0''.30$ at Principe (Bertotti *et al.*, 1962; Moyer, 1979). The scientific community regarded the eclipse data as confirmation of the general theory of relativity, and Einstein became an instant worldwide celebrity (Pais, 1982, pp. 299–324). Note that the two uncertainty intervals overlap each other, and both cover Einstein's prediction of $1''.75$, but not the Newtonian value of $0''.875$, based on a classical particle moving with a speed c in a hyperbolic orbit past the Sun. Without the report of the uncertainty of the measurements, this early confirmation of the general theory of relativity would have had less credibility. In fact, had Eddington averaged the solar deflection values to get $1''.80$ and reported a combined uncertainty of $0''.21$, the prediction would have been even more spectacular. Eddington's reason for not combining the values may have been that he thought it possible that one or both of them were biased.

1.1 Measurement as a Control Process

Making measurements is similar to a production process: A sequence of prescribed operations produces an end product. Sometimes the end product is merely a number from a sensor; more often it is the result of a data reduction procedure, which could be as simple as an arithmetic mean or so complex it takes many hours to execute on a fast computing machine. Like the production process, the measurement process needs to be in a state of *statistical control*, with statistical properties that are invariant in time. The use of *control charts* (Shewhart, 1931; Grant and Leavenworth, 1980) to monitor statistical control is recommended. When a state of control is achieved, we can assume that the universe of observations is stable, and it makes sense to describe the observations in terms of a probability distribution with fixed parameters that can be claimed to represent physical reality.

Statistical control is just as important in the scientific laboratory as in the factory, and the dicta laid down by Deming (1950) for statistical process monitoring apply. In particular, we should not attempt to use statistical methods to compensate for a measurement process that lacks control. Instead, the root cause of the problem (e.g., instrument failure, procedures, environment, personal, etc.) should be identified and corrected.

1.2 Measurement Error

We use the 1993 definitions of measurement error provided by International Standards Organization (ISO, 1993a, 1993b), presented in Table 1.

Table 1. ISO definitions relative to modeling measurement systems.

Term	Definition
Error of a measurement	Result of a measurement minus the true value of the measurand.[a]
Random error of a measurement	Result of a measurement minus the mean that would result from an infinite number of measurements of the same measurand carried out under conditions of repeatability.[b]
Systematic error of a measurement	Mean that would result from an infinite number of measurements minus a true value of the measurand.[c]

[a] Since a true value cannot be determined in practice, a conventional value is used.

[b] (1) Random error is equal to error minus systematic error. (2) Random error can only be estimated for a finite set of measurements.

[c] (1) Systematic error is error minus random error. (2) Systematic error cannot be completely quantified. Like the true value, it cannot be completely known.

The simplest model for a measurement process in a state of statistical control without systematic error is given by the equation

$$x_i = \mu + \delta + \epsilon_i; \quad i = 1, 2, \ldots, n. \tag{1}$$

The parameter μ represents the true value of the quantity being measured; δ is a constant (systematic) error; and the ϵ_i represent the random errors (in the sense defined in Table 1) in the measurement system. The ϵ_i are zero-mean, independent, identically distributed random variables with a common finite variance σ^2. [Although Eisenhart (1963) has criticized the concept of error as the difference between the measured value and the true value as operationally meaningless, it is often useful to consider a true value as being a result that would be provided by an idealization of the measurement process.] In many cases μ itself is a random variable because the value of the quantity under measurement is not constant. The optimum estimate of μ (in the sense of maximum likelihood) depends on the probability distribution of the errors ϵ_i. If the distribution is known, then the analyst can craft the form of the estimator to have optimal statistical properties. However, in practice the analyst rarely knows the distribution of errors; frequently he simply assumes it to be normal—thus the ubiquitous use of the mean in reducing experimental data. However, even in a state of statistical control, the distribution of errors need not be normal and could be asymmetrical with a long tail; in this case the arithmetic mean will perform very poorly. In such cases *robust* statistical procedures are helpful. Robustness is a somewhat vague property of statistical procedures. Informally, a robust procedure performs well under both the assumed distribution and departures from the assumptions. This subject is treated in more detail in Sec. 3.

2. BASIC STATISTICAL CONCEPTS

What is the difference between the subject of probability and the subject of statistics? While statistical methods use the theory of probability, the two subjects are different. It is possible to take courses in probability and yet learn little about the subject of statistics. In a nutshell, probability is the forward problem, while statistics is the inverse problem. In probability problems, we postulate the parameters of various distributions, and we make predictions of outcomes (data). The conceptual flow is from model to data. In doing statistical problems, we are given outcomes (data), and we make inferences about a model that describes the process that created the data. The conceptual flow is from data to model. The subject of probability tends to use deductive reasoning, while statistics uses inductive reasoning. In this sense statistics is really similar to the basic scientific endeavor: make observations and inductively proceed to learn about the world.

2.1 Population and Sample

One of the most basic distinctions in statistics is that between population and sample. A *population* is a finite or infinite set of objects, where each object has one or more attributes of interest. Usually, we study a population by making observations on a finite *sample* from the population, and then make inferences to the population as a whole. In some situations, the population is an abstraction; we pretend that the data we have is but one realization of what might have been. The philosophical problems with this conceptualization of statistical inference have caused some (DeFinetti, 1972; Ramsey, 1980; Lindley, 1985) to adopt a completely subjective interpretation of statistics—the Bayesian approach, as opposed to the frequentist approach. The frequentists consider the parameters in statistical models as fixed (but unknown) quantities that are to be estimated from the observed data. It is the parameter *estimator* that is random and not the parameter. In contrast, Bayesians consider the estimators as the given data and the parameters as random. These must be assigned a prior distribution of possible values based on the information about the parameters that is available before observations. The observations (data) then modify the prior distribution to produce a new distribution called the posterior distribution. While the vast majority of professional statisticians would regard themselves as frequentists, it must be said that the Bayesian approach is both well thought out and logical. A number of statisticians have opted for an eclectic approach, using one or the other approach depending on the nature of the problem at issue. Our discussions here are frequentist; Efron (1978) provides an excellent review on the controversy between the subjective and objective viewpoints.

2.2 Random Variables

Mathematically we define a random variable as a mapping that assigns a number to a random outcome. The term "random variable" is somewhat confusing; a more appropriate term would be "random function," where the domain would be the set of experimental outcomes and the range would be the set of real numbers. Random variables provide the basic machinery for the mathematical theory of statistics. The idea of a variable that can appear with varying degrees of probability does not occur in ordinary analysis or in mathematical logic. Nevertheless, random variables are an extremely useful concept in statistics because we can operate on them as if they were ordinary numbers, subject to the laws of arithmetic. Random variables can appear in sums, products, ratios, or powers, or as the elements in infinite series, vectors, matrices, or tensors. Random variables can also appear as the arguments of functions, or as the coefficients of differential equations. The common practice in mathematical statistics is to use upper-case roman letters to denote random variables and lower-case roman letters to denote the numerical values that the random variables can assume.

A random variable is completely defined by its *distribution function* $F(x)$ (also called the cumulative distribution function), which is the probability that the random variable X has a value less than some given number, say x. Thus we can make statements such as

$$P[X < x] = F(x). \qquad (2)$$

In this equation, the term on the left is a statement of probability, the symbol P being shorthand for using the word "probability." The symbol X denotes some random variable, while x denotes a real number. In contrast, the term on the right is conventional, in the sense that we can substitute some function for the variable F and some number for the variable x and get a meaningful statement. Thus if we substitute "3" for x and "multiply by 0.02 and square" for F, we get a meaningful statement that has a truth value:

$$P[X < 3] = (0.2 \times 3)^2. \tag{3}$$

On the other hand, we cannot substitute any of the common mathematical objects for X and get a meaningful statement.

If the set of possible numerical values for a random variable is finite or countably infinite, then the random variable is said to be *discrete,* and we can write

$$P[X = x_k] = p_k, \quad k = 1, 2, \ldots. \tag{4}$$

If there is a function $f(\cdot)$ such that we can write the distribution as

$$F(x) = \int_{-\infty}^{x} f(t)dt, \tag{5}$$

then the random variable is said to be continuous, and $f(x)$ is called the *probability density* function of the random variable whose distribution function is F.

2.3 Expectations

An important topic in the mathematical theory of statistics is the *expectation* $E[X]$, the expected or mean value of a random variable X; it is the first moment of its probability density function:

$$E[X] = \int_{-\infty}^{\infty} xf(x)dx \text{ (continuous variable)}, \tag{6}$$

$$E[X] = \sum_{k=1}^{\infty} p_k x_k \text{ (discrete variable)}. \tag{7}$$

For a discrete distribution the expected value need not be a realization (example: the mean number of children per family is 2.31). Indeed, for some distributions, the expected value does not exist because the integral does not converge.

Is the expectation value in some sense expected? Yes. According to the (weak) *law of large numbers,* the average becomes less dispersed about the expectation value of the parent distribution as n increases:

$$\lim_{n\to\infty} \{P(|\bar{x}_n - E[X]|)\} > \epsilon] = 0, \quad \bar{x}_n = \frac{1}{n}\sum_{i=1}^{n} x_i. \tag{8}$$

where ϵ is any positive number.

The *variance* is the expectation of the square of the random variable about its mean:

$$\mathrm{Var}[X] = E[(x - E[X])^2]. \tag{9}$$

The variance provides a measure of how dispersed the realizations of the random variable are about the mean. The mean and the variance give a summary description of the random variable, and when the distribution function is Gaussian, these two quantities completely characterize it.

2.4 Moments of Distributions

There are other important numerical characteristics of a random variable, namely, its higher-order moments. The rth moment μ_r' of X is defined as

$$\mu_r' = E[x^r], \tag{10}$$

and the moments centered about the mean are given by

$$\mu_r = E[(X - \mu_1')^r]. \tag{11}$$

The second centered moment is the variance.

Do the moments—when they exist—completely characterize a random variable? For most distributions of practical interest the answer is yes. Two distributions with equal moments for all orders would be identical. A notable exception is the lognormal (frequently used to model particle sizes). This distribution is not uniquely determined by its moments in the sense that the infinite sequence of moments for any given lognormal distribution could also belong to another distinct distribution.

Why are moments important in statistics? Why not stay with distributions? The answer is that we need moments because in general it is much more difficult to get an estimate of the distribution function from data than it is to get estimates of the moments. Data sampling a single random variable (univariate data) with a Gaussian distribution, for example, requires knowledge of only the first two moments (two numbers). On the other hand, multivariate data (i.e., data sampling distributions of multiple random variables) are far more complex. For Gaussian data of dimension k, we need k first-order moments, and $k(k + 1)/2$ independent second-order moments and joint moments (the elements of a symmetric matrix of dimension k), for a total of $k(k + 3)/2$ independent numbers [$k(k + 1)$ numbers in all]. Finally, for non-Gaussian multivariate data, we need knowledge of higher-order moments and joint moments—tensor quantities (McCullagh, 1987).

The moments of a distribution (when they exist) may be found from the *characteristic function,* which is essentially the Fourier transform of its density function:

$$\phi(t) = E(e^{itX}) = \int_{-\infty}^{\infty} f(x)e^{itX}dx = 1 + \sum_{k=1}^{\infty} \mu_k' \frac{(it)^k}{k!}, \tag{12}$$

and

$$\mu_r' = (-i)^r\left[\frac{d^r\phi(t)}{dt^r}\right]_{t=0}. \tag{13}$$

In some cases the moments may exist and not the characteristic function. For example, the lognormal distribution has moments given by

$$\mu_r' = \exp(r\zeta + r^2\sigma^2/2), \tag{14}$$

where ζ and σ are parameters of the distribution, but the characteristic function does not exist (the moment expansion series does not converge). The problem lies in the fact that other distributions have the same moment sequence. Kendall *et al.* (1983) present a detailed discussion of when the moments uniquely determine a distribution.

The logarithm of the characteristic function defines the *cumulants* or *semi-invariants* κ_r of the distribution:

$$\ln \phi(t) = \sum_{r=1}^{\infty} \kappa^r \frac{(it)^r}{r!}, \tag{15}$$

$$\kappa_r = (-i)^r\left[\frac{d^r \ln \phi(t)}{dt^r}\right]_{t=0}. \tag{16}$$

The first two cumulants, κ_1 (the mean of the distribution) and κ_2 (the variance), provide measures of the location and spread of the distribution, while those of higher order give more subtle information. For example, the third cumulant, κ_3, the third central moment, measures asymmetry in the sense that for all symmetrical distributions, κ_3 vanishes. However, to guarantee symmetry, all odd-order cumulants must vanish, and the distribution must be determined by its moments.

There is a one-to-one correspondence between the cumulants κ_r and the moments μ_r or μ_r'. The conversion formulas for the first four orders in each direction are

$$\kappa_1 = \mu_1', \tag{17a}$$

$$\kappa_2 = \mu_2 = \mu_2' - \mu_1'^2, \tag{17b}$$

$$\kappa_3 = \mu_3 = \mu_3' - 3\mu_2'\mu_1' + 2\mu_1'^3, \tag{17c}$$

$$\kappa_4 = \mu_4 - 3\mu_2^2 = \mu_4' - 4\mu_3'\mu_1' - 3\mu_2'^2 + 12\mu_2'\mu_1'^2 - 6\mu_1'^4, \tag{17d}$$

and

$$\mu_1' = \kappa_1, \quad \mu_1 = 0; \tag{18a}$$

$$\mu_2' = \kappa_2 + \kappa_1^2, \quad \mu_2 = \kappa_2; \tag{18b}$$

$$\mu_3' = \kappa_3 + 3\kappa_1\kappa_2 + \kappa_1^3, \quad \mu_3 = \kappa_3; \tag{18c}$$

$$\mu_4' = \kappa_4 + 4\kappa_1\kappa_3 + 3\kappa_2^2 + 6\kappa_2\kappa_1^2 + \kappa_1^4, \quad \mu_4 = \kappa_4 + 3\kappa_2^2. \tag{18d}$$

Kendall *et al.* (1983) provide conversions between moments and cumulants up to order ten.

Two important properties of cumulants are scaling,

$$\kappa_r(aX + b) = a^r\kappa_r(X), \quad r > 1, \tag{19a}$$

$$\kappa_1(aX + b) = a\kappa_1(X) + b, \tag{19b}$$

and additivity,

$$\kappa_r\left(\sum X_i\right) = \sum \kappa_r(X_i). \tag{19c}$$

Central moments of all orders are scalable in this sense, but only μ_2 and μ_1 are additive.

2.5 The Ubiquitous Normal Distribution

The normal distribution (also called the Gaussian distribution) plays a key role in the theory of statistics and data analysis. It seems to dominate the subject both in theory and in practice. The normal or Gaussian probability density of mean μ and variance σ^2 is

$$f(x) = \frac{1}{(2\pi)^{1/2}\sigma}\exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right]. \tag{20}$$

A popular shorthand way to denote that a random variable X is normally distributed with mean μ and variance σ^2 is $X \sim N(\mu,\sigma^2)$.

What are the salient mathematical properties of the normal distribution that make it so useful? First, we note that the normal distribution is uniquely determined by its mean and variance, since all its higher-order cumulants vanish. Hence any other continuous distribution with appropriately small higher-order cumulants can be approximated by a normal distribution with the same mean and variance. We can gain more insight from the following observation: The cumulants of the average of n independent identically distributed random variables are given simply by $n\kappa_r/n^r$. Therefore, as n increases, the higher-order cumulants vanish much faster than the first two, and the distribution of the average approaches that of the normal distribution. This explains the famous central-limit theorem (Gnedenko and Kolmogorov, 1954).

Another important mathematical property of the normal distribution is its entropy. The normal distribution has the maximum entropy for all continuous distributions that vanish nowhere and have finite second moments (Cover and Thomas, 1991). Since entropy is a measure of uncertainty, the normal distribution is a maximum-uncertainty distribution. This makes the normal distribution the appropriate model for many random phenomena. See the seminal article on this subject by Jaynes (1957).

2.6 Estimation and Efficiency

A common problem in statistical analysis is the estimation of the parameters of the distribution of a parent population from a sample of observations. In general the estimate is expressed as some function of the observations. The numerical value that the function takes is called a *statistic.* Since the observations are random variables, the statistic is random. If we use the statistic to estimate the unknown parameter(s) say, θ, then in a sequence of repeated realizations of the observations, the statistic will fluctuate about the true value of the parameter. A statistical estimator is an algorithm that operates on the data under consideration to yield one (or more) numerical value that corresponds to the distribution parameter(s). Good estimators will give values that are close (in some well-defined sense) to the true value of the parameter. The estimator, being itself a random variable, has a distribution, and the quality of the estimator will depend on this distribution. The distributions of many estimators approach normality as the sample size increases (asymptotic normality) because of the central-limit theorem. Hence the asymptotic properties of the estimator are described by the expectation and variance of the distribution of the estimator. If the mean equals the unknown parameter, the estimator is unbiased; if the mean tends to the parameter as the sample size increases, the estimator is asymptotically unbiased. The variance of the estimator provides a measure of the quality known as its efficiency. The asymptotically normal estimator with the smallest variance for a given sample size n as $n \to \infty$ is known as the *efficient* estimator. The asymptotic relative efficiency (ARE) of a given parameter estimator is the ratio of the variance of the efficient estimator for that parameter to the variance of the given estimator. The ARE is then a number less than 1 (100%) and measures the effectiveness of an estimator relative to the best estimator for the same parameter. The ARE is an important concept for exploratory data analysis.

A powerful parametric estimation technique whose extensive use in statistical analysis was pioneered by Fischer uses the maximum-likelihood principle. Assume n statistically independent observations sampling the same distribution, $\{x_1,x_2,\ldots,x_n\}$. Furthermore, assume for simplicity that the distribution is a function of a single parameter θ. The joint probability of the n observations as a function of θ is called the likelihood function and can be written (in a Bayesian sense) as

$$L(x|\theta) = f(x_1|\theta)f(x_2|\theta)\cdots f(x_n|\theta), \tag{21}$$

where $f(x|\theta)$ stands for a generic, univariate or multivariate, continuous or discrete distribution. The maximum-likelihood principle chooses θ, the maximum-likelihood estimator of θ, as the value that maximizes $L(x|\theta)$. For a large class of distributions satisfying certain restrictions, the maximum-likelihood estimator is asymptotically normal and efficient.

3. EXPLORATORY DATA ANALYSIS

The analysis of data usually consists of two phases, exploratory and confirmatory. In the exploratory phase the analyst seeks to discover important patterns and features in the data without the knowledge of a specific probability model. On the other hand, the confirmatory phase is both more formal and more technical; it uses the mathematical methods of statistical inference to draw conclusions from observations and to assign a measure of uncertainty to the conclusions. Sometimes the results of the exploratory phase are so convincing that the analyst may skip the confirmatory phase. We emphasize that there is no set recipe for doing exploratory data analysis. Scientists and statisticians have always done some form of exploratory analysis in the course of their work. Four basic themes permeate the practice of exploratory data analysis: resistance, residuals, transformation, and display (Hoaglin, 1983). Analysts usually use all four themes in combination in a given analysis. We present various tools that we believe are especially helpful.

3.1 Resistant and Robust Estimators

The working style of classical parametric statistical estimation is to derive optimal estimates of parameters in distributional models. For example, the sample variance s^2 of the population variance σ^2, defined by

$$s^2 = \frac{1}{n-1}\sum (x_i - \bar{x})^2, \tag{22}$$

is an unbiased and (asymptotically) optimally efficient estimator. Unfortunately, in classical statistical estimation, we are dealing with functionals on the space of probability distributions that are nowhere continuous in any statistically reasonable topology (Hampel, 1973). Because of this lack of continuity, the classical estimators often become extremely suboptimal for even small changes in the assumed distribution. Hampel points out that mathematical theorems on optimality can be dangerous and misleading when applied to real-world data. For example, if we sample from a contaminated normal distribution, the estimate of the population standard deviation becomes extremely suboptimal (Tukey, 1960). Just how small a contamination will induce a significant drop in efficiency is surprising. An example of a contaminated normal is given by

$$F(x) = (1 - \epsilon)\Phi(x) + \epsilon\Phi(x/3), \tag{23}$$

where Φ is the standard (mean 0, standard deviation 1) normal distribution. The contaminated normal given by Eq. (23) has slightly thicker tails than a normal distribution, depending on the value of ϵ. For $\epsilon = 0.0018$ (which means that we sample from the outlier distribution only once in 550 trials), the mean deviation, given by

$$\frac{1}{n}\sum_{i=1}^{n} |x_i - \bar{x}|, \tag{24}$$

becomes more efficient than the standard deviation. For many situations this amount of contamination would be undetectable from the data alone.

Some theorems from mathematical statistics appear to give results that require no assumption of a distribution. For example, the Gauss–Markov theorem states that for any distribution, the arithmetic mean provides a minimum-variance estimate of the mean of the distribution. But this requires the existence of a mean and a finite variance, and cases arise where this requirement is not satisfied. An extreme example, but nevertheless one that often approximates reality, is the Cauchy distribution with density function

$$f(x) = \frac{1}{\pi}\frac{b}{b^2 + (x - a)^2}\,. \tag{25}$$

The sample mean does not estimate the center of symmetry a because the first moment about the point a is undefined. In this case we would need a robust estimator, such as the median, to estimate the parameter a.

The subject of robust estimation attempts to deal in a systematic fashion with these problems. Tukey (Andrews *et al.*, 1972) refers to robust statistics (in analogy with computers) as "third-generation statistics," after parametric statistics and nonparametric statistics. In general, robustness refers to the property of resistivity to changes from assumed "standard conditions." A *resistant* estimator is one that is insensitive to aberrations or outliers in the data. Resistance can be considered a numerical property, while robustness is more of a statistical property. The most important robustness property is the robustness of *efficiency*. An estimator has robustness of efficiency if its variance is minimal or nearly so across a range of distributions. Estimators that are both resistant and robust are essential for exploratory data analysis.

An *outlier* is an observation that deviates strongly from the bulk of the data—it appears not to belong to the rest of the data. Frequent causes of outliers in physical science data are equipment failures, software bugs, transcription errors, and faulty experimental procedure. However, sometimes such observations arise from the very nature of the population under study. An outlier is definable only with respect to a model distribution, and if the observation represents an improbable sample from the assumed distribution, the analyst must decide if the observation is extraneous, and does not belong to the population, or if the model must be changed. Thus, the distinction between outliers and data can be subtle; a sample from some non-normal distributions will naturally have observations that look like outliers. Only if we know the underlying distribution can we craft the appropriate estimator, with optimal or nearly optimal properties such as efficiency, using the mathematical theory of statistics. But this is not within the spirit of exploratory data analysis, where we usually do not know the distribution. Mathematically this means that we need estimators that are nearly optimal (or at least not severely suboptimal) for the normal distribution as well as for a broad class of non-normal distributions. This problem was the subject of much empirical and theoretical research in statistics during the 1970s. Before we discuss those results, we review a few basic concepts.

3.1.1 Resistant Estimates of Location

First we review estimates of *location*, or the central tendency of the data. The mean is an estimate of location. Given a set of observations that we label $x_1, x_2, \ldots, x_N$, the sample mean $\bar{x}$, calculated by

$$\bar{x} = \frac{1}{N}\sum_{i-1}^{N} x_i, \tag{26}$$

is an estimate of the first moment of the probability density $f(x)$:

$$\int_{-\infty}^{\infty} xf(x)dx. \tag{27}$$

When the density function is the normal or Gaussian density [Eq. (20)], the sample mean is an optimal estimator for the first moment μ. However, even one aberrant observation can sometimes cause the mean to produce misleading results. Thus for exploratory data analysis, we need to replace the mean by a resistant estimator such as the *median*. The median is calculated by finding the value such that half of the observations are larger and half are smaller. While the median is resistant, it is not the most statistically efficient estimator across a broad range of distributions. For example, when the data are normal, the median has only $2/\pi$ the efficiency of the mean. However, if the median is substituted for the mean only when the difference between the two is large, then an efficiency of 90%–95% can be achieved, depending on the sample size (Andrews *et al.*, 1972). A number of very sophisticated computer-intensive estimators of location are also available (Mosteller and Tukey, 1977; Hoaglin, 1983).

3.1.2 Resistant Estimates of Scale

The sample standard deviation

$$\text{s.d.} = \left[\frac{1}{N-1}\sum_{i=1}^{N}(x_i - \bar{x})^2\right]^{1/2} \tag{28}$$

provides an estimate of the spread or *scale* of the data, but like the mean it lacks both resistance and robustness, and we need a substitute for exploratory data analysis. Scale estimators should be location invariant and scale equivalent: If w is measure of scale, then

$$w(a + bx_1, a + bx_2, \ldots, a + bx_N) = |b| w(x_1, x_2, \ldots, x_N). \quad (29)$$

The standard deviation has this property, as well the median absolute deviation (MAD) defined by

$$\mathrm{MAD} = \mathrm{median}\{|x_1 - M|, |x_2 - M|, \times \ldots, |x_N - M|\}, \quad (30a)$$

$$M = \mathrm{median}\{x_1, x_2, \ldots, x_N\}. \quad (30b)$$

An estimate of the standard deviation of an assumed normal population is then given by

$$s = (2/\pi)\mathrm{MAD}. \quad (31)$$

Simulation studies (Lax, 1975; Tukey *et al.*, 1977) indicate that MAD has good robustness and resistance for a broad range of heavy-tailed non-Gaussian distributions, but it is not highly efficient for Gaussian data.

3.1.3 The Resistant Line

Given bivariate data (x_i, y_i), we often want to fit a straight line of the form

$$y_i = \alpha + \beta x_i, \quad i = 1, 2, \ldots, N. \quad (32)$$

The usual technique is to use the method of least squares, which has no resistance to aberrant observations—a single point can dominate the fit. Fortunately, there is a technique for bivariate data based on medians that does provide a resistant fit.

The technique works by dividing the data into three groups, a left, middle, and right group, each with about the same number of points. For each group the medians of the x and y values are calculated. This produces three summary points, (x_L, y_L), (x_M, y_M), and (x_R, y_R). The slope is then calculated by

$$\hat{\beta} = (y_R - y_L)/(x_R - x_L), \quad (33)$$

and the intercept is given by

$$\hat{\alpha} = \tfrac{1}{3}[(y_L - \hat{\beta}x_L) + (y_M - \hat{\beta}x_M) + (y_R - \hat{\beta}x_R)]. \quad (34)$$

However, it is more convenient to work with the line recentered about the median of all the x values:

$$\hat{y} = \alpha^* + \hat{\beta}(x - x_M). \quad (35)$$

The quantity α^* is called the *level*. The residuals from the conventional least-squares fit,

$$\hat{\epsilon}_i = y_i - (\hat{\alpha} + \hat{\beta}x_i), \quad (36)$$

have the following property: When another line is fitted to the residuals by least squares, the slope and level are zero. However, this will not be the case with the resistant line fit. To preserve this desirable property, we must adjust the level and slope by an iterative procedure until the residuals become nearly zero. Each step in the iteration uses the residuals from the prior step to get a new resistant fit with slope and level updated as follows:

$$\hat{\beta}_1 = \hat{\beta}_0 + \delta_1, \quad \hat{\beta}_2 = \hat{\beta}_1 + \delta_2, \ldots. \quad (37)$$

Here δ_1 is the slope from the resistant fit to the residuals from the initial fit, and so on. The levels are updated in a similar fashion. Convergence problems can occur for some data sets, but safe iteration schemes are available (Johnstone and Velleman, 1981), as well as published software for doing resistant fits (Velleman and Hoaglin, 1981).

3.2 Looking at Residuals in an Exploratory Analysis

The residuals are what remain after a summary or fitted model is subtracted from the data. A careful examination of the residuals is an essential step in an exploratory analysis. When resistant techniques (such as the resistant line) are used to do fitting, aberrant points will produce dramatically extreme residuals. Graphical display of the residuals is also essential to reveal any systemic patterns in the residuals, which would indicate that the chosen fit model is not appropriate.

3.3 Transformation of Data

Transformation of the data (also called *re-expression*) is the process of finding the appropriate scale (e.g., logarithmic or square root) that simplifies the analysis. Transformations are used to make data with a skewed distribution more symmetrical, to stabilize the spread across different groups, or to make the variance more nearly constant. For example, data that consist of counts (e.g., neutron counting) often fit the Poisson distribution,

$$p(k) = e^{-\lambda}\lambda^k/k!, \tag{38}$$

where k is the number of counts detected in a fixed interval, and λ is the corresponding mean. The variance of the Poisson distribution equals its mean, and therefore Poisson-distributed counts exhibit increasing variance with increasing intensity. This often complicates the analysis or processing of such data. However, the square root of the Poisson counts has a variance asymptotically equal to 1/4.

3.4 Transformations to Induce Normality

Since the normal distribution has very convenient properties and has been extensively studied, it is frequently desirable to transform random variables to a form that is normally or approximately normally distributed. The transformation of the correlation coefficient provides a good example. If $x_1, x_2, \ldots x_n$ and $y_1, y_2, \ldots y_n$ are samples from a bivariate normal distribution with population correlation coefficient ρ, then the sample correlation coefficient r is bounded, $-1 \le r \le 1$, and thus poorly represented by a normal distribution. Therefore the following transformation (Fisher, 1915) is appropriate:

$$Z = \tfrac{1}{2}\ln\frac{1+r}{1-r} = \operatorname{artanh}(r). \tag{39}$$

The transformed variable Z has the range $-\infty \le Z \le \infty$; it is approximately normally distributed and has mean and variance given by (Gayen 1951)

$$E(Z) = \operatorname{artanh}(\rho) + \frac{\rho}{2(n-1)} \times \left(1 + \frac{5+\rho^2}{4(n-1)}\right) + o(n^{-2}), \tag{40a}$$

$$\operatorname{var}(Z) = \frac{1}{n-1} \times \left\{1 + \frac{4-\rho^2}{2(n-1)} + \frac{22-6\rho^2-3\rho^4}{16(n-1)^2}\right\} + o(n^{-3}). \tag{40b}$$

Using the Fisher Z transform, the analyst can test the sample correlation against any assumed value for the true correlation ρ. For example, how large a sample correlation r do we need to have a reasonable (2σ) confidence that the true correlation ρ is nonzero? The Fisher Z transform readily answers this question: For $n = 10$, $|r| > 0.6$; for $n = 30$, $|r| > 0.4$; and for $n = 100$, $|r| > 0.2$ (assuming, again, a normal population). The Fisher Z transform should be used with care, however; r is neither robust nor resistant, and outliers could render this test useless.

4. ESTIMATION AND ERROR ANALYSIS

4.1 Parametric Estimation

Generally when we make observations (measurements) in the physical sciences, we think of the observations as a sample from some conceptual (if not actual) population of possible observations. Our interest focuses on the *variation* within the population. Sometimes we regard the variation as a nuisance effect (noise), while at other times the variation is itself the object of study. These ideas lead to the subject of *parameter estimation*. In the frequentist approach to statistics, we describe the population by some probability distribution with fixed (nonrandom) unknown parameters. Here the sample space is on the data. In contrast, in the Bayesian approach, the sample space is defined on the parameters; the observations are taken as fixed quantities, and a probability distribution is assigned to the parameters to be estimated. In this section, we adopt the frequentist approach, where the parameter *estimate* is a random quantity calculated from the random data, as opposed to the parameter *value* that we wish to estimate.

Given a set of data (the sample), we need to deal with two basic questions:

1. What function of the data do we use to estimate the unknown parameter?
2. How accurate is the estimate?

First, we discuss the classical approach using linear unbiased minimum-variance estimates (LUMVE) [or best linear unbiased estimates (BLUE)]. The classical approach requires some knowledge of the parametric form of the distribution that describes the data. Later, we briefly discuss computer-intensive approaches to parameter estimation that require much less knowledge of the distribution that describes the data—usually only statistical independence of the samples.

4.1.1 Single Estimate with Known Variance If the set $\{y_1,y_2,\ldots y_N\}$ represents values assumed to be drawn from a population with variance σ^2 and a fixed, but unknown, mean μ, then

$$\bar{y} = m'_1 = \frac{1}{N}\sum_{i=1}^{N} y_n \tag{41}$$

is the best estimate of μ in the sense that of all the linear combinations of the observations $\{y_1,y_2,\ldots,y_N\}$ with expectation μ, it has the smallest variance. The variance of $\bar{y}$ is σ^2/N.

If the observations $y_1, y_2, \ldots, y_N$ are drawn from a set of populations with different variances but a common mean μ, then the weighted average

$$\bar{y} = \frac{1}{W}\sum_{i=1}^{N} w_n y_n \text{ with } W = \sum_{i=1}^{N} w_n \tag{42}$$

is an unbiased estimate of μ. Furthermore, if we set $w_n = 1/\sigma^2$, then the weighted average becomes a minimum-variance unbiased estimate with variance σ^2. This statement of the problem is somewhat unrealistic because usually we do not know σ^2, although we might have a good estimate from prior experiments or from the underlying physical theory. The reciprocal of the variance is often called the precision (Frodesen *et al.*, 1979) of the measurement. A commonly made error is to combine measurements or estimates with unequal precisions without using the appropriate weighting factors.

4.1.2 Single Estimate with Unknown Variance If neither the mean nor the variance of the population is known, both must be estimated from the data. An unbiased estimate of σ^2 is provided by

$$s^2 = \frac{1}{N-1}\sum_{n=1}^{N}(y_n - \bar{y})^2 = \frac{N}{N-1}(m'_2 - m'^2_1), \tag{43}$$

where

$$m_k = \frac{1}{N}\sum_{n=1}^{N} y_n^k. \tag{44}$$

Sample moments are denoted by m_k and m'_k to distinguish them from the population moments μ_k and μ'_k. Strictly speaking, s^2 is the sample estimate of the variance of the distribution of y, but it is common to call it simply the sample variance. The variance of the sample, $m_2 = m'_2 - m'^2_1$, gives the maximum-likelihood estimate of the variance of the distribution of y, but it is a biased estimate. The variance of $\bar{y}$ as an estimate of μ (the variance of $\bar{y} - \mu$) is σ^2/n; this itself is estimated by s^2/n. The variance of s^2 is $2\sigma^4/(N - 1)$ for y_n drawn from a normal distribution.

4.1.3 Multiple Estimates—Least-Squares Fitting An important problem in data analysis is the fitting of models to data. By "model," we mean some linear or nonlinear relation between one or more independent variables (also called explanatory variables, regressors, or carriers) x_i and a dependent variable (or response) y_i, usually expressed in the form of an explicit equation. Least squares has been the predominant method of fitting models to data for almost 200 years despite the many criticisms of its shortcomings. Virtually every general textbook on statistics treats the subject, sometimes to the exclusion of all others, and any treatment of data analysis would be deficient without a thorough discussion of this important topic. The method owes its popularity to its simplicity and mathematical tractability. It is basically a numerical technique and can be treated without recourse to its statistical connections, as is typically done in textbooks on numerical analysis, where least squares is generally discussed in the context of solving overdetermined systems of linear equations.

The method of least squares had its origins in scientific data analysis, specifically in various empirical investigations in astronomy and geodesy where it was necessary to combine measurements in order to estimate certain quantities. While most scientists and mathematicians would regard Gauss (1809) as the progenitor of the method of least squares, priority in publication belongs to Legendre (1805). Evidently conditions were ripe for its discovery because Adrain (1808) independently discovered and published the method in America at about the same time. Many statisticians still feel that Legendre's exposition is unsurpassed in its lucidity (Stigler, 1986). He proposed the idea of minimizing the sum of squared errors and derived what we now call the normal equations. Legendre offered no proofs for the superiority of this technique, whereas Gauss deduced his first proof of the normal law of error from the postulate that the arithmetic mean is the most probable value associated with a set of equally good measurements.

In many situations the set of data $\{y_1,y_2,\ldots y_N\}$ does not consist of observations of a single quantity y, but values of different quantities that may often be reduced to a set of observations y_n ($n = 1, 2, \ldots N$) of expressions $g_n(x_1,x_2,\ldots,x_M;p_j)$ containing M unknown quantities x_i as well as known parameters p_j. The functions g_n might be the same function evaluated for different values of the known parameters, or the set $y_n = g_n(x_i)$ may be physically different quantities. For the application of least squares it is only necessary that at least one subset of M expressions $y_n = g_n(x_i)$ can be solved for a unique set of values of the M unknowns x_i. Then, if $N > M$, the least-squares algorithm will provide the best estimate of the set of M unknown quantities, in the same sense that an appropriately weighted mean provides the best estimate of the value of a single variable.

4.1.3.1 The Linear Case. The simplest situation involves expressions in which the quantities to be determined appear linearly. A typical example is the determination of the coefficients a_i in the expansion of an expression in terms of a set of base functions:

$$y(z) \approx Y(z) = \sum a_i f_i(z). \tag{45}$$

The given data are the pairs (z_n,y_n), $n = 1, 2, \ldots, N$, and the weights w_n. If the observations are independent (two different observations y_n and y_m are uncorrelated), then we have $w_n = 1/\sigma_N^2$, the reciprocal of the variance of the distribution from which the observation y_n is assumed to be drawn, under the assumption that the value of z_n is exact. The weights may also be relative values whose normalization s_0^2 (the variance to be assigned to unit weight) will be determined from the "goodness of fit" of the data. The estimate of the variance σ_n^2 is then given by $s_n^2 = s_0^2/w_n$.

The fitted coefficients a_i are found from

$$a_i = \sum_{j=1}^{M} V_{ij}Z_j, \tag{46}$$

where V_{ij} are elements of the covariance matrix V, the inverse of the weight matrix W:

$$(V^{-1})_{ij} = W_{ij} = \sum_{n=1}^{N} w_n f_i(z_n) f_j(z_n), \tag{47}$$

and the z_j are given by

$$z_j = \sum_{n=1}^{N} w_n f_j(z_n). \tag{48}$$

The variance of a fitted value of $y(z)$ (interpolated or extrapolated) is given by

$$\sigma^2(y) = \sum_{ij} f_i(z) V_{ij} f_j(z). \tag{49}$$

It is convenient to use an orthonormal basis for the set $f_i(z)$ with the inner product defined in terms of a finite summation, giving the orthonormality condition expressed by

$$\sum_n f_i(z_n) f_j(z_n) = \delta_{ij}; \tag{50}$$

however, the standard orthogonal functions (such as Legendre polynomials) are usually defined over a continuous interval, with the inner product defined by integration over that interval, and in this case orthonormality is expressed by

$$\int f_i(z) f_j(z) dz = \delta_{ij}. \tag{51}$$

Since the finite sum only approximates the integral even if the data points are uniformly spaced, the matrix W fails to be diagonal. Appropriate selection of the data points z_n can preserve orthogonality, but this is usually not an option. Alternatively, polynomials that are orthogonal over the specific data set can be generated. If the basis set is orthogonal over the data, the weight matrix **W** is diagonal and the expansion coefficients are independently evaluated: $a_i = Z_i/W_{ii}$. In general, with an approximately orthogonal basis, the weight matrix **W** will be approximately diagonal, and the off-diagonal terms will be small ($W_{ij}^2 \ll W_{ii}W_{jj}$). This has advantages for computational precision ($V_{ii} = W_{ii}^{-1}$), as well as in the physical interpretation of the fitted coefficients, which are then approximately statistically independent.

The "goodness of fit" of the data is measured by

$$S^2 = \sum_{n=1}^{N} w_n(y_n - \hat{Y}_n)^2 = \sum_{n=1}^{N} y_n w_n y_n - \sum_{ij=1}^{M} Z_i V_{ij} Z_j, \tag{52}$$

where $\hat{Y}_n$ is the fitted value of y_n. If the weights w_n are the reciprocals of the variances of the input data y_n, the distribution of S^2, considered as a sampling from a population defined by the distributions of the y_n, is the χ^2 distribution with $\nu = N - M$ degrees of freedom.

If $(S^2 - \nu)/\sqrt{2\nu - 1} \gg 1$, the fitted residuals are inconsistent with the precision of the observations and the fit can be improved by including additional functions f_i in the basis set. Basis functions should be retained or added to the fit if their inclusion produces a significant decrease in the value of S^2/ν. (If the basis set is not orthogonal, the presence of an additional basis function will alter the contributions of the existing functions to the value of S^2).

If w_n are only relative weights, S^2 is only proportional to a χ^2-distributed variable; the weights (and the variances) can be normalized by multiplying each w_n by the factor ν/S^2, and the covariance matrix **V** by the factor S^2/ν. In this case, χ^2 can no longer be used as a basis for evaluating "goodness of fit."

4.1.3.2 Example: Fitting Data by a Straight Line. If the data set (x_n, y_n, w_n) is to be fitted by a straight line $y = a + bx$, the fitted values of a and b are

$$a^* = (1/D)(S_y S_{xx} - S_{xy} S_x), \tag{53a}$$

$$b^* = (1/D)(S_1 S_{xy} - S_x S_y), \tag{53b}$$

with $S_1 = \Sigma_n w_n$, $S_x = \Sigma_n w_n x_n$, $S_{xx} = \Sigma_n w_n x_n^2$, $S_y = \Sigma_n w_n y_n$, $S_{xy} = \Sigma_n w_n x_n y_n$, $S_{yy} = \Sigma_n w_n y_n^2$, and $D = S_1 S_{xx} - S_x^2$. The covariance matrix of the fitted coefficients is

$$\begin{pmatrix} V_{aa} & V_{ab} \\ V_{ba} & V_{bb} \end{pmatrix} = \frac{1}{D}\begin{pmatrix} S_{xx} & -S_x \\ -S_x & S_1 \end{pmatrix}. \tag{54}$$

The goodness of fit is

$$S^2 = \sum_n w_n(y_n - a^* - b^* x_n)^2 = S_{yy} - a^* S_y - b^* S_{xy} \tag{55}$$

with $\nu = N - 2$ degrees of freedom.

The variance $s^2(y)$ of a point on the fitted line $y = a^* + b^* x$ is given by

$$s^2(y) = \left(\frac{S^2}{\nu}\right)\frac{1}{S_1}\left(1 + \frac{(xS_1 - S_x)^2}{D}\right) = \left(\frac{S^2}{\nu}\right)\left(\frac{1}{S_1} + \frac{(x - \bar{x})^2}{S_{xx} - S_x^2/S_1}\right), \tag{56}$$

where

$$\bar{x} = \frac{S_x}{S_1} = \frac{\sum w_n x_n}{\sum w_n} \tag{57}$$

is the mean value of x in the data. If the weights w_n are the reciprocals of the variances of the observed values y_n, the first factor in parentheses may be omitted and the variance evaluated on the basis of "internal consistency"; including the first factor produces the variances evaluated on the basis of "external consistency." If a straight line is a valid representation of the data, and if the data are in fact independent with variances $1/w_n$, the two expressions are equally valid estimates of the variance since in this case the expectation of $S^2 = \chi^2$ is $\nu = N - 2$. If χ^2/ν lies outside acceptable limits, the data should be examined for possible inconsistencies, or refitted by some other curve, or the weights may be accepted as relative values. When the assigned weights are not based on *a priori* information on the variances of the data but have only relative significance, the factor S^2/ν (which is an evaluation of the uncertainty to be associated with unit weight) normalizes the variances of the data based on the mean square deviation of the data from the fitted straight line.

4.1.3.3 Nonlinear Data, Linear Approximation. When the functional relationships between the observations and the unknown quantities are not linear, the least-squares algorithm may be applied to a linearized set of equations. Let x_i^0 be a set of approximations to the unknown quantities x_i, and introduce a new set of quantities u_i and z_n. The simplest choice is $x_i = x_i^0 + u_i$ and $y_n = g_n(x_i^0) + z_n$. A first-order Taylor expansion of the observational equations then leads to a linearized set

$$z_n = \sum_{i=3}^{M} \left.\frac{\partial g_n}{\partial x_i}\right|_{x_j} u_i + e_n, \tag{58}$$

where e_n is the residual error. Equivalent expressions are obtained by writing either $x_i = x_i^0(1 + u_i')$ and $y_n = g_n(x_i^0)(1 + z_n)$ or $u_i'' = \ln(x_i/x_i^0)$ and $z_n = \ln(y_n/g_n(x_i^0))$.

The solution of this set of equations has the same form as the solution given above for linear least squares with the identification

$$W_{ij} = \sum_{n=1}^{N} \frac{\partial g_n}{\partial x_i}, \quad Z_j = \sum_{n=1}^{N} \frac{\partial g_n}{\partial x_i} w_n z_n,$$
$$u_i = \sum_{i=1}^{M} V_{ij} Z_j, \quad \text{where } \mathbf{V} = \mathbf{W}^{-1}. \tag{59}$$

4.1.3.4 Matrix Formulation. Let the linearized approximation of the observational equations be expressed as

$$\mathbf{z} = \mathbf{y} - \mathbf{y}^0 = \mathbf{Au} + \mathbf{e}, \tag{60}$$

where $\mathbf{y}$ is a vector of observed data, $\mathbf{x}^0 + \mathbf{u}$ is the vector of parameters to be fitted in the least-squares adjustment, and $\mathbf{A}$ is a known matrix. The elements of $\mathbf{A}$ are $\partial y_n/\partial x_i$ ($N \times M$ matrix), evaluated at the set of fixed values, from which the data z_n and u_i represent deviations. The *input covariance matrix* $\mathbf{v}$ comprises the variances and covariances of $\mathbf{e}$ for the input data ($N \times M$). The input weight matrix is the reciprocal matrix $\mathbf{w} = \mathbf{v}^{-1}$. The output estimates of the least-squares fit are

$$\mathbf{u}^* + \mathbf{VA'wz} \text{ with } \mathbf{V} = (\mathbf{A'wA})^{-1}, \tag{61}$$

where the prime indicates the transposed matrix. The weight matrix for the fitted quantities is $\mathbf{W} = \mathbf{A'wA} = \mathbf{V}^{-1}$ and the covariance matrix is $\mathbf{V} = \mathbf{W}^{-1}$. The adjusted data are $\mathbf{y}^* = \mathbf{y}^0 + \mathbf{Au}^*$; the residuals of the fitting are $\mathbf{r} = \mathbf{y} - \mathbf{y}^* = \mathbf{Dz} - \mathbf{z}^* = \mathbf{z} - \mathbf{Au}^*$.

The data $\eta = \mathbf{y} - \mathbf{y}^0$ span a vector space with metric $\mathbf{w}$; in this space length can be defined: $|\mathbf{a}| = \mathbf{a'wa}$, and the scalar product of $\mathbf{a}$ and $\mathbf{b}$ is $\mathbf{a'wb}$. The matrix $\mathbf{P} = \mathbf{A}(\mathbf{A'wA})^{-1}\mathbf{A'w}$ is a projection operator:

$$\mathbf{PP} = \mathbf{P} \text{ and clearly } \mathbf{wP} = \mathbf{P'w}. \tag{62}$$

The space of the observed data, $S(z)$, is separated into two orthogonal subspaces, $S(Pz)$ and $S(r)$;

$$z = Pz + r, \quad r = z - Pz,$$
$$z'wPr = z'wP(z - Pz) = 0. \tag{63}$$

The goodness of fit is given by

$$S^2 = r'wr = z'wr = z'wz - (u^*)'Wu^*. \tag{64}$$

4.1.4 Student's Distribution When x is drawn from a Gaussian distribution, the probability of a value of $|\bar{x}|/\sigma_{\bar{x}}$ larger than t_p may be easily calculated from the tabulated values of the normal distribution; but for small sample sizes, where we have only an estimate of the variance, we must take into account the uncertainty in that estimate. For a normal distribution, the variance of s^2 is $2\sigma^4/n$. When the data are normal and the estimate s^2 is based on a sample of size n, the ratio $(\bar{y} - \mu)/\bar{y}$ has a Student's distribution (Student, 1908) with $\nu = n - 1$ degrees of freedom. For $\nu \gg 1$, the ratio

$$\sqrt{\frac{\nu - 2}{\nu}}\,\frac{\bar{y} - \mu}{s} \tag{65}$$

has a distribution that is approximately normal with zero mean and unit variance, whereas for $\nu = 1$, the Student distribution is a Cauchy distribution.

4.2 Error Propagation

Errors in the variables of a function will produce errors in its evaluation. If the errors in a set of measurements are assumed to be random variables, the result will be a random variable. Let the error in x_i be ϵ_i; then η, the error in y, is

$$\eta = \sum_i \frac{\partial f}{\partial w_i} \epsilon_i + \tfrac{1}{2} \sum_{i,j} \frac{\partial^2 f}{\partial w_i \partial w_j} \epsilon_i \epsilon_j + \ldots . \tag{66}$$

If the errors ϵ_i have means δ_i (systematic error) and a covariance matrix (random error)

$$v_{ij} = \overline{\epsilon_i \epsilon_j} - \delta_i \delta_j, \tag{67}$$

the mean value and variance of y are

$$\bar{y} = f(x_i^0) + \sum_i \frac{\partial f}{\partial x_i} \delta_i + \tfrac{1}{2} \sum_{i,j} \frac{\partial^2 f}{\partial x_i \partial x_j} (\delta_i \delta_j + v_{ij}) + \ldots = f(x_i^0 + \delta_i) + \tfrac{1}{2} \sum_{i,j} \frac{\partial^2 f}{\partial x_i \partial x_j} v_{ij} + \ldots \tag{68}$$

and

$$\sigma^2(y) = \sum_{i,j} \frac{\partial f}{\partial x_i} \frac{\partial f}{\partial x_j} v_{ij} + \ldots . \tag{69}$$

If the errors are uncorrelated, then $v_{ij} = \sigma_i^2 \delta_{ij}$, and Eq. (69) becomes

$$\sigma^2(y) = \sum_{i,j} \left(\frac{\partial f}{\partial x_i} \right)^2 \sigma_i^2 + \ldots . \tag{70}$$

For a function of a single variable x with variance σ^2, the mean and variance of y are

$$\bar{y} = f(x) + \tfrac{1}{2} f''(x) \sigma^2 + \ldots , \tag{71a}$$

$$\sigma^2(y) = [f'(x)]^2 \sigma^2. \tag{71b}$$

Since, in the evaluation of experimental data, the true means x_i are not known but are only approximated, the second-derivative terms in $\bar{y}$ may often be omitted, since they can be much smaller than the unknown contributions from the first-order errors.

4.3 Bayesian Statistics, Inverse Probability

The joint probability density of x and y, $p(x,y)$, can be written in two equivalent forms:

$$p(x,y)dxdy = p(x|y)dxp_2(y)dy = p(y|x)dyp_1dx, \tag{72}$$

where $p(x|y)dx$ is the conditional probability of the occurrence of x when it is known that y has occurred, and $p(y|x)dy$ is the conditional probability of the occurrence of y when it is known that x has occurred. When the distribution of x depends on a parameter (or set of parameters) denoted by y, the probability density of x for a fixed set of parameters is $p(x|y)$. The unconditioned (or *a priori*) probability densities of x and y are

$$p_1(x) = \int p(x|y)p_2(y)dy, \tag{73a}$$

$$p_2(y) = \int p(y|x)p_1(x)dx, \tag{73b}$$

and hence

$$p(y|x) = \frac{p(x|y)p(y)}{\int p(x|y')p(y')dy'} \tag{74}$$

(Bayes's theorem). The conditional probability $p(y|x)$ is also known as the *a posteriori* probability.

Probability theory is concerned with the properties of the distribution of x for a given set of parameters (the mean, variance, etc.). Bayes's theorem provides the basis for determining estimates of the values of the unknown parameters from a set of observations $p(y|x)$ when the observed data are considered to be given quantities rather than sampled random variables (inverse probability).

4.4 Measurement Uncertainty

The observed variability of the results of a physical measurement is often related to the measurement process itself rather than to a variability in the value of the quantity being measured; the data do not represent a sampling from a population of different objects, but from a population of approximate observations of a unique quantity. In the evaluation of a measurement, one is presented with a set of observations y_j from which, on the basis of the available information, an inference is to be made about the "best" value to be assigned to that quantity. The stated result is incomplete unless it is accompanied by an indication of the *uncertainty* to be attached to the stated value. This uncertainty describes neither the *error* in the measurement nor the distribution of possible errors—a given measurement result has only a single, unknown, error.

The *analysis of error* of a measurement process is based on the introduction of a statistical distribution, considered as an ensemble of results that could be obtained in repetitions of the measurement process. The distribution of errors is then described in terms of the means and variances of the given process. By itself, the error distribution is unable to describe fixed *systematic errors* that are unchanged in every repetition. These must be treated separately.

Uncertainty is the incompleteness of the knowledge of the value of the measurand associated with the given result of a measurement. It comprises, in general, many components, some of which may be evaluated from the statistical distribution of the results of series of measurements; other components are evaluated from assumed probability distributions on the basis of experience and external information. The quantitative measure of this (also called "uncertainty") is a parameter that characterizes the dispersion of the values that could reasonably be attributed to the measurand, recognizing that the stated measurement result itself should be the best available estimate of that value.

The evaluation of uncertainty is based on *inverse probability*. Whereas error analysis cannot treat fixed systematic errors to which a random variable cannot be assigned, uncertainty is based on the degree of belief in the values of quantities, both "random" and "systematic," that contribute to the lack of knowledge of the quantity being measured (the measurand).

A measurement of the quantity Y yields a result y. The error in this measurement is $\epsilon = Y - y$, although the concept of measurement error as the difference between true value and measured value can be criticized as being not meaningful operationally. If the measurement is repeated many times, it is appropriate to consider the distribution of the errors ϵ_i. The error ϵ can be expressed as the sum of a random error ϵ_r with zero mean and a specified variance, and a fixed systematic error ϵ_s with zero variance and nonzero mean. In order to specify this decomposition, it is necessary to consider "faithful realizations" of a defined measurement process, such that the statistical frequency distribution remains fixed. On this basis one can describe the error of the measurement process.

For a given set of observations, the observed mean $\bar{y}$ may be taken as the best estimate of $Y + \epsilon_s$; an estimate δ of the systematic error is also required in order to obtain $\bar{y} - \delta$, the estimate of Y that is the result of the measurement. Specifying the measurement uncertainty requires an evaluation of the uncertainty of each of the components. If all that is known about the systematic error is that ϵ_s lies between a and b, the best estimate is $\delta = (a + b)/2$, and the uncertainty of this estimate is $u^2(\epsilon_s) = (b - a)^2/12$. This result is equivalent to assuming a uniform distribution for ϵ_s between the limits a and b, but it can also be defined from a Bayesian approach based on maximum-entropy considerations, without the specific introduction of a probability distribution. The Bayesian viewpoint considers the data to be fixed quantities, not samples from a distribution.

Uncertainty components, which are equivalent to variances, and more generally to the elements of a covariance matrix, combine like variances. When $y = F(\xi_1, \xi_2, \ldots)$, where $\xi_1, \xi_2, \ldots$ represents the full set of all quantities (random or systematic) contributing to the uncertainty of F, the uncertainty is given by

$$u^2(F) = \sum_j \left(\frac{\partial F}{\partial \xi_j}\right)^2 u_j^2 + 2 \sum_{k<j} \frac{\partial F}{\partial \xi_j} \frac{\partial F}{\partial \xi_k} u_{jk}. \qquad (75)$$

All uncertainties are treated equally, whether evaluated from information based on a statistical evaluation of repeated observations or from other information.

The parameter used to indicate the uncertainty may be a standard deviation (or a given multiple of it), or the width of an estimated confidence interval, but any propagation of uncertainty or composition of uncertainty components must be based on the uncertainty variance.

5. STATISTICAL GRAPHICS

One of the most powerful statistical tools is an appropriate graph. The human psychovisual system is unmatched in its ability to process pictorial information, and thereby to detect patterns and relationships. The important word is "appropriate." While the psychovisual system is powerful, it can be misled, and making informative statistical graphs is an acquired skill. While we lack a detailed theory for good statistical graphics, we do have the fruits of much research on the relation between human perception and statistical graphics that can guide the search for effective displays (Cleveland and McGill, 1984).

The subject of statistical graphics is too large for a comprehensive treatment here; thus, we limit the discussion to a few topics appropriate for physical science data. These topics are expanded in works by Chambers *et al.* (1983), Cleveland and McGill (1988), and Cleveland (1994). For a brief history of the subject, see Beniger and Robyn (1978).

We can identify at least three broad categories of statistical graphics: description and communication, analysis, and exploration. Some graphs will fall into more than one category, depending on the context of the data.

5.1 Description and Communication

Pie charts, bar graphs, iconographic displays, and color maps are popular graphics. They are typically found in technical and business reports, in the electronic and print media, and in advertisements, where they are generally used to communicate a concise summary of statistical information. Many computer packages can make these plots and embellish them with color, shading, fill, perspective views, and intensity variations. Some embellishments will distort the data presented and should be avoided. For example, using a perspective view to display a bar graph usually obscures the quantitative information presented, because the data are inherently two dimensional. Another common display technique is to encode numerical magnitudes into iconographic symbols. This can dramatically distort data having a wide range of values when the area of the icon is made proportional to the magnitude being presented.

5.1.1 Pie Charts, Dot Plots, and Bar Graphs The data analyst should avoid pie charts. Pie charts are seldom used by scientists, but are all too common in business and the print media. The problem is that the viewer must make judgments of angles, and the psychovisual system is not good at this; one cannot easily order the variables displayed by their magnitudes, unless the discrepancies are large (Cleveland, 1994). The bar chart is a good alternative when the length of the label is not a problem.

A dot plot is a graphical technique for displaying labeled measurement data. The labels appear as horizontal text to the left of the ordinate axis. Large dots indicate measurement values and are connected by horizontal dotted lines to the corresponding label. Thus, the length of the horizontal line is proportional to the value of the datum. Perception of the data is generally enhanced by ordering the data—say, from smallest at the top to largest at the bottom. One exception is if the labels themselves have a natural ordering. There are a number of variations on the basic dot plots. The bar chart is also a good alternative when the length of the label is not a problem.

5.1.2 Histograms The histogram is the most popular method of displaying the distributional characteristics of a set of data. A histogram is essentially an estimate of the probability density function and is formed by partitioning the data range into a set of intervals or bins (not necessarily equally spaced) and plotting the count of the number of data values that fall in each interval versus the midvalue of the respective bin. The histogram is convenient because it is simple to construct and can be presented with little or no explanation. However, there are serious drawbacks. The shape of the histogram can be sensitive to the number and location of the bins, and it can give an extremely poor estimate of the probability density. Often the bin widths are chosen arbitrarily.

The following formula determines the approximate optimal width of the bins (Diaconis and Freedman, 1981):

$$h = 1.8s(n^{-1}\ln n)^{1/3}, \tag{76}$$

where h is the bin width, n is the number of data points, and s is an estimate of the standard deviation. This formula will approximately minimize the maximum absolute deviation between the resulting histogram and the underlying density distribution. If a robust measure of spread is used instead of the standard deviation (see Sec. 4.3), s should be rescaled to match the standard deviation. For example, the *interquartile range* IQ is the distance between the upper and lower quartiles of the data. In this case, put s = IQ/ 1.349.

5.1.3 Probability-Density Plots Density plots are excellent presentations of the distribution of a set of measurements. Like the histogram, the density plot will usually require little or no explanation and will reveal skewness and multimodality in the distribution of the data.

We discuss nonparametric density estimation, the situation where the analyst has no *a priori* knowledge of the distribution. An excellent method of density estimation is the kernel estimate, discussed in detail by Silverman (1986a). Here the estimate of the density function f at any point x is given by

$$\hat{f}(x) = \frac{1}{nh} \sum K\left(\frac{x - X_i}{h}\right), \tag{77}$$

where n is the number of data points, h is called the window width, and X_i ranges over all the data points. The kernel function K is normalized so that

$$\int_{-\infty}^{\infty} K(x)dx = 1. \tag{78}$$

The choice of the kernel function K is of secondary importance; the Gaussian kernel

$$K(x) = (2\pi)^{-1/2} \exp(-x^2/2) \tag{79}$$

is usually satisfactory. The bias and variance of the density estimate depend critically on the window width h; in fact, the integrated square bias is proportional to h^4 but does not depend on the sample size n, and therefore large n will not necessarily make the bias negligible. On the other hand, the variance is proportional to the inverse of the product nh. Thus the window width provides a trade-off between systematic and random error: As h increases the estimate becomes smoother.

The optimum value of h would minimize the total mean-squared error, but this value depends on the unknown density (Silverman, 1986a). The following rule of thumb for choosing h (Silverman, 1986b) seems to work well:

$$s = \left[\frac{1}{n - 1} \sum_{i=1}^{n} (x_i - \hat{x})^2\right]^{1/2}, \tag{80a}$$

$$A = \min(s, IQ/1.349), \tag{80b}$$

$$h = 1.06An^{-1/5}. \tag{80c}$$

If an accurate estimate of the density is of critical importance, then the analyst should apply more refined techniques (Silverman, 1986a, 1986b).

5.2 Probability Plotting Methods

Probability plotting methods are especially useful tools for data analysis. They are used to compare samples and distributions. We limit the discussion here to one-dimensional data; generalizations for multivariate data are available (Gnanadesikan, 1977; Eastern and McCulloch, 1990). The major probability plots are quantile–quantile plot, Poissonness plot, empirical cumulative distribution plot, percentile plot, and symmetry plot. We confine the discussion here to the quantile–quantile plot and the Poissonness plot; for additional information, the reader should consult the excellent article by Wilk and Gnanadesikan (1968).

5.2.1 The Notion of a Quantile Quantiles are useful for graphing distributions. The p *theoretical* quantile is a number q on the abscissa of the distribution function such that $F(q) = p$; the 0.5 quantile would be median of the distribution. On the other hand, the p *empirical* quantile is defined from the observed data, and it is that observation such that approximately a fraction p of the data is less than the observation and a fraction $1 - p$ is greater. A set of empirical quantiles $\{q_i\}$ for a one-dimensional data sample may be easily calculated. Given a set of samples $\{x_1, x_2, \ldots, x_n\}$, first the data are sorted in ascending order: $\{x_{(1)}, x_{(2)}, \ldots, x_{(n)}\}$; then q_i is set equal to $x_{(i)}$, and the p_i associated with q_i is calculated according to

$$p_i = (i - c)/(n - 2c + 1). \tag{81}$$

The choice of a value for c is a minor technical consideration; usually $c = 0.5$, yielding

$$p_i = (i - 0.5)/n, \tag{82}$$

but other values are also suitable depending on the assumption for the underlying distribution (Kimbell, 1960). Given an arbitrary probability p, the associated quantile may be calculated by linear interpolation between the two nearest sample quantiles. After the analyst calculates the quantiles and probabilities, he can construct a number of useful probability plots.

5.2.2 Empirical Quantile–Quantile Plots An especially powerful graphical method for comparing the distributions of two data sets is the empirical quantile–quantile (EQQ) plot. Apparently, this technique was first introduced in 1914 (Eastern and McCulloch, 1990), but was not extensively used until it was reintroduced in the 1960s (Wilk and Gnanadesikan, 1968). We construct an EQQ plot by plotting the quantiles of one data set against the quantiles of the other. If the two data sets have unequal numbers of points, then one uses the probabilities associated with the smaller set, and then adjusts the quantiles in the larger set by interpolation to match the probabilities.

If the two random samples of data come from the same distribution, then the EQQ plot will produce points that fluctuate about the line $y = x$. Departures from this line give detailed information on how the two distributions differ. The EQQ plot is sensitive to differences between the distribution tails. If the points scatter about the line $y = b + ax$, then the two distributions differ as to mean and standard deviation. For example, when data sets come from two different normal distributions, the plotted points will scatter about the line

$$y = (\sigma_y/\sigma_x)(x - \mu_x) + \mu_y. \tag{83}$$

The EQQ plot is the best technique for comparing two distributions when *a priori* knowledge is lacking, better than comparing various numerically calculated statistics or comparing histograms or density functions. When the two distributions are equivalent in the sense that the associated random variables are related by a linear transformation, most methods of comparison will disguise this fact; the EQQ plot will not.

The data analyst should first try to transform each of the data sets, to make them as normally distributed as possible, as this will facilitate interpretation. In some cases this transformation is essential. For example, suppose we have two random variables Y_1 and Y_2, each lognormally distributed as follows:

$$Y_1 = e^X, X \sim N(0,1); \tag{84a}$$

$$Y_2 = e^{aX+b}. \tag{84b}$$

We see that the first lognormal is derived from a normal distribution with zero mean and unit variance. The second is derived from a normal with mean b and standard deviation a. If we compare Y_1 to Y_2 using an EQQ plot, we will not get a straight line. However, if we first transform both Y_1 and Y_2 using the logarithm, then the plotted points will scatter about the line $y = ax + b$ because we are comparing two normal distributions.

5.2.3 Theoretical Quantile–Quantile Plots The theoretical quantile–quantile plot or probability plot can be used to compare an empirical data set against a specified reference distribution. If $F(\cdot)$ is the cumulative distribution of the reference distribution, then the QQ plot is constructed by plotting the empirical quantiles of the data against the theoretical quantiles of the reference distribution given by

$$F^{-1}\left(\frac{i - 0.5}{n}\right). \tag{85}$$

When the reference distribution is the normal distribution, then constructing the theoretical QQ plot is equivalent to using probability paper. However, in the case of probability paper, the probability values are displayed instead of the normal quantiles. For the normal distribution,

$$F^{-1}(x) = \Phi^{-1}(x), \tag{86a}$$

where

$$\Phi(x) = \frac{1}{(2\pi)^{1/2}} \int_{-\infty}^{x} \exp\left(\frac{-t^2}{2}\right) dt. \tag{86b}$$

Rational approximations for the inverse normal distribution Φ^{-1} are available (Abramowitz and Stegun, 1970). These approximations are derived by a rearrangement of truncated Chebyshev expansions—the method of "telescoping" of power series (Lanczos, 1956).

5.2.4 Interpreting QQ Plots Interpreting both empirical and theoretical QQ plots takes some practice. The beginner tends to expect more order and linearity than he usually gets. Training plots to help the beginner gain experience are available (Daniel, 1976; Daniel and Wood, 1980). In some cases, analysts will find it useful to have a summary statistic for a probability plot. In fact, the theoretical QQ plot with a normal distribution is related to one of the most powerful omnibus statistical tests for normality—the Shapiro–Wilk test (Shapiro and Wilk, 1965), based on the correlation between the observed order statistics of the sample and the expected order statistics from the standard normal distribution (zero mean, unit variance). High values of correlation (near unity) accept normality; low values reject it. Published tables provide critical values (Shapiro and Francia, 1972) of the correlation coefficient using the following approximation for the expected order statistics for the normal distribution (normal quantiles):

$$q_i = \Phi^{-1}\left(\frac{i - 3/8}{n + 1/4}\right). \tag{87}$$

The critical values of the correlation coefficient are near unity.

5.2.5 Poissonness Plot The Poissonness plot (Hoaglin, 1980) is a probability plot designed to help diagnose whether the Poisson probability distribution is the appropriate model for a set of counted data (non-negative integer quantities). This plot is an excellent way of detecting aberrant points in an otherwise well-behaved distribution.

To construct the plot, the measurements must first be sorted into bins and the number of counts in each bin recorded. The bins should sequentially span the integers from zero to the maximum number of observed counts. Thus, K_0 is the number of measurements that are 0, K_1 is the number of measurements that are 1, etc.; some of the K_i may be zero. The total number of measurements N must satisfy

$$N = \sum K_k. \tag{88}$$

If the counts are Poisson distributed, then $\text{Prob}[K = k] = p(k)$ given by Eq. (37). The expected value of K_k is

$$E[K_k] = Ne^{-\lambda}\lambda^k/k!, k = 0, 1, \ldots. \tag{89}$$

If we take the natural logarithm of both sides, then

$$\ln(K_k) = \ln(N) - \lambda + k\ln(\lambda) - \ln(k!). \tag{90}$$

We plot $\ln(k!K_k)$ against k, leaving out points where $K_k = 0$. If the resulting plot looks straight, then the Poisson distribution is appropriate. The advantage of using the Poissonness plot is the aberrant points may be easily identified as those that obviously depart from a straight line. If the Poissonness plot indicates that the Poisson model is appropriate, and there are not aberrant points, then the maximum-likelihood estimate for λ,

$$\hat{\lambda} = \frac{1}{N}\sum kK_k, \tag{91}$$

can be used. Otherwise, we fit a straight line that ignores (or down weights) the aberrant points; the estimate of $\ln(\lambda)$ is the slope of the fitted line. If possible, the cause of the aberrant points should be determined.

5.3 Exploration

The data analyst uses exploratory graphs to uncover features and patterns in the data without assumptions about the behavior or the mechanism that generated the data. They help the analyst discover appropriate transformations and distributional models. There is an extensive literature of graphics for exploratory data analysis (Tukey, 1977; Chambers *et al.*, 1983; Snee and Pfeifer, 1983). The discussion here is limited to scatter plots.

5.3.1 Scatter Plots The scatter plot is used to study the relationship between two variables; to be used effectively, it must be carefully planned and embellished to bring out features in the data. Sometimes one of the variables is a response and the other a factor, and the analyst seeks to discover a "lawlike" relationship between the variables; in other cases, the goal is to determine the statistical dependence between two variables, where neither is regarded as a response or factor. It is important to choose the appropriate plotting symbol, aspect ratio, tic-mark spacing, and data span for the axes (Cleveland and McGill, 1984). When one is looking for statistical dependence, the plotting symbols should not be connected by lines, and no grid lines should appear in the body of the plots (Cleveland, 1994).

5.3.2 Time-Series Plots A special type of scatter plot obtains when one of the variables consists of uniformly spaced values—the time-series plot. Here we have special considerations that do not apply to scatter plots where neither variable is uniformly spaced. When we study time-series data, we look for trends, seasonal effects, short-term correlation, oscillations, jump phenomena, spikes, and outliers. We especially want to know whether the series is evolving with statistical uniformity. What we discover from the time-series plot influences how we model the data. There are four basic types of time-series plots, each enhancing a different aspect of the data:

1. The symbol plot. Here the data are plotted as symbols without connecting lines. This plot is best for studying long-term trends in the data because it minimizes the visual impact of outliers. However, it also inhibits the perception of local time order and any periodic components.
2. The connected-symbol plot. Here the observations are plotted as symbols with connecting lines. This plot enhances local time order and works well for noisy data since the individual points are perceived. However, plots with many points look cluttered.
3. The connected-point plot: The observations are plotted as points with connecting lines. This type of plot, while popular, is usually the least appropriate choice. The individual points lose their identities, and detection of positive autocorrelation (short-term smoothness) is difficult. Noise and outlier observations tend to create a cluttered and distracting picture. Use this plot only for data with a high degree of overall smoothness.
4. The vertical-line plot. Here, the observations are plotted as vertical lines to the reference baseline. This type of plot is appropriate when local time order is important and the number of points is large. The disadvantage of this plot is that outliers have enhanced visual impact.

5.3.3 Box Plots Box plots are good for an initial look at data (McGill and Larsen, 1978; Chambers *et al.*, 1983). The order statistics are coded into a rectangular icon, with a horizontal line segment marking the median and vertical lines extending to outliers. The analyst can quickly identify aberrant points and skewness in the underlying distribution. If the data can be grouped into various categories, then a series of icons is appropriate.

5.4 The Use of Color in Statistical Graphics

Using color effectively requires considerable skill. The beginner should use one color for the basic plotting frame and axis labeling (black or white) and strictly limit the use of color when embellishing the plot—better no color than misused color. Using too many colors, which results in a confusing jumble, is the most common mistake. While the color encoding of categorical variables works well, assigning different hues to continuously varying numerical magnitudes should be avoided because it usually makes the plot more difficult to interpret. Using gray levels works better. There are other potential problems in using color; size distortion effects can occur in the coloring of statistical maps, since saturated primary colors apparently cause misperception of the relative sizes of colored areas (Cleveland and McGill, 1983). These authors also point out that we do not fully understand the effect of color on people's perceptions.

5.5 Dynamic Graphics

Dynamic graphics is a technique for the visualization of three- (or higher) dimensional data by using interactive computer animation. In most implementations, the data are presented as a rotating point cloud where the user can select the axis of rotation and various features of the display; subsets can be highlighted, marked or labeled, or masked out. The movement of the point cloud in real time gives an effective illusion of depth.

One of the original implementations was the PRIM-9 system (Fishkeller *et al.*, 1974), designed for the analysis of high-energy physics research data. This system used special display hardware connected to a mainframe computer (IBM 360/91) and is the prototype for modern interactive graphics workstations. All of the features of PRIM-9 (and more) have become available since the mid-1980s on stand-alone applications that run on personal computers and workstations.

6. THE IMPACT OF COMPUTERS ON DATA ANALYSIS

In the 1950s and 1960s the routine (as opposed to research) use of computers in statistics was generally limited to automating classical procedures. That state of affairs began to change in the 1970s with the introduction of computer-intensive methods for doing statistics, such as the *bootstrap* (Efron, 1979), and techniques for handling high-dimensional data (Friedman and Tukey, 1974). The quality of the numerical software also began to improve significantly in the late 1970s. For example, Golub had introduced orthogonal techniques for doing least-squares problems as early as 1968, but it took nearly a decade for that superior and essential numerical technology to appear in the regression routines in statistical packages. By the mid-1990s computers had a significant impact on all phases of data analysis activity—data collection, storage, organization, retrieval, editing, display, analysis, and report generation. Moreover, the cost of doing calculations has become almost trivial, and so millions of calculations are feasible even for routine problems. We discuss a few computer-intensive methods that are especially interesting and useful to the data analyst.

Not all statistical computer techniques are new; some had to wait for the computer to be implemented. A good example is Fisher's *method of randomization.* First proposed in the 1930s by R. A. Fisher, tests based on the method of randomization using a maximally appropriate test statistic have very desirable mathematical properties—most powerful, consistent, unbiased, etc. However, despite these excellent mathematical properties, the method of randomization remained little more than a statistical curiosity, having been used by Fisher in a purely conceptual manner in doing certain proofs. The problem is that the distribution of a test statistic is conditional on the observed data. Each new application of the method has a new and unique distribution, making it impossible to compute a set of tables that may be used repeatedly. This forced the use of nonparametric techniques, where the observed data are replaced by their ranks and the test is carried out on the ranked data. This causes a loss of information and diminishes the power of the test as compared to the corresponding distribution-based parametric test, or the test using the method of randomization. With fast and inexpensive computing, Fisher's method has been resurrected (Good, 1994).

6.1 Computer-Intensive Methods for Parameter Estimation

In many cases we lack knowledge of the distribution that describes the data under consideration, and we have too few samples to fit a distribution with any confidence. The sample mean and its standard error $S/\sqrt{N}$, where S is given by Eq. (58), provide an *automatic algorithm* for estimating the mean and the accuracy of the estimate, regardless of the actual distribution that describes the data—the distribution need only have finite first and second moments. Unfortunately, the minimum-variance unbiased-estimator approach does not provide automatic algorithms for parameters other than the mean. However, if we are willing to perform many numerical calculations, we can find the accuracy of parameter estimates from the sample data alone.

Suppose we have a sample $\{y_1, y_2, \ldots y_N\}$ from a distribution F, and θ is the parameter of interest. If we use maximum-likelihood estimation to determine θ, the accuracy of the estimate is $1/\sqrt{(\text{Fisher information})}$. The *Fisher information* is defined as the reciprocal of the variance of an efficient estimate of a parameter. It is a fundamental quantity that measures the amount of information about the parameter being estimated that is contained in the sample data. Mathematically, the Fisher information $J(\theta)$ is given by

$$J(\theta) = E_0\left(\frac{\partial}{\partial\theta}\log[f(x;\theta)]\right)^2. \tag{92}$$

The Fisher information has the right property as an information measure because $J(\theta)$ for N independent identically distributed random variables is N times the $J(\theta)$ of one of the variables. The important connection to the accuracy of estimators is given by the Cramér–Rao inequality, which states that for unbiased $\hat{\theta}$,

$$\mathrm{var}[\hat{\theta}] \geq 1/J(\theta). \tag{93}$$

Therefore, $J(\theta)$ gives us a lower bound on the mean-squared error of the estimator and thus provides a measure of the accuracy of estimators. The problem is that often we cannot calculate $J(\theta)$ because the functional form of the estimator is too complicated, and we do not know F. If we knew F, then we could use computer simulation to resample from F, and the simulation would provide information on the variance of the estimator.

The difficulty of not knowing F can be overcome as follows. We can calculate a surrogate $\hat{F}_n$ for F, known as the *empirical cumulative distribution function* (Wilk and Gnanadesikan, 1968), from the primary sample $\{y_1, y_2, . . . y_N\}$. And we can get a surrogate sample $\{y_1^*, y_2^*, . . . , y_N^*\}$ by a process of resampling from $\{y_1, y_2, . . . y_N\}$. Efron recognized that the relationship between $\{y_1, y_2, . . . y_N\}$ and F is similar to the relation between $\{y_1^*, y_2^*, . . . , y_N^*\}$ and $\hat{F}_n$ (Efron, 1979). If we generate many realizations of $\{y_1^*, y_2^*, . . . , y_N^*\}$ by a repeated resampling from $\{y_1, y_2, . . . y_N\}$, we can calculate a new parameter estimate for each realization. Efron coined the term *bootstrap sampling* for this process, and the distribution of $\hat{\theta}$ is called the *bootstrap distribution* of the parameter estimate. While the bootstrap distribution of the parameter estimate is not identical to the distribution that would be obtained by actually sampling from F, it is usually close, and it can be used to calculate many useful things, such as the standard error of the estimate.

Application of the bootstrap technique to compute the standard error of estimates is straightforward. Given a sample $\{y_1, y_2, . . . y_N\}$, B bootstrap replications are generated by use of simple random sampling with replacement from the primary sample. This means that each of the y_n has probability equal to $1/N$ of being drawn in any one replication. Estimate values of $\hat{\theta}_i{}^*$ are generated by using each of the B replications as if it were the primary data, and the bootstrap estimate and its standard error are then given by

$$\hat{\theta}^* = \frac{1}{B}\sum_{i=1}^{B} \hat{\theta}_i^*, \tag{94a}$$

$$\mathrm{SE}(\hat{\theta}) = \left(\frac{1}{B-1}\sum_{i=1}^{B} (\hat{\theta}_i^* - \hat{\theta}^*)^2\right)^{1/2}. \tag{94b}$$

The above gives an automatic algorithm for finding the standard error for a wide and useful class of estimates, including very complicated functions of the sample data such as an eigenvalue of a random matrix. However, the bootstrap procedure can fail under some circumstances. If the estimate is not a smooth enough function of the data, the empirical distribution will not be a good approximation to the actual distribution. If resources permit, it is a good idea to inspect a histogram of the bootstrap replications of the sample. For refinements to the procedure to be used when something goes wrong, see Efron and Tibshirani (1993).

How many replications are necessary? Surprisingly few! Efron says that B rarely needs to exceed 200, and $B = 50$ often produces satisfactory estimates of the standard error (Efron and Tibshirani, 1993). However, large numbers of replications are needed to compute confidence intervals.

6.2 Modern Computing Resources for Data Analysis

Commercial data analysis software originally came in the form of packages designed to be run on mainframe machines and minicomputers in batch environments. Many of these original packages then migrated to the time-sharing environment and finally to workstations and personal computers. The early statistical software packages often failed to provide for data organization, retrieval, and editing, or they would implement these functions with a difficult and limited command syntax—a legacy of their evolution from mainframe machines. Statistical graphics capabilities were either nonexistent or primitive. By the 1990s the situation had changed. Packages that exploit graphical user interfaces (GUIs) became available for workstations and personal computers, thereby making the tasks of data analysis much easier to carry out.

The selection of an appropriate computer platform for doing data analysis is a daunting task, given the variety of hardware, operating systems, and application software available. The situation is further complicated by the nature of the computer industry itself. Both hardware and software are constantly changing, and both can become obsolete very quickly. Nevertheless, a computer platform is essential for doing data analysis, and some choices must be made. Here we try to give some guidelines based on our personal experience, with the caveat that we cannot guarantee the accuracy, timeliness, or completeness of this information.

There are three basic (but not independent) choices to be made: hardware, operating system, and application software. Usually the choice of hardware determines the operating system, and so we will describe the major operating systems. As of 1995, the three dominant operating systems for workstations and personal computers are Unix, DOS/Windows, and MacOS, with DOS/Windows having about 90% of the personal computer market. Unix is the operating system generally found on workstations, which are more costly than personal computers. The applications that run under Unix on workstations also tend to be much more expensive than those that run on personal computers. Unix is the most stable operating system, but it is also the most difficult for the inexperienced user. More applications are available for DOS/Windows than for MacOS, but many of the useful programs are available for both. MacOS and the associated hardware tend to be easier to use and configure. Almost any decision made will be rendered obsolete by technical changes in a few months. We believe that the prudent strategy is to select the most stable system, which generally means choosing hardware and software that have been operating reliably for at least a year, rather than the latest technology.

6.2.1 Software Packages for Doing Data Analysis Some of the data-analysis software packages developed for modern workstations and personal computers provide for almost all of the necessary functions to do good data analysis. They are strong on graphics and are highly interactive. A good example is the *S* system for data analysis and graphics, originally developed by Bell Laboratories but now only available as SPLUS from Statistical Sciences Inc., which holds exclusive license. *S* is also a full language where the user can easily define new functions and extend the capabilities of the package. Compiled FORTRAN and C code can also be linked. SPLUS is available for most popular Unix-based platforms. We have no experience with the available DOS/Windows version, and no version is currently available for MacOS. There is extensive documentation available for SPLUS, including four text books. An active news group (s-new@utstat.toronto.edu) provides regular help on using *S*. The s-news traffic has also been archived at statlib with a good search engine.

A MacOS application designed especially for exploratory data analysis is *Data Desk,* available from the Data Description Company. This package exploits the Macintosh graphical interface operating system. Other heavily marketed packages are *JMP, Systat,* and *Statview,* available for both MacOS and DOS/Windows. *Matlab* is mainly a numerical linear algebra package; it can be used for data analysis, but it lacks any extensive set of specific built-in functions. *Mathematica* and *Maple* are both packages for doing symbolic and numerical algebra and calculus. Mathematica has versions that run on all the major platforms. Both are more useful for mathematical statistics than for data analysis. Each has a powerful programming language with a steep learning curve. From what is currently available, we believe the system of choice for doing data analysis is *S* running on a workstation.

An alternative to commercial data-analysis packages is provided by subroutine libraries, such as those distributed by The International Mathematical and Statistical Libraries Inc. (IMSL) and the National Algorithms Group Library (NAG). Both are costly, but NAG is known to distribute reliable, high-quality software. The disadvantage of these libraries is that the user must write his own software around the subroutines, which can be costly and time consuming. This approach is recommended for either specialized problems or production applications.

GLOSSARY

Bayesian: One who interprets probability subjectively. A Bayesian can assign a probability, in the sense of a "degree of belief," to a nonrepetitive event (contrast with **Frequentist**).

Bootstrap: A technique for calculating estimation error without knowing the distribution of the data.

Confidence Interval: A measure of the uncertainty of a parameter estimate, in the form of an interval within which the value of the parameter is expected to lie with a stated probability.

Cumulants: A set of numbers that describe a probability distribution, particularly how much it deviates from the normal distribution. An often simpler alternative to moments. The cumulants are, in a sense, the orthogonal components of the moments.

Entropy: An information-theoretic concept measuring the uncertainty of a distribution. Related to, but distinct from, thermodynamic entropy.

Estimator: A statistic (a function of the data) that provides an approximation to the value of a parameter of the probability distribution that describes the data.

Expectation: The average or mean value of a probability distribution.

Fisher Information Matrix: A measure of the fundamental amount of information in a random sample. It is additive over independent experiments; the information in n data points is n times the information in one data point.

Frequentist: One who interprets probability as the limit of the ratio of the number of times an event occurs to the number of experiments in which it could occur. A frequentist will not assign a probability to an event that is fundamentally nonrepetitive (contrast with **Bayesian**).

Independent Events: Two events are independent if the occurrence of one provides no information about the probability of occurrence of the other. The joint distribution of independent variables is the product of the independent distributions.

Inference: The process of drawing conclusions about the distribution of a population on the basis of a sample from that population. Inference is frequently with respect to the determination of the parameters of a family of distributions.

Likelihood: A parameter in statistical inference, associated with an assumed model, proportional to the probability of the data given the truth of the model. The likelihood is not necessarily a probability.

Measurand: A particular physical quantity subject to measurement.

Moment: One of a set of parameters of a probability distribution that specifies its properties and that can often completely define it. The most common moments are defined in a manner analogous to moments in mechanics.

Parameter: A scalar or vector quantity, either discrete or continuous, that indexes the probability distribution with respect to some family of distributions.

Random Variable: A mapping from outcomes of an experiment to numbers. A variable that may take any of a set of values, and with which is associated a probability distribution.

Residual: The difference between the observed value and the fitted (estimated) value.

Resistant Estimate: A data-analysis estimate of a model parameter not sensitive to outliers in the data. A numerical concept.

Robust Estimate: An estimate (of a parameter) that is not sensitive to the form of the distribution of the data. The robustness is with respect to the inference to be drawn from the available data. A statistical concept.

Statistical Control: The condition achieved when the parameters defining the distribution can be assumed to be constant, so that the statistical characteristics of the process are stable in time.

Statistical Model: A set of probability laws that describe or determine experimental or observational outcomes. Often synonymous with assumed distribution.

INTRODUCTION

A remarkable feature of bulk matter—gases, liquids, solids, plasmas, and so on—is that the properties of systems composed of large numbers of particles ($\sim 10^{23}$) can be often described by very simple physical laws. Examples of such laws are the equations of equilibrium thermodynamics, of fluid dynamics, of solid mechanics, and of magnetohydrodynamics. The aim of statistical mechanics is to predict the properties of systems composed of large numbers of particles in terms of the mechanical properties of the individual particles and of the forces between them. One of the goals of this field is to explain why the properties of macroscopic systems obey simple laws and to calculate the specific properties of each system of interest.

Statistical mechanics can be divided into two main areas, each of which attempt to explain a body of experimental results for large systems. *Equilibrium statistical mechanics* attempts to derive the laws of thermodynamics and to calculate thermodynamic functions and other equilibrium properties of matter in terms of the microscopic properties of the system of particles. *Nonequilibrium statistical mechanics* attempts to derive the equations that describe transport of mass, energy, and momentum in the system; to describe the approach to thermodynamic equilibrium; and to compute the values of macroscopic, nonequilibrium properties such as the coefficients appearing in the transport equations in terms of the microscopic behavior of the system of particles.

The central idea of statistical mechanics is the following: Suppose one is interested in computing some property of a system composed of a large number of particles that depends in some way on the dynamical processes in the system. For example, one might want to compute the force that a fluid exerts on a piston placed in the fluid, or the flow of energy across a small area in the system over a small time interval. It is not possible to compute these properties exactly for any individual system, since the equations of motion are too complex, and the initial conditions needed to solve them are not usually known. Instead the property of interest is computed by determining its *average* value, taken over a suitable ensemble of similarly prepared systems.

Statistical mechanics is successful in predicting properties of large systems because

1. the values of most of the quantities of experimental interest are not sensitive to

digital Encyclopedia of Applied Physics

the particular microscopic state of the system, and
2. the ensemble average is usually much easier to compute than the exact value.

Fluctuations about the average value are usually small provided the system is sufficiently large and the ensemble has been properly constructed. The fact that the system is large, while leading to enormous complexity on the microscopic scale, leads to regular, simply describable behavior on a macroscopic scale.

The science of statistical mechanics has its origin in the mid-nineteenth century. Scientists such as J. Herapath and J. J. Waterston tried, with some degree of success, to explain experimental observations of Boyle's law, and of the ratio of specific heats of gases, on the basis of a simple, atomic description of a gas. Their ideas were extended by Joule and by Clausius, and the subject became a major research area with notable successes due to work of Maxwell and Boltzmann on the kinetic theory of gases, toward the end of the century (Brush, 1976).

Maxwell and Boltzmann both realized that the arguments they had advanced to understand the thermodynamic and transport properties of dilute gases could be extended to more complicated systems. In 1877 Boltzmann published the formula

$$S = k_B \log W, \tag{1}$$

where W is the probability of a particular macroscopic state of the system, k_B is Boltzmann's constant,

$$k_B = 1.380\,658 \times 10^{-23}\,\mathrm{J\,K^{-1}}, \tag{2}$$

and S is the entropy of the system in the particular macroscopic state. In order to provide a foundation for this formula and to justify its use in computing the thermodynamic properties of large systems for particles, Maxwell and Boltzmann introduced the "ergodic hypothesis," namely, that every microscopic state of the system, consistent with an overall constraint of fixed energy, is as likely to occur as any other. Using this formulation for the relation between the thermodynamic entropy and the underlying microscopic description of a system, Maxwell and Boltzmann were able to provide a basis for the computation of the thermodynamic properties of large systems of interesting particles that included, but was not restricted to, dilute gases. This, together with a study of the ergodic hypothesis, has been a major topic of research since their time. The modern formulation of equilibrium statistical mechanics is due to J. W. Gibbs, who based the calculation of thermodynamic properties of a system on the use of an appropriate ensemble and described the properties of the microcanonical, the canonical, and the grand canonical ensembles (Gibbs, 1960). Because of its elegance and simplicity, Gibbs's formulation of statistical mechanics is the one used today.

Of course, even with the methods of Maxwell, Boltzmann, and Gibbs, certain features of the thermodynamic properties of systems could not be explained until the correct mechanical picture of microscopic systems become clear with the advent of quantum mechanics in the twentieth century.

While the work of Maxwell, Boltzmann, and Gibbs led rather directly to a complete formulation of equilibrium statistical mechanics, the development of nonequilibrium statistical mechanics has taken a much longer time. This branch of statistical mechanics was, in fact, a central focus of the study of the properties of dilute gases by Maxwell and Boltzmann. The Boltzmann transport equation for dilute gas is still a topic of modern research, in both physics and mathematics, and much recent work has been devoted to extending it to higher densities, and to finding appropriate descriptions of transport in other, more complicated systems.

In this article the foundations of both equilibrium and nonequilibrium statistical mechanics for classical systems are presented. The extension to quantum mechanical systems and the application of statistical mechanics to specific problems are discussed in other articles (see STATISTICAL MECHANICS, QUANTUM). For many purposes the full quantum treatment of the microscopic state of the system is not required. For example, we can use classical mechanics to treat the translational motions of particles in gases and liquids at room temperatures and quantum mechanics to treat their internal states. When there is a slow exchange of translational and internal energies, a treatment of many of the macroscopic properties of a fluid can be based entirely on classical statistical mechanics.

1. PHASE SPACE AND ENSEMBLE DISTRIBUTION FUNCTIONS

As stated above, the essential idea of statistical mechanics is to replace a computation of the exact value of some mechanical quantity of interest for a large system by the computation of the ensemble average of that quantity, taken over an ensemble of mechanically identical, and appropriately prepared, systems. To set up the ensemble we consider a collection of N particles, each with f canonical coordinates and f canonical momenta, and with these we construct a $2Nf$-dimensional space, called phase space or Γ space. One point in Γ space specifies the complete set of coordinates and momenta for every particle at one instant of time. The time development of the system is represented by a trajectory in Γ space, which is determined by the solution of the equations of motion of the system.

An ensemble is constructed by considering all possible replicas of the system that satisfy the same macroscopic conditions at some initial instant of time, and assigning an initial probability distribution $\rho(\Gamma)$ such that $\rho(\Gamma)d\Gamma$ is the probability that one of the replicas, chosen at random, will be in the $2Nf$-dimensional volume element $d\Gamma$ about the point Γ in Γ space at the initial instant. The fact that each system in the ensemble develops in the course of time according to the equations of motion implies that the probability distribution function $\rho(\Gamma,t)$ is a function of time, having the value $\rho(\Gamma)$ only at the initial instant. If the classical equations of motion for the canonical coordinates and momenta are Hamilton's equations

$$\dot{q}_i = \frac{\partial H}{\partial p_i}, \qquad \dot{p}_i = -\frac{\partial H}{\partial q_i}, \tag{3}$$

for $i = 1, \cdots, Nf$, where (q_i,p_i) represent the canonical coordinates and momenta, respectively, for the Nf degrees of freedom for the system, and $H(q_1,p_1,\cdots q_{Nf},p_{Nf})$ is the Hamiltonian for the system of N particles, then $\rho(\Gamma,t)$ satisfies the equation

$$\frac{\partial \rho(\Gamma,t)}{\partial t} + \{\rho(\Gamma,t),H\} = 0. \tag{4}$$

Here $\{\rho(\Gamma,t),H\}$ is the Poisson bracket of ρ and H. Equation (4) is called the classical Liouville equation. The ensemble average of a dynamical quantity $A(\Gamma)$ is, in general, time dependent and is denoted by $\langle A(\Gamma,t)\rangle$ where

$$\langle A(\Gamma,t)\rangle = \int d\Gamma A(\Gamma)\rho(\Gamma,t), \tag{5}$$

where we use

$$\int d\Gamma \rho(\Gamma,t) = \int d\Gamma \rho(\Gamma) = 1. \tag{6}$$

Equation (6) is a consequence of Liouville's equation and shows that the interpretation of $\rho(\Gamma,t)$ as a probability density holds for all time, not only at the initial instant. One further important consequence of Liouville's equation is the *conservation of volume in phase space.* That is, consider a region in Γ space occupying some Γ-space volume $V_\Gamma(0)$, and follow the region in time, as the points in the region follow their trajectories according to the laws of motion. Then the volume of the region that the points occupy at a time t later, $V_\Gamma(t)$, is equal to the initial volume $V_\Gamma(0)$.

A special class of ensemble distribution functions is of great importance for equilibrium statistical mechanics. These are the *stationary* ensembles such that $\rho(\Gamma,t)$ does not depend on time. It follows from Liouville's equation, Eq. (4), that $\rho(\Gamma,t)$ will remain constant in time, if the Poisson bracket of ρ with the Hamiltonian vanishes. The most important set of such functions are those where the distribution function is a function only of the Hamiltonian H, and of other constants of the motion.

2. THE MICROCANONICAL ENSEMBLE

The formulation of equilibrium statistical mechanics established by Maxwell and Boltzmann is based on the following stationary ensemble. We consider a mechanically isolated system whose energy lies in the range

E to $E + \delta E$. Then we choose a stationary phase-space distribution function $\rho(\Gamma)$ to have the form

$$\rho(\Gamma) = \begin{cases} \text{const. for } E \leq H(\Gamma) \leq E + \delta E, \\ 0 \quad \text{otherwise,} \end{cases} \tag{7}$$

where $H(\Gamma)$ is the value of the Hamiltonian at the phase point Γ and is the total energy of the system. This ensemble is called the *microcanonical ensemble.* In many formulations of the microcanonical ensemble, Eq. (7) is replaced by the equivalent relation, for large systems,

$$\rho(\Gamma) = (1/\Omega)\delta(H(\Gamma) - E), \tag{8}$$

where $\delta(H(\Gamma) - E)$ is the Dirac delta function that defines a $(2Nf - 1)$-dimensional surface, the constant-energy surface, in Γ space. The principal justification for the use of the ensemble to describe the macroscopic properties of a (virtually) isolated system is that the results so obtained are entirely in accord with experimental results, apart, of course, from quantum effects, which require a more quantum mechanical formulation of the microcanonical ensemble. In the next section we discuss a more fundamental justification of the microcanonical ensemble based on *ergodic theory.*

The constant Ω^{-1} appearing in Eq. (8), or equivalently, the constant appearing in Eq. (7), is determined by the normalization conditions, Eq. (6), imposed on the phase-space distribution function. By considering Eq. (8), for example, we determine Ω as

$$\Omega = \int_{A(E,V\{N_\alpha\},z_1\cdots z_j)} \frac{dA(\Gamma)}{|\mathrm{grad}\, H|_E}, \tag{9}$$

where $dA(\Gamma)$ denotes a differential "area" element about the point Γ on the surface in Γ space determined by the condition that $H(\Gamma) = E$. This surface has one less dimension than the total number of dimensions of Γ space. In Eq. (8), $|\mathrm{grad}\, H|_E$ is the magnitude of the $2Nf$-dimensional gradient of the Hamiltonian, evaluated on the surface $H(\Gamma) = E$, that is

$$|\mathrm{grad}\, H|_E = \left\{ \sum_{i=1}^{Nf} \left[\left(\frac{\partial H}{\partial q_i}\right)^2 + \left(\frac{\partial H}{\partial p_i}\right)^2 \right] \right\}^{1/2}_{H(\Gamma)=E}. \tag{10}$$

The value of this gradient may depend on the particular point on the energy surface in the integration in Eq. (9). The region of integration in Eq. (9) is over the constant-energy surface defined by the condition $H(\Gamma) = E$ but subject to the physical constraints imposed on the system. That is, the particles of the system may each be confined to a spatial volume V, and the number of particles of each species α, N_α, must be specified. If the different species of particles have different numbers of mechanical degrees of freedom, then the total dimension of Γ space is given by the sum $2\Sigma N_\alpha f_\alpha$, where f_α is the number of degrees of freedom of each particle of species α. In addition it may be necessary to specify certain intensive quantities, denoted by $z_1, \cdots, z_j$, such as the values of electric, magnetic, or gravitational fields, to determine completely the thermodynamic state of the system. Thus $A(E,V,\{N_\alpha\},z_1,\cdots,z_j)$ denotes that part of the constant-energy surface that is consistent with these constraints.

The microcanonical distribution is used to provide a statistical description of the thermodynamics of isolated systems where the total energy E, the volume of the (physical) system V, the number of particles of each species α, N_α, and the intensive quantities $z_1, \cdots, z_j$ are all specified.

Boltzmann's postulate provides the essential connection between the thermodynamic properties of an isolated system in equilibrium and quantities evaluated in microcanonical ensemble. That is, the *statistical thermodynamics* of an isolated system is determined by the relation

$$S(E,V,\{N_\alpha\},z_1,\cdots z_j) = k_\mathrm{B} \ln\Omega(E,V,\{N_\alpha\},z_1\cdots z_j), \tag{11}$$

which was anticipated by Eq. (1). The quantity Ω is called the *microcanonical partition function,* and it represents the total "measure" in Γ space occupied by systems with energy E. Because of the presence of the gradient in the integral of Eq. (9), one cannot identify Ω with the $(2Nf - 1)$-dimensional area of the constant-energy surface, but rather with a measure on the surface. In Eq. (11), S is to be identified with the thermodynamic entropy as a function of the indicated variables. The statistical expressions for other thermodynamic quantities can be obtained by using ordinary thermodynamic relations. For example, the thermodynamic temperature, T, is given by

$$T^{-1} = \left(\frac{\partial S}{\partial E}\right)_{V,\{N_\alpha\},z_1,\cdots,z_j}. \tag{12}$$

The equilibrium average of any dynamical quantity $f(\Gamma)$ is given in the microcanonical ensemble by

$$\langle f(\Gamma)\rangle = \frac{1}{\Omega(E,V,\cdots)} \int_{A(E,V,\cdots)} \frac{dA(\Gamma)f(\Gamma)}{|\text{grad } H|_{H=E}}. \tag{13}$$

As an example we consider a nearly ideal gas of N identical particles of mass m contained in a volume V and compute the number of such particles with momentum p at a point r, in equilibrium. For this quantity, the microscopic density of particles at point r with momentum p is given by

$$f(\Gamma) = \sum_{i=1}^{N} \delta(r_i - r)\delta(p_i - p). \tag{14}$$

The equilibrium average can be computed using Eq. (13) and is

$$n(r,p) = \langle f(\Gamma)\rangle = \frac{N}{V}\left(\frac{3N}{4\pi Em}\right)^{3/2}\left(1 - \frac{p^2}{2mE}\right)^{3N/2} \tag{15}$$

for large N. Then using Eq. (12) to identify the temperature, we obtain, as $N \to \infty$, $V \to \infty$, $N/V = n$, the number density, and $k_BT = 2E/3N$,

$$n(r,p) = n[2\pi m k_B T]^{-3/2} \exp\left(-\frac{p^2}{2mk_BT}\right), \tag{16}$$

which is the Maxwell–Boltzmann distribution function for an ideal gas.

The fundamental relation between the macroscopic and the statistical formulations of thermodynamics, $S = k_B \ln\Omega$, provides a microscopic interpretation for the fact, embodied in the second law of thermodynamics, that the entropy of an isolated system increases whenever any of the constraints on the system are relaxed without changing the energy and the system spontaneously proceeds to a new equilibrium state. Very simply, the relaxing of the constraint has the effect of increasing the total measure Ω of the constant-energy surface because more of the surface becomes available as a possible physical state for the members of the ensemble.

3. THE ERGODIC HYPOTHESIS

The use of the microcanonical ensemble to compute the thermodynamic equilibrium properties of macroscopic systems, while successful, requires justification. Two problems need to be addressed:

1. Can one prove that a large isolated system will, in the course of time, approach a state of thermodynamic equilibrium?
2. Can one prove that this state of thermodynamic equilibrium is properly described by the microcanonical ensemble?

One approach to the resolution these questions was formulated by Boltzmann and forms the subject of ergodic theory. One identifies the measurement of the dynamical property of a single system, $f(\Gamma)$, with the time average of the quantity over some time interval, denoted $\bar{f}_T$, as

$$\bar{f}_T = \frac{1}{T}\int_{t_0}^{t_0+T} dt f(\Gamma(t)), \tag{17}$$

where $\Gamma(t)$ denotes the point on the trajectory of the system in Γ space at time t, t_0 is some initial time, and T is the duration of the experiment. If the system does approach an equilibrium state, then as $T \to \infty$, $\bar{f}_T$ should approach the value of $f(\Gamma)$ as measured in the thermodynamic equilibrium state where a steady value of the measurement is expected. The ergodic hypothesis states that as the trajectory of the phase point develops in time, it spends a certain amount of time in every region of the constant-energy surface, consistent with the macroscopic constraints discussed earlier. The amount of time that the system spends in a particular region is, according to the ergodic hypothesis, proportional to the measure of that region, if one follows the trajectory for a long enough time. This is the heart of the hypothesis, and it is often referred to as the hypothesis of equal *a priori* probabilities. By dividing up the constant-energy surface into a large number of regions, each with a small but nonzero measure, one can conclude that

$$\lim_{T\to\infty}\frac{1}{T}\int_{t_0}^{t_0+T} dt f(\Gamma(t)) = \frac{1}{\Omega(E,V,\cdots)}\int\frac{dA(\Gamma)f(\Gamma)}{|\mathrm{grad}\,H|_{H=E}} \tag{18}$$

if the ergodic hypothesis is correct. Therefore, if one can prove the ergodic hypothesis, one can conclude that whatever the value of $\bar{f}_T(\Gamma)$ may be for some finite time T, this value will always approach the value as computed by statistical mechanics using a microcanonical ensemble distribution function, Eq. (8). This approach has nothing to say about the details of the approach of $\bar{f}_T(\Gamma)$ to its equilibrium value as $T \to \infty$, and that forms the subject of nonequilibrium statistical mechanics to be discussed in Sec. 6.

To justify the ergodic hypothesis, one must carefully examine the microscopic dynamical behavior of the system, and this study has provided a number of physical and mathematical researches, generally called ergodic theory (Halmos, 1956). The first important result in this direction was provided by Birkhoff's individual ergodic theorem, which asserts that for a Hamiltonian dynamical system, the limit as $T \to \infty$ of the time average $\bar{f}_T(\Gamma)$ exists, for almost all initial points for the trajectories and for integrable functions $f(\Gamma)$. However, since the theorem does not rule out the possibility that the limiting function may vary from one trajectory to another, and thus not be equal to the microcanonical average of f, it is not enough to ensure the correctness of the ergodic hypothesis. Therefore one needs to study the circumstances under which the limiting time average is equal to a constant, independent of trajectories, and thus, with some simple arguments, equal to the microcanonical ensemble average. Such systems are called ergodic. Recently Ya. G. Sinai and co-workers have shown that some simplified hard-sphere systems are ergodic (Sinai, 1970). In fact, they were able to show that despite the purely deterministic nature of these systems, they exhibit behavior that is similar in many respects to a purely random system typified by a coin-toss experiment. This feature of the systems studied by Sinai and co-workers is called the Bernoulli property, and it, in turn, implies the ergodic behavior of the system. Because of the considerable mathematical difficulties involved, very little is known about the ergodic behavior of more realistic systems.

Other approaches to justifying the use of the microcanonical ensemble distribution rely on the fact that no physical system can be truly isolated. Rather, any system is always subjected to random perturbation from its surroundings. These random perturbations may affect the phase-space trajectories in such a way that the time average of a dynamical quantity approaches the ensemble average, whether or not the dynamical system, considered in strict isolation, has the ergodic property.

In any event, the microcanonical ensemble has proven, by its success in predicting thermodynamic properties of large systems, that it is a simple and reasonable starting point for a statistical theory of thermodynamic equilibrium.

4. THE CANONICAL AND GRAND CANONICAL ENSEMBLES

Very often in experimental situations one is interested in the thermodynamic properties of a system that is kept in contact with a large heat bath with which the system can exchange energy, or energy and particles. Examples are readily found in experiments that explore the equation of state and phase equilibrium phenomena of pure substances or mixtures (see PHASE EQUILIBRIA), or in light-scattering experiments that explore the properties of a small subregion, the scattering volume, of a large system. In this latter case, the subregion is not separated from the rest of the system by any sort of boundaries so that an exchange of particles and energy with the rest of the system is taking place at all times.

The microcanonical ensemble, discussed above, can be used to obtain a statistical mechanical description of a system in contact with a heat bath with which it can exchange energy or energy and particles. The procedure is to regard the system plus the heat bath as a large isolated system and to use the microcanonical distribution for the whole system. In carrying out this procedure it is important to distinguish between the case where the system and bath exchange only energy, and the cases where both energy and particles are exchanged. In the former case we construct an ensemble distribution for the system (not the system plus bath) called the *canonical ensemble,* and in the latter, where the system exchanges both energy and particles with the bath, we construct an ensemble distribution for the system called the grand canonical ensemble, after Gibbs.

If the system exchanges only energy with the heat bath, the microcanonical distribution function for the entire system is $\rho_{\text{tot}}(\Gamma_1,\Gamma_2)$, given in a $(2N_1 f_1 + 2N_2 f_2)$-dimensional phase space compared by combining the Γ space for the system, Γ_1, and that for heat bath, Γ_2, by

$$\begin{aligned}\rho_{\text{tot}}(\Gamma_1,\Gamma_2) = \Omega_{\text{tot}}^{-1}\delta(H_1(\Gamma_1) + H_2(\Gamma_2)\\ + H_{12}(\Gamma_1,\Gamma_2) - E).\end{aligned} \tag{19}$$

Here the subscripts 1 and 2 denote the system of interest and the heat bath, respectively, and we ignore, for the moment, that the system of interest may be composed of particles of different species, α. The $H_i(\Gamma_i)$, $i = 1,2$, are the Hamiltonian functions of system i, and Γ_i is the phase-space point for system i, and $H_{12}(\Gamma_1,\Gamma_2)$ is a Hamiltonian function that describes the interaction between the system and the heat bath. Next we assume that both the system and heat bath are sufficiently large that the interaction energy H_{12} can be neglected in Eq. (19). As we are not at all interested in the heat bath, we integrate $\rho_{\text{tot}}(\Gamma_1,\Gamma_2)$ over all the variables of the heat bath to obtain a normalized phase-space distribution function for the system of interest alone. This is easily seen to be

$$\begin{aligned}\rho(\Gamma_1) = \Omega_2(E - H_1(\Gamma_1))\\ \times\left[\int d\Gamma_1\Omega_2(E - H_1(\Gamma_1))\right]^{-1},\end{aligned} \tag{20}$$

where Ω_2 is the microcanonical partition function for the heat bath. We consider the heat bath to be very large, large enough that we can expand the entropy of the heat bath about its value at energy E, so as to obtain

$$\begin{aligned}\Omega_2(E - H_1(\Gamma_1)) &= \exp[S_2(E - H_1(\Gamma_1))/k_{\text{B}}]\\ &\cong \exp\{[S_2(E) - H_1/T + \cdots]/k_{\text{B}}\}\\ &\cong e^{S_2/k_{\text{B}}}e^{-\beta H_1},\end{aligned} \tag{21a}$$

where $\beta = (k_{\text{B}}T)^{-1}$, T is the temperature of the heat bath. For the distribution function, we obtain, using Eq. (20),

$$\rho(\Gamma_1) = e^{-\beta H_1(\Gamma_1)}\left[\int d\Gamma_1 e^{-\beta H(\Gamma_1)}\right]^{-1}. \tag{21b}$$

This resulting distribution function is the normalized canonical ensemble distribution function for a system in contact with a heat bath at temperature T. The statistical thermodynamics for this system is most easily obtained by considering the variation of the average energy of the system with respect to β, the volume V, and the intensive variables $z_1, \ldots, z_j$, where the average energy is $U = \langle E\rangle_c$, with

$$\langle E\rangle_c = \int d\Gamma_1 H(\Gamma_1)e^{-\beta H(\Gamma_1)}\left[\int d\Gamma_1 e^{-\beta H(\Gamma_1)}\right]^{-1}. \tag{22}$$

By examining the variation of U with respect to the variables β, V, z_1, $\cdots$, z_j and comparing it with the thermodynamic formula

$$dU = TdS - PdV + \sum_j X_j dz_j, \tag{23}$$

one determines the proper relation between statistical and thermodynamic properties. In Eq. (23), P is the pressure of the system, and $X_i dz_i$ is the work done on the system when the parameter z_i is varied. The result of this analysis is that the temperature of the heat bath and the system are the same, as expected in thermodynamic equilibrium, and that the connection between the thermodynamic properties of the system and statistical mechanical ensemble averages is most easily expressed by the relation

$$e^{-\beta F} = Z. \tag{24}$$

Here F is the Helmholtz free energy of the system, and Z, the canonical partition function of the system, is, almost, but not quite, the normalization factor in Eq. (22). Instead it is

$$Z = \frac{1}{\prod_\alpha N_\alpha! h^{NF}}\int d\Gamma_1 e^{-\beta H(\Gamma_1)} \tag{25}$$

The additional prefactors $[\Pi_\alpha N_\alpha! h^{NF}]^{-1}$, where h is Planck's constant, are not required by the thermodynamic identity, Eq. (23), since the identity determines $\ln Z$ up to an arbitrary constant. This arbitrary constant is determined by the condition that the classical partition function agree with the limit of the quantum mechanical version of the canonical partition function in the limit $h \to 0$. This accounts for the prefactor in Eq. (24). The $N_\alpha!$ appear because all the particles of species are identical and permutations of their particle indices do not lead to a new quantum state, and the h^{NF} counts the number of quantum states, such that the number of states in $dq_i dp_i$ is $dq_i dp_i/h$.

An earlier discussion of the canonical partition function by Gibbs also produced the $(\Pi_\alpha N_\alpha!)^{-1}$ in Eq. (25). Gibbs argued that if this prefactor were not present in Z in Eq. (24), the entropy so obtained would not be extensive and would lead to an entropy of mixing if two containers of an identical ideal gas were combined into one. Such an entropy of mixing is inconsistent with thermodynamics, and its paradoxical occurrence in the earlier formulation of the canonical ensemble was referred to as the *Gibbs paradox.* The paradox does not appear if the partition function is formulated properly. Of course, until the advent of quantum theory and the notion of discrete quantum states, it was not possible to obtain an absolute value of thermodynamic functions from statistical thermodynamics, and Planck's constant did not appear in the partition function.

In the case that chemical reactions are taking place in the system, the set of particle numbers $\{N_\alpha\}$ is defined to be the numbers of the constituent particles that are unaffected by the reaction (e.g., protons, electrons, or atoms of each element), and the numbers of the reacting chemical species are regarded as thermodynamic parameters to be fixed by the equilibrium conditions.

If the system has a fixed volume V but can exchange energy and particles with a heat bath, and the heat bath is sufficiently large, we can again use the microcanonical distribution function for the entire system to show that the probability of finding the system when it has N_α particles of each species α, and at phase point $\Gamma(\{N_\alpha\})$, is

$$\rho(\Gamma(\{N_\alpha\})) = \Xi^{-1} \times \exp\left(\sum_\alpha \beta N_\alpha \mu_\alpha\right) \exp[-\beta H(\Gamma(\{N_\alpha\}))]; \tag{26}$$

here $\Gamma(\{n_\alpha\})$ is a point in the $(\Sigma 2N_\alpha f_\alpha)$-dimensional Γ space for a system with N_α particles of each species α, where f_α is the number of mechanical degrees of freedom of species α. This distribution is the grand canonical distribution, and Ξ, the normalization factor in Eq. (26), is the grand canonical partition function given by

$$\Xi = \sum_{N_1=0}^{\infty} \cdots \sum_{N_k=0}^{\infty} \exp\left(\beta \sum_\alpha N_\alpha \mu_\alpha\right) \times \int d\Gamma(\{N_\alpha\}) e^{-\beta H(\Gamma(\{N_\alpha\}))}. \tag{27}$$

In Eqs. (26) and (27) we suppose that there are k distinct types of particles, $\alpha = 1, \cdots, k$; the parameters β and $\{\mu_\alpha\}$ are characteristics of the heat bath.

The grand canonical distribution function provides a description of open systems, and the relation between the statistical and thermodynamic description of such systems is provided by

$$P(T,V,\{\mu_\alpha\},z_1 \cdots z_j)V = k_B T \ln\Xi, \tag{28}$$

where P is the pressure, $T = (k_B\beta)^{-1}$ is the temperature, and the μ_α are the chemical potentials of the species α.

It is generally believed that for large systems, the thermodynamic functions should not depend sensitively on whether it is exchanging particles and/or energy with a heat bath. Consequently the computed thermodynamic properties of a large system should be the same regardless of the ensemble used in their computation. Therefore, one would expect to be able to prove the *equivalence of ensembles* for very large systems of physical interest. One does not expect, however, that the equivalence of ensembles will hold for a computation of fluctuations in the thermodynamic quantities. For example, the grand canonical ensemble allows for fluctuations in the species numbers N_α, but the microcanonical and canonical ensembles do not.

We are interested in computing values of thermodynamic functions for systems that are large enough that the effects of boundaries can be neglected. Then we consider the *thermodynamic limit,* where for the microcanonical ensemble $E \to \infty$ and $V \to \infty$ in such a way that the energy per unit volume E/V remains fixed at its value for the finite system;

for the canonical ensemble $V \rightarrow \infty$, and the particle numbers $N_\alpha \rightarrow \infty$ in such a way that the particle densities N_α/V remain fixed; and for the grand canonical ensemble, $V \rightarrow \infty$, and the mean particle numbers $\langle N_\alpha \rangle \rightarrow \infty$ such that the mean densities $\langle N_\alpha \rangle/V$ are fixed. In the thermodynamic limit one computes specific values of the extensive thermodynamic functions such as the entropy or free energies per particle, or per unit mass. There is considerable literature detailing the microscopic properties that a system must have for its specific thermodynamic properties to exist in the thermodynamic limit, and establishing the equivalence of the various ensembles for calculating the specific quantities. The conditions on microscopic properties, such as the interaction potentials between particles, are sufficiently general that the existence of the specific value of the extensive quantities in the thermodynamic limit is ensured for a wide variety of systems of physical interest (Ruelle, 1969).

5. APPLICATIONS OF EQUILIBRIUM STATISTICAL MECHANICS

The methods of equilibrium statistical mechanics have been applied to calculate thermodynamic and other properties of a wide variety of systems. The simplest applications are the studies of properties of system of noninteracting particles, such as very dilute gases of monatomic or polyatomic molecules, or harmonic crystals, where the noninteracting "particles" are the normal modes of the crystal. The computation of the properties of systems of interacting particles is more difficult, but notable progress has been made in the computation of the properties of dense gases, and in developing techniques to treat phase transitions, particularly the liquid–gas and paramagnetic–ferromagnetic phase transitions (see PHASE TRANSITIONS IN SOLIDS). The liquid–solid phase transition, i.e., "freezing," though, is still poorly understood. Various solid–solid transitions, and phase changes in the arrangement of atoms absorbed on solid surfaces, have been under active study with considerable success. Among the many other problems that have been successfully treated by the methods of classical equilibrium statistical mechanics are the conformational properties of polymers, the helix-coil transition in DNA-like molecules, the properties of various types of magnetic systems, and the properties of plasmas and of stellar matter. The theoretical understanding of the equilibrium properties of such systems has been aided considerably by the use of computers. In addition to the fact that many difficult calculations are a routine matter for computers, the use of computer-simulated molecular dynamics has led to a deeper understanding of the properties of fluid and solids (see SIMULATION BY MOLECULAR DYNAMICS). In this section we discuss briefly some of the abovementioned applications.

5.1 The Properties of Ideal Systems

Ideal systems are characterized by the property that the Hamiltonian function for them can be written as a sum of energies that are a positive definite quadratic form in the canonical coordinates and momenta. Typical examples are a dilute gas of atoms where the interactions between the atoms can be neglected, and the total energy is simply the sum of the kinetic energies of each particle. Other examples are a dilute gas of polyatomic molecules whose energies can each be written as the sum of a translational kinetic energy, a rotational kinetic energy, quadratic in the angular momenta about each of the principal axes of rotation of the molecule, and a vibrational energy comprising the kinetic and potential energies of each of the normal modes of the molecule. Any couplings between translational, vibrational, and rotational motions are neglected. Another example of an ideal system is a purely harmonic solid with an energy that can be written as a sum of the kinetic and potential energies of each of the normal modes.

The properties of such systems are easy to evaluate because the various partition functions are quite simple. For example, the canonical partition function of N noninteracting molecules or of an ideal solid with N normal modes can be written as

$$Z_{\text{ideal}} = \frac{1}{N! h^{NF}} \left[\int d^s p \int d^s q \; e^{-\beta H_1(\mathbf{q},\mathbf{p})} \right]^N, \qquad (29)$$

where $\mathbf{p},\mathbf{q}$ denote all the canonical momenta and coordinates for one particle (or normal mode), and $H_1(\mathbf{q},\mathbf{p})$ is the Hamiltonian function for one particle (or normal mode), quadratic in the appropriate coordinates and momenta. Since the integrals appearing in Eq. (29) are at most the integrals of Gaussian forms, Z_{ideal} is easily determined. The internal energy of the system, U, is obtained from the general relation

$$U = \langle E\rangle = -\frac{\partial \ln Z}{\partial\beta} = N\sum_{i=1}^{s}\frac{k_{\mathrm{B}}T}{2} = Nsk_{\mathrm{B}}T/2. \tag{30}$$

In Eq. (30), s denotes the number of quadratic terms in the Hamiltonian function for each particle. For example, $s = 3$ for an atom, $s = 7$ for a diatomic molecule (three translational degrees of freedom, two rotational degrees of freedom, and two to account for the kinetic and potential energies of vibration of the molecule). For a harmonic crystal N is equal to the total number of normal modes of the crystal, and $s = 2$ for each mode. Equation (30) is often referred to as the *law of equipartition of energy.* It predicts that the specific heat at constant volume C_v is a constant for such systems, given by

$$C_v = Nsk_{\mathrm{B}}/2. \tag{31}$$

The failure of Eq. (31) to hold for low temperatures, and the variation of C_v with temperatures even for very dilute noninteracting systems, was one of the indications that classical physics does not adequately describe molecules and crystals and that quantum effects are important.

5.2 Fluctuations

The canonical ensemble describes a system in contact with a thermal reservoir. As a result the energy of the system does not maintain a fixed value, but rather it undergoes fluctuations. The mean square fluctuations of the energy of a system in contact with a heat bath can easily be calculated by means of the canonical ensemble distribution function, as follows. We are interested in the quantity $\langle(E - \langle E\rangle)^2\rangle$, which expresses the mean square fluctuations of energy. This quantity is given, in the canonical ensemble (for a system of identical particles), by

$$\begin{aligned}\langle(E - \langle E\rangle)^2\rangle &= \frac{1}{ZN!h^{NF}}\int d\Gamma[H(\Gamma) - \langle E\rangle]^2 e^{-BH(\Gamma)}\\ &= \frac{1}{ZN!h^{NF}}\int d\Gamma H^2(\Gamma)e^{-BH(\Gamma)} - \langle E\rangle^2\\ &= \frac{1}{ZN!h^{NF}}\frac{\partial^2}{\partial\beta^2}\int d\Gamma e^{-BH(\Gamma)} - \langle E\rangle^2\\ &= k_{\mathrm{B}}T^2\left(\frac{\partial\langle E\rangle}{\partial T}\right)_{N,V} = k_{\mathrm{B}}T^2C_v.\end{aligned} \tag{32}$$

Thus the mean square energy fluctuations are proportional to the specific heat at constant volume. This result also obtains for quantum systems as well. One of the many interesting consequences of the result is that the mean square fluctuation in the energy per particle vanishes as N^{-1} in the thermodynamic limit.

Similarly, a system in contact with a reservoir with which it can exchange both energy and particles undergoes fluctuations of both energy and density. The energy fluctuations are still given by the last term on the right-hand side of Eq. (32), with the various thermodynamic functions evaluated in the grand canonical ensemble. The density fluctuations can be determined from the mean square fluctuations in particle number $\langle(N - \langle N\rangle)^2\rangle$, where the mean number of particles in the system $\langle N\rangle$ is given, in the grand canonical ensemble (for a system of identical particles), by

$$\langle N\rangle = k_{\mathrm{B}}T\left(\frac{\partial n\Xi}{\partial\mu}\right)_{V,T,z_1\cdots z_i}. \tag{33}$$

Then the fluctuation in particle number is given by

$$\langle(N - \langle N\rangle)^2\rangle = k_{\mathrm{B}}T\left(\frac{\partial\langle N\rangle}{\partial\mu}\right). \tag{34a}$$

The right-hand side of Eq. (34a) can be expressed in terms of more customary thermodynamic functions, as

$$\langle(N - \langle N\rangle)^2\rangle = \langle N\rangle^2k_{\mathrm{B}}T\kappa_T/V, \tag{34b}$$

where κ_T is the isothermal compressibility of the system,

$$\kappa_T = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T \tag{35}$$

with P the pressure of the system. To relate this result to density fluctuations, one need only write the density $n = N/V$ in Eq. (34) to obtain

$$\langle (n - \langle n\rangle)^2\rangle = \langle n\rangle^2 k_B T\kappa_T/V, \tag{36}$$

a result that shows that the density fluctuations vanish as $V \to \infty$.

Density fluctuations in an open system are responsible for the scattering of light by the system. This accounts for, among other things, the blue color of the sky, and the phenomenon of critical opalescence in the vicinity of the critical point of a phase transition, where the isothermal compressibility becomes large (see CRITICAL PHENOMENA).

5.3 Distribution Functions

Using the appropriate phase-space distribution functions for the microcanonical, canonical, and grand canonical ensembles, one can compute the distribution functions that describe the properties of an equilibrium system in more detail than do the thermodynamic functions. Furthermore, the thermodynamic functions themselves can be expressed in terms of integrals of products of the equilibrium distribution functions with functions such as the potential energy of interaction of two particles in the system, or other appropriate microscopic functions.

For most applications of statistical mechanics to fluid systems, the most important distribution functions are the one-particle and two-particle distribution functions $n_1(\mathbf{r},\mathbf{p})$ and $n_2(\mathbf{r},\mathbf{p},\mathbf{r}'',\mathbf{p}'')$, respectively, defined by

$$n_1(\mathbf{r},\mathbf{p}) = \left\langle \sum_{i=1}^{N} \delta(\mathbf{r}_i - \mathbf{r})\delta(\mathbf{p}_i - \mathbf{p})\right\rangle \tag{37a}$$

and

$$n_2(\mathbf{r},\mathbf{p},\mathbf{r}',\mathbf{p}') = \left\langle \sum_{i=1}^{N} \sum_{j\neq i} \delta(\mathbf{r}_i - \mathbf{r})\delta(\mathbf{p}_i - \mathbf{p}) \times \delta(\mathbf{r}_j - \mathbf{r}')\delta(\mathbf{p}_j - \mathbf{p}')\right\rangle, \tag{37b}$$

where, as above, the angular brackets denote an average over one of the equilibrium ensemble distribution functions. Here we consider a fluid system of monatomic particles where the canonical variables are the positions of the particles $\mathbf{r}_1, \cdots, \mathbf{r}_N$, and the corresponding translational momenta $\mathbf{p}_1, \cdots, \mathbf{p}_N$. The quantity $n_1(\mathbf{r},\mathbf{p})$ is the probability of finding a particle at point $\mathbf{r}$ in the fluid with momentum $\mathbf{p}$, and $n_2(\mathbf{r},\mathbf{p},\mathbf{r}'',\mathbf{p}'')$ is the probability of finding one particle at point $\mathbf{r}$ in the fluid with momentum $\mathbf{p}$, and another at point $\mathbf{r}''$ with momentum $\mathbf{p}''$ (Uhlenbeck and Ford, 1962).

If we consider a fluid system with N-particle Hamiltonian

$$H(\Gamma) = \sum_{i=1}^{N} \frac{p_i^2}{2m} + \Phi(\mathbf{r}_1,\cdots,\mathbf{r}_N),$$

where $\Phi(\mathbf{r}_1,\cdots,\mathbf{r}_N)$ is the potential energy of interaction between the particles, usually assumed to be the sum of pairwise central potentials $\phi(|\mathbf{r}_i - \mathbf{r}_j|)$,

$$\Phi(\mathbf{r}_1,\cdots,\mathbf{r}_N) = \sum_{i<j} \phi(|\mathbf{r}_i - \mathbf{r}_j|) \tag{38}$$

in the absence of external fields, then the one-particle distribution function is the Maxwell–Boltzmann distribution function

$$n_1(\mathbf{r},\mathbf{p}) = n\phi_0(\mathbf{p}), \tag{39a}$$

where $n = N/V$ in the microcanonical and canonical ensembles, and $\langle N\rangle/V$ in the grand canonical ensemble, and $\phi_0(\mathbf{p})$ is the equilibrium momentum distribution function

$$\phi_0(\mathbf{p}) = \left(\frac{\beta}{2\pi m}\right)^{3/2} \exp\left(-\frac{\beta p^2}{2m}\right). \tag{39b}$$

Equation (39a) must be corrected if the system is placed in an external field, such as a gravitational field. The latter case leads to the barometric formula for the variation of density with height.

The two-particle distribution function can be expressed as

$$n_2(\mathbf{r},\mathbf{p},\mathbf{r}',\mathbf{p}') = \phi_0(\mathbf{p})\phi(\mathbf{p}')\langle N(N - 1) \times \delta(\mathbf{r}_1 - \mathbf{r})\delta(\mathbf{r}_2 - \mathbf{r}')\rangle. \tag{40a}$$

The quantity in the angular brackets on the right-hand side of Eq. (39) cannot be calculated further without specifying the interaction between the particles. It is customary to write this quantity—the probability of finding one particle at $\mathbf{r}$ and another at $\mathbf{r}''$—in terms of the so-called radial distribution function $g^{(2)}(\mathbf{r},\mathbf{r}'')$ as

$$\langle N(N-1)\delta(\mathbf{r}_1-\mathbf{r})\delta(\mathbf{r}_2-\mathbf{r}')\rangle = n^2 g^{(2)}(\mathbf{r},\mathbf{r}'), \tag{40b}$$

so that n_2 becomes

$$n_2(\mathbf{r},\mathbf{p},\mathbf{r}',\mathbf{r}') = n^2\phi_0(\mathbf{p})\phi_0(\mathbf{p}')g^{(2)}(\mathbf{r},\mathbf{r}'). \tag{41}$$

The radial distribution function differs slightly among the ensembles, since its integrals over $\mathbf{r}$ and $\mathbf{r}''$ lead to average quantities that are different in the grand canonical ensemble from their values in the other ensembles. For a large enough system $g^{(2)}(\mathbf{r},\mathbf{r}'')$ is only a function of $|\mathbf{r}-\mathbf{r}''|$, and it can be determined as a function of spatial separation, temperature, and density by theoretical analysis, by computer studies, and by light-scattering experiments. In Fig. 1 we illustrate this function for hard-sphere molecules. One can easily see the oscillations in this function, which show that there is a short-range ordering of particles in a fluid that is sufficiently dense, which is one indication of the more detailed ordering of particles that is found in a crystalline solid (Hansen and McDonald, 1986).

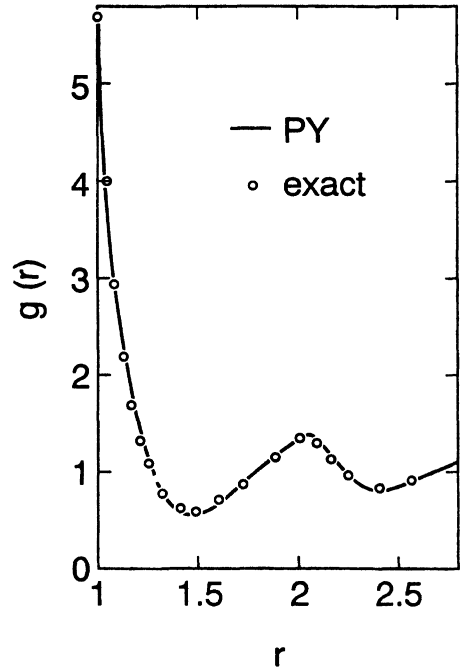

FIG. 1. A plot of the pair correlation function $g(r)$ for a hard-sphere fluid at $V/V_0 = 1.51$ where V_0 is the volume of close packing of the spheres. The points are the results of computer simulations, and the curve is the result of an approximate theory due to Percus and Yevick. Here r is measured in units of the hard-sphere diameter. [Figure from Hansen and McDonald (1986).]

In the case that the potential energy of interactions among the particles can be expressed as a sum of central, pair potentials, the thermodynamic functions of the fluid can be expressed in terms of the radial distribution function. For example, the pressure of the fluid P is

$$P = nk_BT - \frac{4\pi n^2}{6}\int_0^\infty dr r^2\phi'(r)g^{(2)}(r), \tag{42}$$

where $\phi'(r)$ is the derivative of $\phi(r)$ with respect to the separation r. Equation (42) can also be obtained from the virial theorem of classical mechanics and is often called the virial equation of state.

Although we have chosen to illustrate the use of distribution functions here with examples appropriate for fluid systems, very similar discussions can be given for magnetic or other systems.

5.4 Systems of Interacting Particles

The statistical theory of ideal systems described in Sec. 5.1 is, of course, only useful under very limited circumstances, because it is formulated under the assumption that the constituent particles, or modes, of the system do not interact. Methods have been developed in order to incorporate the particle interactions properly into the calculations of thermodynamic properties and equilibrium distribution functions. As long as one is not concerned with describing the properties of a system near a phase transition, which requires a more elaborate treatment, it is often possible to expand the properties of the system about some limiting ideal value in powers of an appropriate small parameter.

Typical of such expansions is the *virial expansion* of the thermodynamic properties of a real gas as a power series in the density of the gas. The virial expansion is motivated by the fact that if the gas is sufficiently dilute, the average distance between the molecules of the gas $\sim(V/N)^{1/3} = n^{-1/3}$ is much greater than the range of the intermolecular potential, σ, say. Thus the reduced density, $n\sigma^3 \ll 1$, is an appropriate small parameter for the representation of the properties of a dilute or moderately dense gas as a power series. J. Mayer and later workers have developed a very refined theory for developing such virial expansions for nonpolar, polar, and even ionic systems (Mayer and Mayer, 1981). In the last case, the virial expansion must be resummed term by term in order to obtain a well-behaved representation for the properties of an ionic system, such as an ionic solution or a plasma.

Typical of such expansions is the virial expansion of the pressure for a dilute or moderately dense gas, which, assuming that the particles interact with pairwise, central forces, has the form

$$\beta P = n + B_2(T)n^2 + B_3(T)n^3 + \cdots, \tag{43}$$

where the second virial coefficient, $B_2(T)$, is given by

$$B_2(T) = -\tfrac{1}{2}\int d\mathbf{r} f(|\mathbf{r}|), \tag{44a}$$

and the third virial coefficient $B_3(T)$ is given by

$$B_3(T) = -\tfrac{1}{3}\int d\mathbf{r}\int d\mathbf{r}'\, f(|\mathbf{r}'|)f(|\mathbf{r}-\mathbf{r}'|) \tag{44b}$$

and similar expressions for the higher virial coefficients B_4, B_5, $\cdots$. Here the function $f(|\mathbf{r}|)$ is the Mayer f function

$$f(|\mathbf{r}|) = e^{-\beta\phi(r)} - 1, \tag{45}$$

where $\phi(r)$ is the potential energy of interaction of two particles separated by a distance $|\mathbf{r}|$. If the potential has a range of σ, then, the Mayer f function vanishes for $|\mathbf{r}| \gg \sigma$, and consequently $B_2(T)$ is of order σ^3, $B_3(T)$ is of order $(\sigma^3)^2$, and the virial expansion becomes a power series in the reduced density $n\sigma^3$. The second virial coefficient, $B_2(T)$, represents the first correction to the ideal-gas equation of state, due to the influence of binary interactions taking place in the gas; B_3 is the next correction due to three-body interactions of three particles in the gas. The higher virial coefficients can be understood in a similar way.

While the virial expansion for the thermodynamic properties of gases is typical of the methods used to compute the equilibrium properties of nonideal systems, it by no means exhausts the wide variety of methods and expansions that have proved to be useful in the direction. High-temperature, low-temperature, weak-coupling, Debye-Hückel, . . . expansions abound in this area. It is safe to say that for many materials there now exists a suitable method for the computation of their thermodynamic properties. However, a suitable understanding and fundamental description of the properties of complicated liquids, solids, or other systems where our understanding of the microscopic details is incomplete is yet to be found.

5.5 Phase Transitions

One of the major areas of research in equilibrium statistical mechanics, for both classical and quantum systems, is to provide a description of the various phase transformations that thermodynamic systems exhibit. For the liquid–gas phase transition it is now possible to make quantitative predictions about the behavior of the thermodynamic and distribution functions near the critical point. The progress was made possible by the application of renormalization-group methods to the problem by Wilson and Kogut (1974), Wilson (1975), Fisher (1974), Kadanoff (1966), Kadanoff *et al.* (1967), Widom (1965), and others (see PHASE TRANSITIONS: RENORMALIZATION AND SCALING).

The theories for phase transitions indicate that near a critical point there are correlations between particles that extend over distances considerably larger than the average spacing between particles or the range of the interparticle potential. These correlations are propagated, so to speak, by the interparticle potential, but they are not very sensitive to the details of the potential. As a result many qualitatively different systems have similar phase-transition properties.

For example, it has been shown that the liquid–gas phase transition has many properties in common with other phase-transition phenomena such as the paramagnetic–ferromagnetic phase transition in metals and the one phase–two phase transition in binary fluid mixtures. It has been possible, in fact, to organize a large number of apparently different types of phase transitions into *universality classes,* such that the critical properties of all phase transitions in any one class are describable by the same set of fundamental parameters, the *critical exponents* (see UNIVERSALITY). These critical exponents describe the way that the various thermodynamic functions either diverge or approach zero as the critical point is approached from different directions in the space of the appropriate thermodynamic variables.

6. NONEQUILIBRIUM STATISTICAL MECHANICS

Nonequilibrium statistical mechanics deals with the time development of an ensemble of similar systems described at some initial time by a nonequilibrium distribution function, and attempts to describe the average behavior of this ensemble. As stated in the Introduction, the goal is to explain why the nonequilibrium behavior of large systems often follows simple laws, such as the equations of fluid dynamics or similar equations for other systems, generally described by the equations of irreversible, or nonequilibrium, thermodynamics.

The thermodynamics of nonequilibrium processes is essentially based on two principal ideas:

1. One can describe the behavior of large systems that are not in equilibrium in terms of local densities of "conserved" quantities, such as the local mass density $\rho(\mathbf{r},t)$, the local momentum density $g(\mathbf{r},t)$, and the local energy density $\epsilon(\mathbf{r},t)$ in a fluid. These local densities satisfy "conservation" laws, which express the fact that mass, momentum, and energy are not created within the system, but instead flow from one region of the system to another.
2. The fluxes of mass, momentum, and energy from one region of the system to an adjacent region are functions, often but not necessarily linear functions, of the gradients of the local densities.

While the first idea is strictly a consequence of the mechanical, macroscopic properties of the system, the second idea embodies some description of a microscopic system that is not often obvious from a knowledge of its microscopic properties, and indeed reflects a kind of randomness in the behavior of large systems. The flux–gradient relations include Fick's law of diffusion, Newton's law of viscosity, Fourier's law of heat conduction, and Ohm's law of electrical conductivity, as well as similar laws appropriate to multicomponent systems, chemically reacting systems, plasmas, and so on. The reason that one suspects that a kind of random behavior of the particles of the system is responsible for these laws is that flux–gradient relations of this form are typical of random-walk models for diffusion, and are not typical of simple mechanical systems where particles do not collide with each other, or with some obstacles placed in the system. Thus one expects that collisions of some sort—between particles, nonlinear interactions between normal modes of a crystal, etc.—are at the heart of the behavior described by nonequilibrium thermodynamics, and thus need to be taken into account in a statistical mechanical theory of nonequilibrium processes.

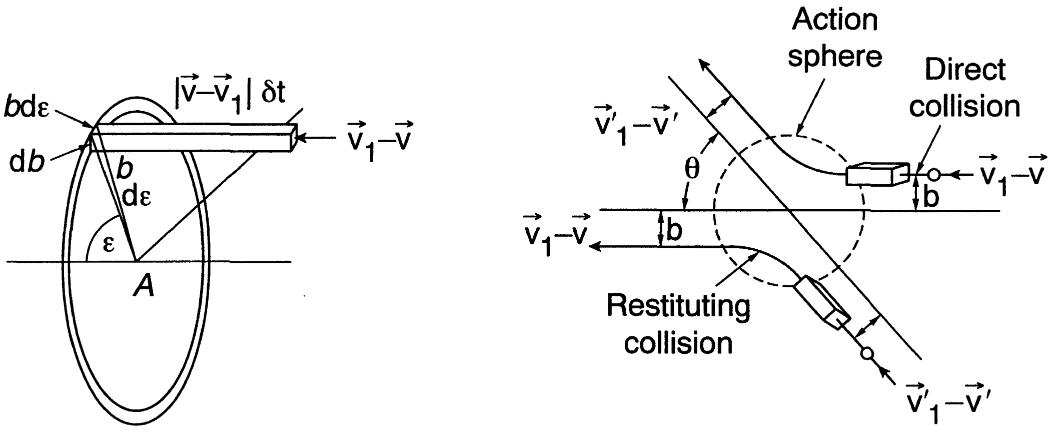
Therefore the problems to which nonequilibrium statistical mechanics addresses itself are to explain and to describe the approach of macroscopic systems to a state of total equilibrium, to describe the behavior of time-dependent fluctuations about equilibrium, and, perhaps the most fundamental problem, to explain why large systems with reversible microscopic dynamics obey irreversible macroscopic laws.

The foundation for the nonequilibrium statistical mechanics of classical systems is Liouville's equation for the time-dependent Γ-space distribution function $\rho(\Gamma,t)$, Eq. (4). In the main, two approaches have been developed for a discussion of irreversible processes. One approach applies to dilute or dense gases, and is part of the subject matter of the kinetic theory of gases. In this approach one tries to develop an equation for the single-particle distribution function $f(\mathbf{r},\mathbf{v},t)$ defined so that $f(\mathbf{r},\mathbf{v},t)d^3r d^3v$ is the number of particles in the system in the spatial region d^3r about $\mathbf{r}$ and in the velocity region d^3v about $\mathbf{v}$, at time t. The major contribution to the theory of this function was made by Boltzmann, who used plausible arguments about the number of collisions taking place in the gas in a small time interval to derive an equation for $f(\mathbf{r},\mathbf{v},t)$ in the case that the gas is dilute. This equation, the *Boltzmann transport equation,* is

$$\frac{\partial f(\mathbf{r},\mathbf{v},t)}{\partial t} + \mathbf{v}\cdot\nabla_r f(\mathbf{r},\mathbf{v},t) = \int d^3v_1 \int_0^{\sigma} b\,db \int_0^{2\pi} d\epsilon\, |\mathbf{v} - \mathbf{v}_1| \times [f(\mathbf{r},\mathbf{v}_1',t)f(\mathbf{r},\mathbf{v}',t) - f(\mathbf{r},\mathbf{v},t)f(\mathbf{r},\mathbf{v}_1,t)]. \tag{46}$$

The left-hand side of Eq. (46) describes the rate of change of f due to free-particle motions, that is, motion where every particle at $(\mathbf{r},\mathbf{v})$ at some time t moves to the point $(\mathbf{r} + \mathbf{v}dt,\ \mathbf{v})$ after a time interval dt. If there were no collisions in the gas, the right-hand side of Eq. (46) would be zero. Instead, some of the particles that started at $(\mathbf{r},\mathbf{v})$ collided with other particles in the gas before they could arrive at $(\mathbf{r} + \mathbf{v}dt,\ \mathbf{v})$. These are counted in the terms on the right-hand side with the negative sign. Still other particles arrived at $(\mathbf{r} + \mathbf{v}dt,\ \mathbf{v})$ without starting at $(\mathbf{r},\mathbf{v})$ but got there as a result of binary collisions with other particles. These are counted in the first term in the integrand on the right-hand side of Eq. (46). b and ϵ represent impact parameters and an azimuthal angle for a binary collision, and $\mathbf{v}'$ and $\mathbf{v}_1'$ are velocities of two particles that collide with collision parameters (b,ϵ) in such a way that one of the particles has velocity $\mathbf{v}$ after the collision. These collisions, which produce particles with velocity $\mathbf{v}$, are called restituting collisions, while those that reduce the number of particles with velocity $\mathbf{v}$ are called direct collisions. This situation is illustrated in Fig. 2.

The Boltzmann transport equation predicts that for an isolated system $f(\mathbf{r},\mathbf{v},t)$ decays in the course of time to its equilibrium value and allows the construction of a nonequilibrium analog for the thermodynamic entropy, the negative of the so-called H function, which increases monotonically in time as the system approaches equilibrium. Moreover, one can derive the hydrodynamic equations for a dilute gas together with expressions for the associated transport coefficients, such as the coefficients of thermal conductivity and viscosity, in terms of the intermolecular potential. These expressions describe the experimental results for dilute gases so well that they are used now to test various intermolecular potential models. In spite of the considerable success of the Boltzmann equation, a complete theory of nonequilibrium processes in gases requires



(a) (b)

FIG. 2. (a) The impact parameter b and azimuthal angle ϵ that describe a binary collision. The origin of the coordinate system is placed at the center of one of the colliding particles. (b) The direct and restituting collisions included in the Boltzmann equation. The origin of the coordinate system is placed on the center of the particle that has velocity v, either before or after the collision. The action sphere denotes the range of the interaction forces between the two particles.

that one be able to derive the Boltzmann equation from the Liouville equation directly, i.e., to replace the plausible argument about the number of collisions by a plausible construction of an initial ensemble and to extend the Boltzmann equation to higher orders in the density so as to treat dense gases. Such a derivation is necessary in order to understand how we can reconcile the irreversible behavior of macroscopic systems with the reversible microscopic equations of motion.

There have been satisfactory derivations of the Boltzmann equation from the Liouville equation (Bogoliubov, 1962; Green, 1958; Green and Piccerelli, 1963; Cohen, 1962). However, the extension of the Boltzmann equation to higher orders in the density is quite involved and not yet completely clear; e.g., the transport coefficients of a dense gas cannot be expanded in a power series in the density; instead, logarithmic terms appear (Dorfman and Cohen, 1967). Computer simulations of molecular dynamics have considerably aided the development of the kinetic theory of dense gases by allowing a detailed examination of the dynamical processes taking place in the gas and by providing quantitative information as to the effects of these processes.

The other approach to the theory of nonequilibrium processes that has been especially successful is called the time-correlation function theory and is due to Green (1952, 1954) and Kubo (1957). This approach seeks special solutions of the Liouville equation for a system that is close to a total equilibrium state from which it has been perturbed by an imposed external field or a gradient in the velocity or temperature of the system. One then studies the behavior of this perturbed equilibrium system with time; shows that, on the average, the hydrodynamic equations are obeyed; and obtains explicit expressions for the transport coefficients. The expression for a typical transport coefficient τ for a classical system has the form

$$\tau = \int_0^\infty dt \langle J(0)J(t)\rangle. \qquad (47)$$

Here J represents an N-particle current that depends on the positions and velocities of all N particles; $J(0)$ is the value of this current at some initial time $t = 0$; $J(t)$ is its value a time t later, obtained by solving the equations of motion for the N-particle system; and the angular brackets denote an average over an equilibrium ensemble, taken in the thermodynamic limit. A similar expression can be given for quantum systems. These expressions are very similar to the Einstein formula for the diffusion coefficient of a particle undergoing Brownian motion. Since the derivations of the time-correlation function formulas are quite general, they apply to a wide variety of systems. However, because one must use the dynamics of an N-particle system to evaluate them, explicit calculation of these formulas presents a formidable problem, similar to, but more difficult than, the evaluation of the partition function. Nevertheless, approximation methods have been developed to evaluate these functions for a number of systems, particularly gases and liquids. Moreover, these functions are particularly suited for computer studies, where the computer follows the dynamics of the system and calculates $\langle J(0)J(t)\rangle$ directly. In addition, the time-correlation functions can be studied experimentally by means of light-scattering or neutron-scattering methods. Each of these various approaches—theory, computer studies, and experiment—stimulates progress in the other two areas.

One of the most striking examples of the progress possible by making use of the interplay between theoretical, computer, and experimental studies is the development of the mode-coupling picture for understanding transport processes in fluid and other systems (Kadanoff and Swift, 1968). This picture was stimulated by two discoveries, one experimental and the other by means of computer-simulated molecular dynamics. Experimentally it was discovered that transport coefficients such as the thermal conductivity show marked anomalies in the vicinity of the critical point of a phase transition (see CRITICAL PHENOMENA). By means of computer simulations, it was found that time-correlation functions such as those appearing in the integrand of Eq. (47) show a characteristic behavior in fluid systems, where for long times, $t \gg t_0$,

$$\langle J(0)J(t)\rangle \approx \alpha_J(t/t_0)^{-d/2}, \qquad (48)$$

where a_J is a numerical coefficient depending on density and temperature, t_0 is some characteristic microscopic time scale such as the mean free time between collisions for a particle in the fluid, and d is the dimension of the system (Alder and Wainwright, 1970). These "long-time tails" have important consequences for the understanding of transport in fluids; for example, one can see that the time-correlation function method for determining the transport coefficients does not lead to sensible results in two dimensions since the integral in Eq. (47) diverges (Dorfman and Cohen, 1970; Ernst *et al.*, 1970). This and similar observations have lead to a considerable body of research into the general structure of hydrodynamic equations for fluids and plasmas.

Mode-coupling theory is able to account for both the critical-point anomalies in transport coefficients (Kawasaki, 1970) and the long-time tails in the time-correlation functions, and has been applied to a study of other nonequilibrium phenomena such as the formation and properties of glasses. The central idea of mode-coupling theory is that microscopic processes in fluids are, to a large extent, governed by hydrodynamic-like processes whereby transport of conserved quantities on a microscopic scale takes place according to hydrodynamic laws, but with large fluctuations about them. The proper treatment of the "molecular hydrodynamics" and the microscopic fluctuations leads to the mode-coupling theory (Boon and Yip, 1991).

To conclude this brief description of nonequilibrium statistical mechanics, we mention that a very basic understanding of the foundations of statistical mechanics is likely to develop from modern research on ergodic theory as well as on nonlinear dynamics and chaos. Some important areas in which new and interesting applications of nonequilibrium statistical mechanics have been made include such topics as crystal growth and pattern formation, the theory of electric conduction in solids, flow properties of superconductors and superfluids, the dynamics of polymers, and the theory of coagulation and polymerization.

7. CONCLUSION

A wide range of equilibrium and nonequilibrium behavior of macroscopic systems can be explained and described quantitatively by the methods of classical statistical mechanics. This approach breaks down only when a quantum mechanical description of the microscopic behavior of the system is necessary.

Practically every area of physics, chemistry, and engineering has been influenced by the ideas of statistical mechanics, and in recent years we have seen the utility of a statistical mechanical approach to problems in biology, in computer science (e.g., simulated annealing, neural networks), and in cosmology (e.g., the "inflationary" cosmology). There is every reason to expect that the ideas and methods of statistical mechanics will continue to develop and to infuse and inform other scientific endeavors, and vice versa.

GLOSSARY

Boltzmann Transport Equation: An equation that describes the nonequilibrium properties of a dilute gas.

Canonical Ensemble: A phase-space distribution that describes the equilibrium properties of a system in contact with a heat reservoir with which it can exchange energy.

Ensemble: A fictitious collection of mechanically identical systems, e.g., a collection of bottles of a fluid, containers of a plasma, etc., which are all initially prepared according to some general macroscopic constraint, but which may have different microscopic configurations. Statistical mechanics replaces the computation of the exact properties of one system by a calculation of the average behavior of an ensemble of similar systems.

Ensemble Distribution Function: A phase-space distribution function that describes the properties of an ensemble of systems at a particular time.

Equilibrium Ensemble Distribution Function: see **Canonical, Grand Canonical,** and **Microcanonical Ensembles.**

Equilibrium One-, Two-, . . . Particle Distribution Function: Functions that provide the average probabilities for finding one, two, . . . particles in small regions of position and momenta for a system in equilibrium.

Equipartition of Energies: A result of equilibrium statistical mechanics for classical systems that have a Hamiltonian function that is a positive definite quadratic form in the canonical coordinates and momenta. According to this result, each quadratic term in the Hamiltonian leads to a contribution of $k_B T/2$ to the total thermodynamic internal energy, where k_B is Boltzmann's constant and T is the temperature.

Ergodic Hypothesis: The hypothesis that the trajectory in phase space describing the dynamical behavior of an isolated system spends equal amounts of time in regions of equal measure on the constraint energy surface (in phase space).

Gamma (or Γ) Space: Phase space.

Gibbs Paradox: A problem pointed out by J. W. Gibbs with early formulations of the classical statistical mechanical prescription for computing the thermodynamic properties, whereby nonzero values were obtained for the entropy of mixing of two identical systems. This problem was corrected by a careful study of the classical limit of the quantum mechanical partition function.

Grand Canonical Ensemble: A phase-space distribution that describes the equilibrium properties of a system in contact with a heat reservoir with which it can exchange energy and particles.

Long-Time Tails: Algebraically decaying terms that appear in the time-correlation functions of microscopic currents for times long compared to some characteristic microscopic times.

Maxwell–Boltzmann Distribution Function: A function of momentum, density, and temperature that describes the momentum distribution of particles in a classical fluid system in thermodynamic equilibrium.

Microcanonical Ensemble: A phase-space distribution that describes the equilibrium properties of an isolated system.

Microscopic Current: A mechanical quantity that describes the microscopic flux of mass, momentum, or energy in a system.

Partition Function: A function determined for each of the equilibrium ensembles by means of which the thermodynamic properties of a system can be computed.

Phase Space: A multidimensional space, with one dimension for each canonical coordinate and one for each canonical momentum of a mechanical system. One point in phase space gives the values of all canonical coordinates and momenta of a mechanical system. An ensemble can be described by a collection of points in phase space.

Time-Correlation Functions: Equilibrium ensemble averages of products of two or more microscopic currents, each evaluated at a possibly different time.

Virial Equation of State: An expression relating the thermodynamic pressure of a fluid system to the temperature, density, pair potential, and the equilibrium radial distribution function of the system.

INTRODUCTION

The density matrix plays a main role in quantum statistical mechanics, as Landau formulated it. The canonical and grand canonical ensembles introduced by Gibbs (see STATISTICAL MECHANICS, CLASSICAL) are expressed by the density matrix using the Hamiltonian and the number operator of the relevant quantum system. The basic concept of ensemble theory is the same in both classical and quantum statistical mechanics. The readers who are not familiar with this concept should look first at the article STATISTICAL MECHANICS, CLASSICAL. Fermi statistics is vital in condensed matter physics. Bose statistics plays an essential role in superconductivity and lasers. The Bose–Einstein condensation for quasiparticles with the dispersion $\epsilon(p) = ap^k$ with $k = \frac{3}{2}$ for three-dimensional helium is also explained in general d dimensions. A general decomposition theory of exponential operators such as the density matrix is also presented, which is shown to be of practical importance to quantum Monte Carlo simulations, as was formulated first in quantum spin systems (Suzuki, 1976). The quantum Monte Carlo method is used in Fermi and Bose systems as well as in spin systems. The simplest theory of phase transitions is the Weiss mean-field approximation (Weiss, 1907), which is equivalent to Landau's phenomenological theory of phase transitions. Bethe (1935) extended the Weiss theory to a cluster effective-field approximation. Even modern critical phenomena can be analyzed using the coherent-anomaly method (Suzuki, 1986) based on a systematic (or coherent) series of mean-field approximations. The linear response theory on transport phenomena was established by Kubo (1957) in the framework of quantum statistical mechanics.

1. DENSITY MATRIX AND ENSEMBLE THEORY

1.1 Definition of Density Matrix

Landau introduced the density matrix ρ by taking into account both the probabilistic character of quantum mechanics and statistics of ensemble theory. First the wave function of the relevant system, ψ, is expanded as a linear combination of the eigenfunctions $\{\psi_j\}$ of the Hamiltonian $\mathcal{H}$: $\psi = \Sigma c_j\psi_j$. The corresponding state in the Hilbert space is expressed as $|\psi\rangle = \Sigma c_j|\psi_j\rangle$. The expectation value of a physical quantity (operator) A over this state is written as

$$\langle\psi|A|\psi\rangle = \sum_{i,j} c_j c_i^*\langle\psi_i|A|\psi_j\rangle, \tag{1}$$

where c_i^* denotes the complex conjugate of c_i. The coefficients $\{c_jc_i^*\}$ in Eq. (1) are statistical quantities in the ensemble theory of statistical mechanics, as was mentioned above. Following Landau, we introduce here the statistical weight w_{ji} as the statistical average of the coefficient $c_jc_i^*$, and consequently the average of the physical quantity A over the corresponding statistical ensemble is expressed in the following matrix form:

$$\bar{A} = \sum_{i,j} w_{ji}\langle i|A|j\rangle = \mathrm{Tr}\,\rho A;\ \rho = (w_{ji}). \tag{2}$$

If we make use of the energy representation diagonalizing the Hamiltonian $\mathcal{H}$ (namely, $\mathcal{H}|\psi_j\rangle = E_j|\psi_j\rangle$), the off-diagonal matrix elements $\{w_{ji}\}$ for $j \neq i$ are considered to be vanishing because of statistical cancellation. In particular, the diagonal element w_{jj} is expressed in the form

$$w_{jj} = e^{-\beta E_j}/Z(\beta);\ Z(\beta) = \sum e^{-\beta E_j} \tag{3}$$

with $\beta = 1/k_BT$ in the canonical ensemble specified by the temperature T (see STATISTICAL MECHANICS, CLASSICAL). Here, k_B denotes the Boltzmann constant given by $k_B = 1.380\,658 \times 10^{-23}$ J K^{-1}. Thus, the density matrix ρ is given by

$$\rho = e^{-\beta\mathcal{H}}/Z(\beta);\ Z(\beta) = \mathrm{Tr}\,e^{-\beta\mathcal{H}}. \tag{4}$$

Similarly, the density matrix of the grand canonical ensemble is given by

$$\rho = \frac{e^{-\beta(\mathcal{H}-\mu\mathcal{N})}}{\Xi(\beta\mu,\beta)};\ \Xi(\alpha,\beta) = \mathrm{Tr}\,e^{-\beta\mathcal{H}+\alpha\mathcal{N}}, \tag{5}$$

where $\mathcal{N}$ denotes the number operator of particles. Here μ denotes the chemical potential determined by the condition

$$N = \mathrm{Tr}\,\mathcal{N}\rho \tag{6}$$

for the given average number of particles, N.

1.2 Definition of Exponential Operators

It is instructive to define here an exponential operator $\exp(-\beta\mathcal{H})$ as

$$e^{-\beta\mathcal{H}} = \sum_{n=0}^{\infty} \frac{(-\beta)^n}{n!}\mathcal{H}^n \tag{7}$$

or equivalently

$$e^{-\beta\mathcal{H}} = (e^{-1/n\beta\mathcal{H}})^n = \lim_{n\to\infty}\left(1 - \frac{\beta}{n}\mathcal{H}\right)^n. \tag{8}$$

The convergence of the above formulas (7) and (8) is assured for bounded operators $\mathcal{H}$, namely, in Banach space.

More detailed explanation of exponential operators will be given later.

1.3 Density Matrix as a Projection Operator

In order to discuss the physical meaning of the density matrix, we consider the projection operator P_j defined by $P_j = |j\rangle\langle j|$ in terms of the eigenstate $|j\rangle(\equiv|\psi_j\rangle)$ of the Hamiltonian $\mathcal{H}$. Thus, we have

$$P_j|\psi\rangle = (\langle j|\psi\rangle)|j\rangle, \tag{9}$$

as shown in Fig. 1.

The density matrix ρ is expressed in the form

$$\rho = \sum_j w(E_j)P_j = \sum_j w(E_j)|j\rangle\langle j|, \tag{10}$$

using the projection operator P_j. Here, $w(E_j)$ denotes the statistical weight of the eigenstate $|j\rangle$ in each ensemble. As shown in Eq. (3), $w(E_j) = e^{-\beta E_j}/Z(\beta)$ in the canonical ensemble and $w(E_j) = \exp[-\beta(E_j - \mu N)] \times \Xi(\beta\mu,\beta)$ in the grand canonical ensemble.

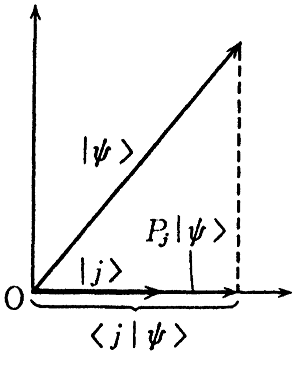

FIG. 1. Schematic explanation of the projection operator P_j.

2. AVERAGE, RESPONSE, FLUCTUATION, AND GENERALIZED PARTITION FUNCTION

In order to evaluate the average and response of an arbitrary physical quantity Q, we introduce here the following generalized partition function:

$$\Omega(\beta,h) = \operatorname{Tr}\hat{\rho} \equiv \operatorname{Tr} e^{-\beta(\hat{\mathcal{H}}-hQ)} \tag{11}$$

with a parameter h conjugate to Q. Here, $\hat{\mathcal{H}}$ denotes $\mathcal{H}$ or $\mathcal{H} - \mu\mathcal{N}$, corresponding to the canonical or grand canonical ensemble.

Then, the average of Q is given by

$$\bar{Q} = \frac{\operatorname{Tr} Qe^{-\beta\hat{\mathcal{H}}}}{\Omega(\beta,0)} = \left[\frac{\partial}{\partial(\beta h)}\log\Omega(\beta,h)\right]_{h=0}. \tag{12}$$

Here, we have used the formula

$$\frac{d}{dx}\operatorname{Tr} e^{A+xB} = \operatorname{Tr} Be^{A+xB}. \tag{13}$$

By the way, it is instructive to remark the following operator identity:

$$\frac{d}{dx}e^{A+xB} = \int_0^1 e^{(1-\lambda)(A+xB)}Be^{\lambda(A+xB)}d\lambda. \tag{14}$$

This yields the following perturbational formula up to the first order of x:

$$e^{A+xB} = e^A\left(1 + x\int_0^1 e^{-\lambda A}Be^{\lambda A}d\lambda + \cdots\right). \tag{15}$$

Now we consider a certain set of physical quantities $\{Q_j\}$. The response of Q_j with respect to the corresponding conjugate field h_k is expressed by

$$\bar{Q}_j(\{h_j\}) = \bar{Q}_j(\{0\}) + \sum_k \chi_{jk}h_k + O(h_k^2), \tag{16}$$

using the formula (14). Here, the response function χ_{jk} is given by

$$\chi_{jk} = \int_0^\beta (\langle Q_k(-i\hbar\lambda)Q_j\rangle - \langle Q_k\rangle\langle Q_j\rangle)d\lambda, \tag{17}$$

where $Q(z)$ denotes the following interaction representation:

$$Q(z) = e^{iz\hat{\mathcal{H}}/\hbar}Qe^{-iz\hat{\mathcal{H}}/\hbar}. \tag{18}$$

Here, $\hbar = h/2\pi$ and h denotes the Planck constant. In particular, if Q_k commutes with the Hamiltonian $\hat{\mathcal{H}}$, then we have

$$\begin{aligned}\chi_{jk} &= \beta(\langle Q_kQ_j\rangle - \langle Q_k\rangle\langle Q_j\rangle)\\ &= \beta\langle (Q_k - \langle Q_k\rangle)(Q_j - \langle Q_j\rangle)\rangle.\end{aligned} \tag{19}$$

Furthermore, χ_{jj} is given by

$$\chi_{jj} = \beta\langle (Q_j - \langle Q_j\rangle)^2\rangle. \tag{20}$$

Thus, the response function χ_{jj} is expressed in terms of the fluctuation of Q_j in the absence of the external field h_j.

For example, the susceptibility of a ferromagnet, $\chi_0(T)$, is expressed in terms of spin correlation functions as

$$\chi_0(T) = \lim_{H\to 0}\frac{1}{H}\mu_B\sum_j \langle S_j^z\rangle_H = \frac{g\mu_B^2}{k_BT}\sum_{i,j}\langle S_i^zS_j^z\rangle. \tag{21}$$

Here, μ_B and g denote the Bohr magneton and the Landé factor, respectively. The total magnetization is expressed by the operator $M = g\mu_B\Sigma_j S_j^z$, where S_j^z denotes the z component of the spin operator S_j^z at the site j. The parameter H in Eq. (21) denotes an external magnetic field, and the average $\langle\cdots\rangle_H$ is defined using the canonical ensemble in the presence of the magnetic field H. Similarly, the specific heat C_v is given by the response of the energy with respect to the inverse temperature β as

$$C_v = \frac{1}{k_BT^2}\langle(\mathcal{H} - \langle\mathcal{H}\rangle)^2\rangle. \tag{22}$$

3. STATISTICAL MECHANICAL EXPRESSIONS OF THERMODYNAMIC FUNCTIONS

Thermodynamic functions such as the Helmholtz and Gibbs free energies are expressed using the partition functions in the canonical and grand canonical ensembles.

3.1 Helmholtz Free Energy

The Helmholtz free energy defined thermodynamically by $F = E - TS$ for the energy E and the entropy S is given microscopically by

$$F = -k_BT\ln Z(\beta), \tag{23}$$

where $Z(\beta)$ denotes the partition function of the canonical ensemble, namely

$$Z(\beta) = \operatorname{Tr} e^{-\beta\mathcal{H}}. \tag{24}$$

Expression (23) is easily derived using the saddle-point method from the Boltzmann principle

$$S = k_B\ln W, \tag{25}$$

where W is the number of states for the specified energy range $E \sim E + \Delta E$. Thus, the entropy (25) is a function of the energy E as $S = S(E)$. The thermodynamic relation

$$\frac{\partial S(E)}{\partial E} = \frac{1}{T} \tag{26}$$

gives the temperature dependence of the energy and entropy. This is the scheme of the microcanonical ensemble. The number of states W is also expressed in terms of the density of states $D(E)$ as

$$W = D(E)\Delta E. \tag{27}$$

Thus, the partition function $Z(\beta)$ is written as

$$\begin{aligned}Z(\beta) &= \operatorname{Tr} e^{-\beta\mathcal{H}} = \sum e^{-\beta E_j} = \int_0^\infty e^{-\beta E}D(E)dE\\ &= \int_0^\infty e^{-\beta(E-TS(E))}dE \simeq \exp[-\beta(E - TS)],\end{aligned} \tag{28}$$

using the saddle-point method. This yields the relation (23).

3.2 Equation of State for Gas and Grand Partition Function

Thermodynamically, the pressure p of a gas in the volume V at the temperature T is given by

$$pV = G - F = \mu N - F, \tag{29}$$

where G is the Gibbs free energy. The grand partition function defined by

$$\Xi(\lambda) \equiv \Xi(\ln \lambda, \beta) = \mathrm{Tr}\, \lambda^{\mathcal{N}} e^{-\beta\mathcal{H}} \tag{30}$$

is related to the partition function $Z_N(\beta)$ for the particle number N as

$$\Xi(\lambda) = \sum_{N=0}^{\infty} \lambda^N Z_N(\beta). \tag{31}$$

Conversely, the partition function $Z_N(\beta)$ is expressed by the following integral:

$$Z_N(\beta) = \frac{1}{2\pi i} \oint \frac{\Xi(\lambda)}{\lambda^{N+1}}\, d\lambda \tag{32}$$

taken counterclockwise over a circle surrounding the origin. This integral is also rewritten as

$$Z_N(\beta) = \frac{1}{2\pi i} \oint \exp[\ln \Xi(\lambda) - N \ln \lambda] \frac{d\lambda}{\lambda}. \tag{33}$$

Using again the saddle-point method in Eq. (33), we arrive at the relation

$$F = -k_{\mathrm{B}}T \ln Z_{\bar{N}}(\beta) = -k_{\mathrm{B}}T \ln \Xi(\lambda) + \mu N, \tag{34}$$

where the number N is given by

$$N = \lambda \frac{\partial}{\partial \lambda} \ln \Xi(\lambda). \tag{35}$$

Thus we obtain the formula (29). Namely, the equation of state for a gas is expressed as

$$pV = k_{\mathrm{B}}T \ln \Xi. \tag{36}$$

As a simple application of Eq. (36), we derive the equation of state for an ideal classical gas as follows. The partition function for a classical gas (see STATISTICAL MECHANICS, CLASSICAL) is given by

$$\begin{aligned} Z_N(\beta) &= \frac{1}{N! h^{3N}} \int \cdots \int e^{-\beta\mathcal{H}} d\Gamma \\ &= \frac{1}{N! h^{3N}} \left(\int \exp\left(-\frac{\beta p^2}{2m} \right) d^3p\, d^3q \right)^N \\ &= \frac{1}{N!} \left[V \left(\frac{2\pi m k_{\mathrm{B}} T}{h^2} \right)^{3/2} \right]^N . \end{aligned} \tag{37}$$

Then, the grand partition function Ξ for this classical system is obtained as

$$\Xi = \sum_{N=0}^{\infty} \lambda^n Z_N(\beta) = \exp\left[\lambda V \left(\frac{2\pi m k_{\mathrm{B}} T}{h^2} \right)^{3/2} \right]. \tag{38}$$

On the other hand, the number of particles is expressed as

$$N = \frac{\partial}{\partial \alpha} \ln \Xi = \lambda \frac{\partial}{\partial \lambda} \ln \Xi = \lambda V \left(\frac{2\pi m k_{\mathrm{B}} T}{h^2} \right)^{3/2}. \tag{39}$$

Thus, we arrive at the equation of state for an ideal classical gas:

$$pV = k_{\mathrm{B}} T \lambda V \left(\frac{2\pi m k_{\mathrm{B}} T}{h^2} \right)^{3/2} = N k_{\mathrm{B}} T. \tag{40}$$

This is the well-known Boyle–Charles law. This result will be used in discussing later the relation among the three expressions p_{cl}, p_{F}, and p_{B} of pressure for an ideal classical gas, the ideal Fermi-particle system, and the ideal Bose-particle system.

4. FERMI STATISTICS

As a typical example of quantum statistical mechanics, we explain here Fermi statistics.

4.1 Symmetry of the Wave Function and Statistics of Quantum Particles

According to quantum mechanics, the state of the relevant quantum system with N particles is described by the wave function $\psi(r_1, r_2, \cdots, r_N)$. Since the quantum particles are indistinguishable among each other, the wave function $\psi(\cdots,r_j,\cdots,r_i,\cdots)$ obtained by the interchange of the two particles specified by the coordinates r_i and r_j is not independent; namely, it can be expressed as

$$\psi(\cdots,r_j,\cdots,r_i,\cdots) = C\psi(\cdots,r_i,\cdots,r_j,\cdots). \tag{41}$$

If we apply this relation once more, then we obtain $C^2 = 1$. Therefore, the constant C in Eq. (41) has to satisfy the requirement $C = \pm 1$. In the case of $C = 1$, the wave function ψ is symmetric and the corresponding particles satisfying this symmetry relation are called Bose particles. The statistics of Bose particles is called Bose statistics. In the case of $C = -1$, the wave function ψ is antisymmetric, and the corresponding particles are called Fermi particles. The statistics of Fermi particles is called Fermi statistics. According to this Fermi statistics, two particles cannot take the same state. This is also called the Pauli principle. These two kinds of statistics are classified by the values of spins of particles. It is derived generally that particles with integer spins obey Bose statistics and particles with half-odd integer spins obey Fermi statistics. For example, electrons (e^-), positrons (e^+), protons (p), and neutrons (n) have spin $\frac{1}{2}$, and they obey Fermi statistics. Photons obey Bose statistics. Composite particles of Bose particles obey Bose statistics. Composite particles of an even number of Fermi particles are easily shown to obey also Bose statistics. Composite particles of an odd number of Fermi particles are shown to be Fermi particles.

4.2 Fermi Statistics and Fermi Distribution

Here we consider an ideal Fermi-particle system whose states are specified using the following one-particle states:

$$\begin{aligned} &\text{states} \rightarrow 1, 2, 3, \ldots, j, \ldots, \\ &\text{energy} \rightarrow \epsilon_1, \epsilon_2, \epsilon_3, \ldots, \epsilon_j, \ldots, \\ &\text{number} \rightarrow n_1, n_2, n_3, \ldots, n_j, \ldots. \end{aligned} \tag{42}$$

In the case of Fermi statistics, the Pauli principle requires the condition that $n_j = 0$ or 1. The total number N and the total energy E of Fermi particles satisfy the following relations:

$$\sum_j n_j = N \quad \text{and} \quad \sum_j n_j\epsilon_j = E, \tag{43}$$

respectively.

The grand partition function $\Xi(\alpha,\beta)$ of an ideal Fermi-particle system is given by

$$\begin{aligned} \Xi(\alpha,\beta) &= \sum_{n_j=0,1} \exp\left(-\beta \sum_j n_j\epsilon_j + \alpha \sum_j n_j\right) \\ &= \prod_{j=1}^{\infty} (1 + e^{-\beta\epsilon_j+\alpha});\ \alpha = \beta\mu. \end{aligned} \tag{44}$$

The average number of particles in the state j is obtained as

$$\begin{aligned} \bar{n}_j &= -\frac{\partial}{\partial(\beta\epsilon_j)} \ln \Xi(\alpha,\beta) \\ &= \frac{e^{-\beta\epsilon_j+\alpha}}{1 + e^{-\beta\epsilon_j+\alpha}} = \frac{1}{e^{\beta(\epsilon_j-\mu)} + 1}. \end{aligned} \tag{45}$$

The chemical potential μ is determined by the condition

$$\bar{N} = \sum_j \bar{n}_j = \sum_j \frac{1}{e^{\beta(\epsilon_j-\mu)} + 1}. \tag{46}$$

The above distribution function (45) of a Fermi particle is called the Fermi distribution, and it is written as

$$f_{\mathrm{F}}(\epsilon) = \frac{1}{e^{\beta(\epsilon-\mu)} + 1}. \tag{47}$$

The chemical potential μ for the Fermi distribution function (47) is called the Fermi level or Fermi energy. This depends on the temperature T. The Fermi energy at $T = 0$ is written as μ_0. The Fermi distribution function $f_{\mathrm{F}}(\epsilon)$ at $T = 0$ becomes a step function, as shown in Fig. 2. At finite temperatures, $f_{\mathrm{F}}(\epsilon)$ becomes a smooth function, as shown in Fig. 2.

The Helmholtz free energy of this ideal Fermi-particle system is given in the form

$$\begin{aligned} \mathrm{F} &= E - TS = -k_{\mathrm{B}}T \ln Z(\beta) \\ &= -k_{\mathrm{B}}T \ln \Xi(\alpha,\beta) + \mu N \\ &= \mu N - k_{\mathrm{B}}T \sum_j \ln(1 + e^{-\beta(\epsilon_j-\mu)}). \end{aligned} \tag{48}$$

The energy of this system is expressed by

$$E = \sum_j \bar{n}_j\epsilon_j = \sum_j \frac{\epsilon_j}{e^{\beta(\epsilon_j-\mu)} + 1}. \tag{49}$$

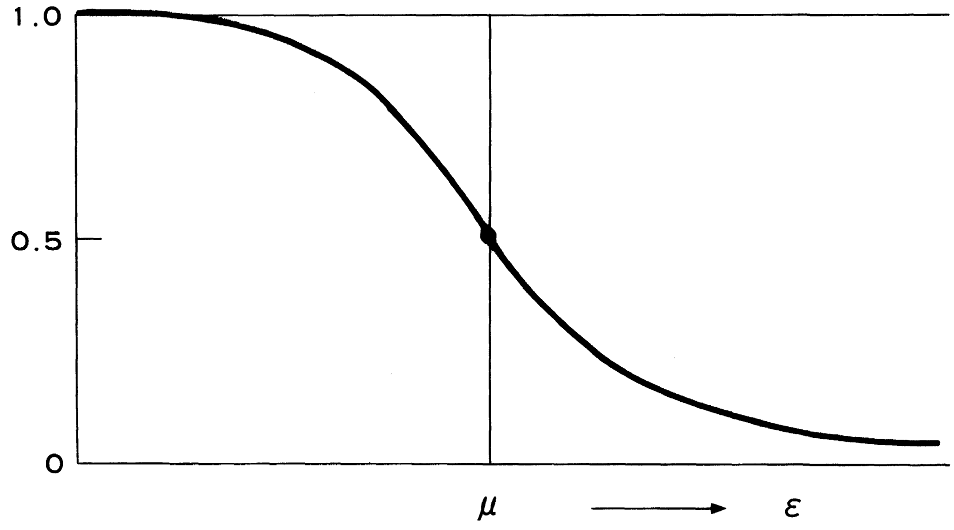

FIG. 2. Fermi distribution function as a function of the energy ϵ. Here μ is the chemical potential or the Fermi level.

The entropy of this Fermi-particle system is given in the form

$$S = -k_B \sum_j \{\bar{n}_j \ln \bar{n}_j + (1 - \bar{n}_j) \ln(1 - \bar{n}_j)\}. \tag{50}$$

If we introduce the density of states $D(\epsilon)$, the energy, the number, and the Helmholtz free energy are expressed by the following integrals:

$$\begin{aligned} E &= \int_0^\infty \epsilon f_F(\epsilon) D(\epsilon) d\epsilon, \\ N &= \int_0^\infty f_F(\epsilon) D(\epsilon) d\epsilon, \\ F &= \mu N - k_B T \int_0^\infty \ln(1 + e^{-\beta(\epsilon - \mu)}) D(\epsilon) d\epsilon. \end{aligned} \tag{51}$$

4.3 Dilute Fermi Gas and Maxwell–Boltzmann Distribution

When the number density of Fermi particles becomes very low, the Fermi distribution $f_F(\epsilon)$ reduces to the classical distribution

$$f_{cl}(\epsilon) = \lambda e^{-\beta\epsilon}, \tag{52}$$

neglecting $+1$ in the denominator of (47) under the condition that $\lambda \equiv e^{\beta\mu} \ll 1$. Equation (52) is called the Maxwell–Boltzmann distribution. The validity of this approximation (classical approximation), namely $\lambda \ll 1$, is assured by the condition

$$\lambda_D \ll r, \tag{53}$$

where r denotes the mean distance of particles, namely $r \simeq \rho^{-1/3}$ for $\rho = N/V$, and λ_D is the thermal de Broglie wavelength defined by

$$\lambda_D = h/\sqrt{3mk_BT} \tag{54}$$

for the mass of a Fermi particle equal to m.

4.4 Degenerate Fermi-Particle System

The state of the Fermi-particle system near $T = 0$ is called degenerate, because almost all levels up to the Fermi level are occupied by Fermi particles. The Fermi level μ_0 at $T = 0$ is determined by the condition

$$N = \int_0^{\mu_0} D(\epsilon) d\epsilon. \tag{55}$$

On the other hand, the energy of an ideal particle is given by $\epsilon = p^2/2m$. Thus, the density of states is evaluated as follows:

$$D(\epsilon) = g_s \frac{d}{d\epsilon}\left(\frac{V}{h^3}\int_0^{\sqrt{2m\epsilon}} 4\pi p^2 dp\right) = 2\pi g_s V\left(\frac{2m}{h^2}\right)^{3/2}\sqrt{\epsilon}. \quad (56)$$

Here, g_s is the spin degeneracy; namely, $g_s = 2$ for electrons. Therefore, the Fermi level μ_0 is given explicitly as

$$\mu_0 = \frac{h^2}{2m}\left(\frac{3N}{4\pi g_s V}\right)^{2/3} = \frac{3N}{2D(\mu_0)}. \quad (57)$$

The following formula is convenient for expanding μ, E, and C_v with respect to T:

$$\int_0^\infty g(\epsilon)f(\epsilon)d\epsilon = \int_0^\mu g(\epsilon)d\epsilon + \frac{(\pi k_B T)^2}{6}g^{(1)}(\mu) + \frac{7(\pi k_B T)^4}{360}g^{(3)}(\mu) + \cdots, \quad (58)$$

where $g^{(n)}(\epsilon)$ denotes the nth derivative of $g(\epsilon)$. Using this formula, we obtain

$$\begin{cases} \mu = \mu_0 - \dfrac{\pi^2}{6}\dfrac{D'(\mu_0)}{D(\mu_0)}(k_B T)^2 + \cdots, \\ E = E_0 + \dfrac{\pi^2}{6}D(\mu_0)(k_B T)^2 + \cdots. \end{cases} \quad (59)$$

Thus, the specific heat of this system near $T = 0$ is shown to be proportional to T as

$$C_v = \frac{dE}{dT} = \frac{\pi^2}{3}D(\mu_0)k_B^2 T + \cdots. \quad (60)$$

The specific heat of electrons has been observed experimentally to behave like Eq. (60) even up to room temperatures.

5. BOSE STATISTICS

Since the number of Bose particles in the state j is allowed to take all the values $n_j = 0, 1, 2, \ldots$, the grand partition function $\Xi(\alpha,\beta)$ of ideal Bose systems is given by

$$\Xi(\alpha,\beta) = \prod_{j=1}^{\infty}\left\{\sum_{n=0}^{\infty}(e^{-\beta\epsilon_j+\alpha})^n\right\} = \prod_{j=1}^{\infty}(1 - e^{-\beta\epsilon_j+\alpha})^{-1}. \quad (61)$$

5.1 Bose Distribution Function

The average number of n_j is thus evaluated as

$$\bar{n}_j \equiv f_B(\epsilon_j) = -\frac{\partial}{\partial(\beta\epsilon_j)}\ln \Xi(\alpha,\beta) = \frac{1}{e^{\beta(\epsilon_j-\mu)} - 1}. \quad (62)$$

Here, the chemical potential is determined by the condition

$$\sum_j \frac{1}{e^{\beta(\epsilon_j-\mu)} - 1} = N. \quad (63)$$

It is seen from (62) that $\mu \le 0$ because of the requirement that $\bar{n}_j \ge 0$ for all $\epsilon_j \ge 0$. The above Bose distribution function (62) also reduces to the Maxwell–Boltzmann distribution function (52) in the low-density limit.

5.2 Bose–Einstein Condensation

An ideal Bose-particle system is shown to show a phase transition at low temperatures as follows. The density of states for ideal particles with mass m is given by

$$D(\epsilon) = 2\pi V\left(\frac{2m}{h^2}\right)^{3/2}\sqrt{\epsilon} \quad (64)$$

or

$$D(p)dp = \frac{V}{h^3}4\pi p^2 dp. \quad (65)$$

Here, we have assumed that the spin degeneracy g_s equals unity (i.e., $g_s = 1$). The total number N is expressed as

$$N = \sum_j \bar{n}_j = \frac{V}{h^3}\int_0^\infty \frac{4\pi p^2 dp}{e^{\beta(p^2/2m-\mu)} - 1} \equiv Vh(T,\mu), \quad (66)$$

where the function $h(T,\mu)$ satisfies the inequality $h(T,\mu) \ge h(T,0)$. This means that Eq. (66) is valid only in the range of density given by $\rho \equiv N/V \ge h(T,0)$. For the density $\rho > h(T,0)$, the number of particles for $\epsilon = 0$ (or $p = 0$) has to be macroscopic. For this requirement, we have $\mu = 0$, and Eq. (66) should be replaced by

$$N = N_0 + Vh(T,0). \tag{67}$$

Here, N_0 denotes the number of particles in the state $\epsilon = 0$. This situation occurs below the critical point T_c defined by

$$h(T_c,0) = \rho. \tag{68}$$

This phenomenon is called the Bose–Einstein condensation. The superfluidity of ^{4}He observed experimentally is closely related to this Bose–Einstein condensation. The function $h(T,0)$ is given more explicitly as

$$h(T,0) = 2.612\left(\frac{2\pi m k_B T}{h^2}\right)^{3/2}. \tag{69}$$

Thus, the critical point of the Bose–Einstein condensation depends on the number density ρ as

$$T_c = \frac{h^2}{2\pi k_B m}\left(\frac{\rho}{2.612}\right)^{2/3} \propto \frac{h^2}{m}\rho^{2/3}. \tag{70}$$

In liquid helium, we obtain $T_c = 3.14$ K from Eq. (70). The condensation density $\rho_0 = N_0/V$ has the following temperature dependence:

$$\rho_0 = h(T,0) - h(T_c,0) = \rho[1 - (T/T_c)^{3/2}]. \tag{71}$$

It is also easily shown that the specific heat of this system behaves like $C_v \propto T^{3/2}$. The temperature derivative of C_v is discontinuous at T_c, and consequently the Bose–Einstein condensation is of third order.

5.3 Bose–Einstein Condensation of Quasiparticles in *d* Dimensions

When there exists an interaction among particles, such interacting particles may be treated as quasiparticles with the new spectrum $\epsilon_p = ap^k$ modified by the interaction, where $a > 0$ and $k > 0$. In most cases, we have $k = 2$, but strong many-body interaction may change the value of k, as in superfluid liquids that show a spectrum with $k = 3/2$. In such a generalized Bose quasiparticle system, the total number of such particles, N, is given in the form

$$N = N_0 + \frac{g_S L^d}{h^d}\int_0^\infty \frac{S_d p^{d-1}dp}{e^{\beta(ap^k-\mu)} - 1}. \tag{72}$$

in d dimensions, where $g_s = 2S + 1$ (spin degeneracy), L denotes the system size, and $S_d = 2\pi^{d/2}/\Gamma(d/2)$. Here $\Gamma(x)$ is the gamma function. The critical point below which this system shows the Bose–Einstein condensation is given by

$$\begin{aligned} T_c &= \frac{a}{k_B}\left(\frac{k\Gamma(d/2)h^d\rho}{2\pi^{d/2}g_s\Gamma(d/k)\zeta(d/k)}\right)^{k/d} \\ &\propto ah^k[\rho/(2S + 1)]^{k/d}. \end{aligned} \tag{73}$$

Here $\zeta(x)$ is the zeta function. This transition occurs for $d > k$.

5.4 Pressures for Ideal Fermi-Particle, Bose-Particle, and Classical-Particle Systems

It is quite interesting to compare the pressures p_F, p_B, and p_{cl} of the ideal Fermi-particle, Bose-particle, and classical-particle systems, respectively, at the same number density. It has been proved (Suzuki, 1994a) that

$$P_F > P_{cl} > P_B \tag{74}$$

for the same number density. Here we have used the inequalities $\ln(1 + x) > x/(1 + x)$ for $x > 0$ and $\ln[1/(1 + x)] < x/(1 - x)$ for $0 < x < 1$. Thus, an effective repulsive interaction appears in an ideal Fermi-particle system because of the Pauli principle and an effective attractive interaction appears in an ideal Bose-particle system.

6. HARMONIC OSCILLATORS AND BLACKBODY RADIATION

According to quantum mechanics, the eigenvalues of the one-dimensional harmonic oscillator described by the Hamiltonian

$$\mathcal{H} = p^2/2m + \tfrac{1}{2}kq^2 \tag{75}$$

are given by $\epsilon_n = (n + \frac{1}{2})h\nu$, where the eigenfrequency ν is expressed as $\nu = (k/m)^{1/2}/2\pi$. The partition function of the system (75), $Z_1(\beta)$, is given as

$$Z_1(\beta) = \sum_{n=0}^{\infty} e^{-\beta\epsilon_n} = \frac{1}{2\sinh(\beta h\nu/2)}. \tag{76}$$

Thus, the average energy of one harmonic oscillator is calculated as

$$\epsilon = -\frac{\partial}{\partial\beta}\ln Z_1(\beta) = \tfrac{1}{2}h\nu + \frac{h\nu}{e^{\beta h\nu}-1}. \tag{77}$$

The specific heat of N independent harmonic oscillators is given by

$$C = N\frac{d\epsilon}{dT} = \frac{N(h\nu)^2}{k_B T^2}\frac{e^{\beta h\nu}}{(e^{\beta h\nu}-1)^2}. \tag{78}$$

This approaches the classical value $C_{\mathrm{cl}} = Nk_B$ in the limit $\beta h\nu \to 0$.

Now we discuss blackbody radiation using the result (77). The photon energy of frequency ν is given by $\epsilon(\nu) = h\nu/[\exp(\beta h\nu) - 1]$. The density of states of photons is written as

$$D(\nu)d\nu = (8\pi V/c^3)\nu^2 d\nu, \tag{79}$$

where c denotes the light velocity. Thus, the energy density of the blackbody radiation is expressed as

$$\rho(\nu)d\nu = \frac{1}{V}\epsilon(\nu)D(\nu)d\nu = \frac{8\pi h}{c^3}\frac{\nu^3 d\nu}{e^{\beta h\nu}-1}. \tag{80}$$

In the low-frequency region (i.e., $h\nu \ll k_B T$), this reduces to the Rayleigh–Jeans law

$$\rho(\nu) = (8\pi\nu^2/c^3)k_B T, \tag{81a}$$

and in the high-frequency region (i.e., $h\nu \gg k_B T$), Eq. (80) reduces to Wien's law

$$\rho(\nu) = (8\pi h/c^3)\nu^3 e^{-h\nu/k_B T}. \tag{81b}$$

7. PARAMAGNETISM IN NONINTERACTING SPIN SYSTEMS

When we treat the magnetism of an atom or an ion, we have to consider the total angular momentum $J\hbar = (L + S)\hbar$, where $L\hbar$ and $S\hbar$ denote the orbital angular momentum and spin angular momentum, respectively. According to quantum mechanical calculations, the magnetic moment operator μ is expressed as

$$\mu = (-e\hbar/2mc)(L + 2S);\ \hbar \equiv h/2\pi. \tag{82}$$

As J is a constant of motion, the average moment $\bar{\mu}$ projected on the direction of J plays a physical role, and it is easily given by

$$\bar{\mu} = -g\frac{e\hbar}{2mc}J;\quad g = \frac{3}{2} + \frac{S(S+1) - L(L+1)}{2J(J+1)}, \tag{83}$$

where

$$\mathbb{S}^2 = S(S+1),\ \mathbb{L}^2 = L(L+1),\ \text{and}\ \mathbb{J}^2 = J(J+1). \tag{84}$$

The quantity g is called the Landé factor. Then the Zeeman energy due to this magnetic moment $\bar{\mu}$ in a magnetic field H is given by

$$-\bar{\boldsymbol{\mu}}\cdot\mathbf{H} = g\mu_B\mathbf{J}\cdot\mathbf{H}, \tag{85}$$

where

$$\mu_B = \frac{e\hbar}{2mc} = \frac{eh}{4\pi mc}. \tag{86}$$

Now we consider a system of N independent spins in a magnetic field H along the z axis. The Hamiltonian of this system is expressed as

$$\mathcal{H} = -g\mu_B\sum_{j=1}^{N} S_j^z H, \tag{87}$$

where S_j^z denotes the z component of the spin operator S_j; namely, $S_j^z = S, S-1, S-2, \ldots, -S+1, -S$. The partition function of this system is calculated as

$$Z_N(\beta) = Z_1^N(\beta);$$
$$Z_1(\beta) = \sum_{m=-S}^{S} e^{\beta g\mu_B m H} = \frac{\sinh[\frac{1}{2}(2S+1)\beta g\mu_B H]}{\sinh(\frac{1}{2}\beta g\mu_B H)}. \tag{88}$$

The average energy of this system is then given by

$$E(T) = -Ng\mu_B SHB_S(\beta g\mu_B SH), \tag{89}$$

where $B_s(x)$ is the Brillouin function defined by

$$B_S(x) = \frac{2S+1}{2S}\coth\left(\frac{2S+1}{2S}x\right) - \frac{1}{2S}\coth\left(\frac{1}{2S}x\right). \tag{90}$$

In the limit of large S, this reduces to the Langevin function

$$L(x) = \coth x - 1/x. \tag{91}$$

The magnetization $M(T,H)$ is thus given by

$$M(T,H) = k_BT\frac{\partial}{\partial H}\ln Z_N(\beta) = Ng\mu_BSB_S(\beta g\mu_BSH). \tag{92}$$

The susceptibility of this system is obtained as

$$\chi_0(T) \equiv \lim_{H\to 0}\frac{M(T,H)}{H} = \frac{N(g\mu_B)^2S(S+1)}{3k_BT}. \tag{93}$$

This is called the Hund equation, and the behavior of $\chi_0(T)$ shown in (93) [namely, $\chi_0(T) \propto 1/T$] is called the Curie law. In particular, it reduces to

$$\chi_0(T) = N\mu_B^2/k_BT \tag{94}$$

in the case of $S = \frac{1}{2}$ for $g = 2$.

8. EXPONENTIAL PRODUCT FORMULA AND QUANTUM MONTE CARLO METHOD

In quantum statistical mechanics, exponential operators such as the density matrix (4) play an important role. It is a crucial problem how to manipulate such exponential operators.

In most cases, the Hamiltonian $\mathcal{H}$ of the relevant quantum system is composed of two or more partial Hamiltonians as $\mathcal{H} = \mathcal{H}_1 + \mathcal{H}_2 + \cdots + \mathcal{H}_q$. In many physical problems, each of these partial Hamiltonians can be easily diagonalized independently, though it is extremely difficult to diagonalize the total Hamiltonian $\mathcal{H}$.

In these situations, it is very convenient to decompose the exponential operator $e^{-\beta\mathcal{H}}$ into the product of the partial density matrices $\{e^{-\beta'\mathcal{H}_j}\}$ with different inverse temperatures β', because it is quite easy to evaluate explicitly the matrix elements of the partial density matrices $\{e^{-\beta'\mathcal{H}_j}\}$ when each of the $\{\mathcal{H}_j\}$ can be diagonalized.

8.1 Trotter Formula

One of the simplest decompositions of an exponential operator $e^{x(A+B)}$ is the Trotter (1959) formula

$$e^{x(A+B)} = (e^{(x/n)(A+B)})^n = \lim_{n\to\infty}(e^{(x/n)A}e^{(x/n)B})^n. \tag{95}$$

The convergence of the limit (95) is easily given in a Banach (namely normed) space, as will be shown later. The Trotter formula (95) is easily extended to the following formula:

$$e^{x(A_1+A_2+\ldots+A_q)} = \lim_{n\to\infty}(e^{(x/n)A_1}e^{(x/n)A_2}\ldots e^{(x/n)A_q})^n. \tag{96}$$

These formulas will be used conveniently in quantum Monte Carlo simulations (Suzuki *et al.*, 1977, 1987; Suzuki, 1993a).

8.2 Quantum Monte Carlo Method

It is extremely difficult to calculate exactly the free energy of the relevant quantum system, because the Hamiltonian $\mathcal{H}$ cannot be diagonalized in most realistic cases. Thus, we need some approximation that can be manipulated explicitly. This is realized by the following approximate mapping.

The partition function $Z(\beta)$ of the relevant system described by the Hamiltonian $\mathcal{H} = \mathcal{H}_1 + \mathcal{H}_2 + \cdots + \mathcal{H}_q$ is expressed as

$$\begin{aligned} Z &= \mathrm{Tr}\exp[-\beta(H_1+H_2+\cdots+H_q)\} \\ &= \lim_{n\to\infty}\mathrm{Tr}\left\{\exp\left(-\frac{\beta}{n}H_1\right)\exp\left(-\frac{\beta}{n}H_2\right)\right. \\ &\quad \left.\times\cdots\exp\left(-\frac{\beta}{n}H_q\right)\right\}^n \\ &= \lim_{n\to\infty}\sum_{\alpha_1}\cdots\sum_{\alpha_{nq}}\langle\alpha_1|\rho_1|\alpha_2\rangle\langle\alpha_2|\rho_2|\alpha_3\rangle \\ &\quad \times\cdots\langle\alpha_q|\rho_q|\alpha_{q+1}\rangle\langle\alpha_{q+1}|\rho_1|\alpha_{q+2}\rangle \\ &\quad \times\cdots\langle\alpha_{nq}|\rho_q|\alpha_1\rangle \\ &\equiv \mathrm{Tr}^{(d+1)}\exp\mathcal{H}_{\mathrm{eff}}^{(d+1)};\quad \rho_j \equiv \exp(-\beta H_j/n), \end{aligned} \tag{97}$$

where $\{|\alpha_j\rangle\}$ denote orthogonal complete sets. Here, $\mathscr{H}_{\text{eff}}^{(d+1)}$ denotes a $(d + 1)$-dimensional effective Hamiltonian defined by

$$\begin{aligned}\mathscr{H}_{\text{eff}}^{(d+1)} &= H_1(\alpha_1,\alpha_2) + H_2(\alpha_2,\alpha_3) \\ &\quad + \cdots + H_q(\alpha_q,\alpha_{q+1}) + H_1(\alpha_{q+1},\alpha_{q+2}) \\ &\quad + H_2(\alpha_{q+2},\alpha_{q+3}) + \cdots + H_q(\alpha_{2q},\alpha_{2q+1}) \\ &\quad \cdots\cdots\cdots\cdots \\ &\quad + H_1(\alpha_{(n-1)q+1},\alpha_{(n-1)q+2}) \\ &\quad + \cdots + H_q(\alpha_{nq},\alpha_1), \end{aligned} \tag{98}$$

with the partial Hamiltonians $H_j(\alpha,\alpha')$ defined by

$$\langle\alpha_q|\exp(-\beta H_j/n)|\alpha_{q+1}\rangle = \exp H_j(\alpha_q,\alpha_{q+1}). \tag{99}$$

Thus, a d-dimensional quantum system can be transformed to the corresponding $(d + 1)$-dimensional quantum system (equivalence theorem; Suzuki, 1976). This transformation is often called the Suzuki–Trotter transformation. Now, we can apply classical Monte Carlo methods such as the Metropolis algorithm to the transformed classical system. Of course, the effective Hamiltonian contains a new type of many-body interactions shown in Eq. (99), and consequently the corresponding algorithms are much more complicated than the ordinary Metropolis algorithm is.

8.3 Explicit Formulations of the Quantum Monte Carlo Method in Spin Systems

It is instructive to formulate the above quantum Monte Carlo method in the one-dimensional transverse Ising model described by the Hamiltonian $\mathscr{H} = \mathscr{H}_1 + \mathscr{H}_2$, where

$$\mathscr{H}_1 = -J\sum_{j=1}^{M}\sigma_j^z\sigma_{j+1}^z \quad\text{and}\quad \mathscr{H}_2 = -\Gamma\sum_{j=1}^{M}\sigma_j^x. \tag{100}$$

Here, the operators σ_j^x and σ_j^z denote the Pauli operators

$$\sigma_j^x = \begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix} \quad\text{and}\quad \sigma_j^z = \begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}. \tag{101}$$

The parameters J and Γ denote the spin interaction and the transverse external field, respectively. Clearly, $\mathscr{H}_1$ does not commute with $\mathscr{H}_2$.

Following the general formulation (97), the partition function of this system is expressed as

$$\begin{aligned} Z &= \operatorname{Tr} e^{-\beta H} = \operatorname{Tr}\exp\left(K\sum_{j=1}^{M}\sigma_j^z\sigma_{j+1}^z + \gamma\sum_{j=1}^{M}\sigma_j^x\right) \\ &= \sum_{\{\sigma_{jk}=\pm 1\}} \langle\{\sigma_{j1}\}|e^{A/n}|\{\sigma'_{j1}\}\rangle\langle\{\sigma'_{j1}\}|e^{B/n}|\{\sigma_{j2}\}\rangle \\ &\quad\times\langle\{\sigma_{j2}\}|e^{A/n}|\{\sigma'_{j2}\}\rangle\langle\{\sigma'_{j2}\}|e^{B/n}|\{\sigma_{j3}\}\rangle \\ &\quad\times\cdots\cdots\cdots\cdots \\ &\quad\times\langle\{\sigma_{jn}\}|e^{A/n}|\{\sigma'_{jn}\}\rangle\langle\{\sigma'_{jn}\}|e^{B/n}|\{\sigma_{j1}\}\rangle, \end{aligned} \tag{102}$$

where $K \equiv \beta J$, $\gamma \equiv \beta\Gamma$, and

$$A \equiv K\sum_{j=1}^{M}\sigma_j^z\sigma_{j+1}^z, \quad B \equiv \gamma\sum_{j=1}^{M}\sigma_j^x. \tag{103}$$

Here $|\{\sigma_{jk}\}\rangle$ denote n sets of the product space $|\{\sigma_{jk}\}\rangle = |\sigma_{1k}\rangle\otimes|\sigma_{2k}\rangle\otimes\cdots\otimes|\sigma_{Mk}\rangle$ with the eigenvectors defined by

$$\sigma_j^z|\{\sigma_{jk}\}\rangle = \sigma_{jk}|\{\sigma_{jk}\}\rangle \quad (k = 1, 2, \ldots, n). \tag{104}$$

More explicitly we have

$$\begin{aligned}\langle\{\sigma_{jk}\}|e^{A/n}|\{\sigma'_{jk}\}\rangle &= \exp\left(\frac{K}{n}\sum_{j=1}^{M}\sigma_{jk}\sigma_{j+1,k}\right) \\ &\quad\times\prod_{j=1}^{M}\delta(\sigma_{jk},\sigma'_{jk}), \end{aligned} \tag{105}$$

and

$$\langle\{\sigma_{jk}\}|e^{B/n}|\{\sigma_{j,k+1}\}\rangle = a_n^M\exp\left(\gamma_n\sum_{j=1}^{M}\sigma_{jk}\sigma_{j,k+1}\right), \tag{106}$$

where

$$a_n \equiv \left\{\tfrac{1}{2}\sinh\left(\frac{2\gamma}{n}\right)\right\}^{1/2} \quad\text{and}\quad \gamma_n \equiv \tfrac{1}{2}\ln\coth\left(\frac{\gamma}{n}\right). \tag{107}$$

Thus, we arrive finally at the partition function of the two-dimensional Ising model:

$$\begin{aligned} Z &= \lim_{n\to\infty} a_n^{Mn}\sum_{\{\sigma_{jk}=\pm 1\}} \\ &\quad\times\exp\left\{\sum_{j=1}^{M}\sum_{k=1}^{n}\left(\frac{K}{n}\sigma_{jk}\sigma_{j+1,k} + \gamma_n\sigma_{jk}\sigma_{j,k+1}\right)\right\}. \end{aligned} \tag{108}$$

This is shown in Fig. 3.

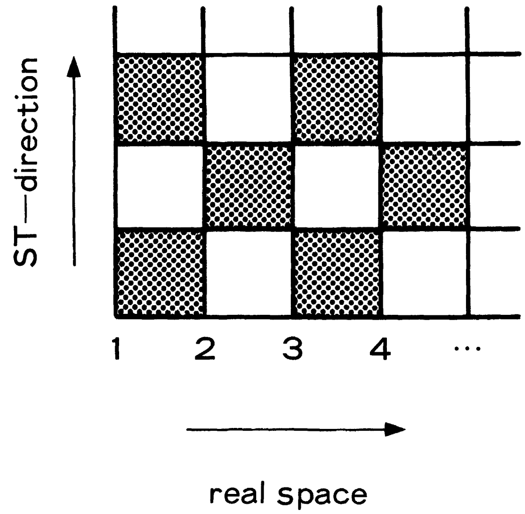

FIG. 3. An example of the two-dimensional Ising model equivalent to the one-dimensional quantum Heisenberg model (figure from Suzuki, 1976). The shaded plaquettes denote a new four-body interaction appearing through the Suzuki–Trotter transformation.

This formulation can be easily extended to other quantum spin systems, and there have been published many articles on explicit applications of the above quantum Monte Carlo method and as well even to Fermi-particle and Bose-particle systems. For example, the magnetic moment $\langle S_i^z \rangle$ at site i of a spin $S = 1$ Heisenberg antiferromagnetic chain has been obtained using the above quantum Monte Carlo method, as shown in Fig. 4.

8.4 General Decomposition Theory of Exponential Operators

The above quantum Monte Carlo method is based on the exponential product formula (96), and consequently the accuracy of simulations for a finite Trotter number n depends on the degree of approximation for decomposition.

For example, we have

$$e^{x(A+B)} = (e^{(x/n)A}e^{(x/n)B})^n + O\left(\frac{x^2}{n}\right). \tag{109}$$

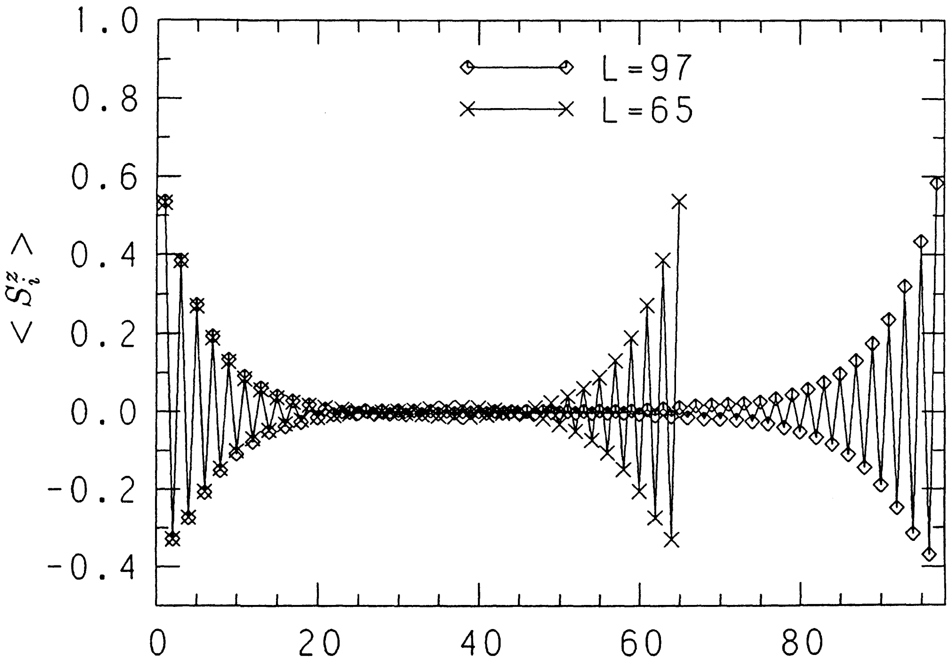

FIG. 4. The spin averages $\langle S_i^z \rangle$ at site i of the $S = 1$ Heisenberg antiferromagnetic chain for the length $L = 65$ and for $L = 97$. The abscissa denotes the position i of the relevant spin S_i^z. (Figure from Miyashita and Yamamoto, 1993.)

The symmetrized product gives a better approximation as

$$e^{x(A+B)} = (e^{(x/2n)A}e^{(x/n)B}e^{(x/2n)A})^n + O(x^3/n^2). \tag{110}$$

If we find a higher decomposition formula

$$e^{x(A+B)} = F_m(x) + O(x^{m+1}) \tag{111}$$

with the form

$$F_m(x) = e^{t_1A}e^{t_2B}e^{t_3A}e^{t_4B} \cdots e^{t_MA}, \tag{112}$$

using some appropriate parameters $\{t_j\}$ proportional to x, then we obtain the following generalized Trotter formula (called the Suzuki–Trotter formula):

$$e^{x(A+B)} = [F_m(x/n)]^n + O(x^{m+1}/n^m). \tag{113}$$

Then, we show how to construct a general higher-order decomposition formula $F_m(x)$ explicitly. One of the most convenient procedures is to make use of the following recursive scheme (Suzuki, 1990): If the mth-order decomposition $Q_m(x)$ is known, then the $(m+1)$th-order decomposition $Q_{m+1}(x)$ is constructed recursively as

$$Q_{m+1}(x) = Q_m(p_1x)Q_m(p_2x) \cdots Q_m(p_sx) \tag{114}$$

with some parameters $\{p_j\}$ $(j = 1, 2, \ldots, 3)$ satisfying the conditions that

$$p_1 + p_2 + \cdots + p_s = 1, \quad \text{and} \quad p_1^{m+1} + p_2^{m+1} + \cdots + p_s^{m+1} = 0. \tag{115}$$

For example, if we start from a second-order symmetric decomposition

$$S_2(x) = e^{(x/2)A}e^{xB}e^{(x/2)A} = S_2^{-1}(-x), \tag{116}$$

then the fourth-order decomposition $S_4(x)$ is obtained as

$$S_4(x) = e^{(p/2)xA}e^{pxB}e^{[(1-p)/2]xA}e^{(1-2p)xB} \times e^{[(1-p)/2]xA}e^{pxB}e^{(p/2)xA}. \tag{117}$$

Here, the parameter p is given by the solution of the equation

$$p^3 + (1-2p)^3 + p^3 = 0; \tag{118}$$

namely,

$$p = \frac{1}{2 - 2^{1/3}}. \tag{119}$$

It should be remarked here that if $S_{2m-1}(x)$ is symmetric, then it is correct up to the $2m$th order, namely,

$$S_{2m-1}(x) = S_{2m}(x). \tag{120}$$

In general, the $2m$th-order decomposition $S_{2m}(x)$ is constructed recursively as

$$S_{2m}(x) = S_{2m-2}(p_mx)S_{2m-2}((1-2p_m)x) \times S_{2m-2}(p_mx) \tag{121}$$

with the parameter $p_m = (2 - 2^{1/m})^{-1}$.

There are many other formulations of exponential products and explicit applications to quantum mechanics, quantum statistical mechanics, laser physics, nonlinear dynamics, and other nonlinear problems.

8.5 Superoperator Formula of Ordered Exponentials

In quantum mechanics and statistical mechanics, the following ordered exponential is frequently used:

$$\begin{aligned} \mathrm{P}\left(\exp \int_0^t \mathcal{H}(s)ds\right) &= 1 + \int_0^t \mathcal{H}(s)ds + \int_0^t dt_1 \int_0^{t_1} dt_2 \mathcal{H}(t_1)\mathcal{H}(t_2) \\ &\quad + \cdots + \int_0^t dt_1 \int_0^{t_1} dt_2 \cdots \int_0^{t_{n-1}} dt_n \mathcal{H}(t_1)\mathcal{H}(t_2) \\ &\quad \times \cdots \mathcal{H}(t_n) + \cdots. \end{aligned} \tag{122}$$

When $\mathcal{H}(t) = \mathcal{H}_1(t) + \mathcal{H}_2(t)$, we can decompose the above-ordered exponential, using the following superoperator $\mathcal{T}$:

$$F(t)e^{s\mathcal{T}}G(t) = F(t+s)G(t) \tag{123}$$

for any operators $F(t)$ and $G(t)$. Then, the following formula holds:

Any ordered exponential can be expressed by an ordinary exponential operator in terms of the super-operator $\mathcal{T}$ as

$$\mathrm{P}\left(\exp \int_t^{t+s} \mathcal{H}(u)du\right) = \exp[s(\mathcal{H}(t) + \mathcal{T})]. \tag{124}$$

Thus, the decomposition of ordered exponentials is reduced to that of ordinary exponential operators.

For example, the first-order and second-order decompositions of the ordered exponential are given by

$$\begin{aligned}\mathrm{P}\left(\exp \int_t^{t+\Delta t} (\mathcal{H}_1(u) + \mathcal{H}_2(u))du\right) &= e^{\Delta t\mathcal{H}_1(t+\Delta t/2)}e^{\Delta t\mathcal{H}_2(t+\Delta t/2)} + O(\Delta t)^2 \\ &= e^{(\Delta t/2)\mathcal{H}_1(t+\Delta t/2)}e^{\Delta t\mathcal{H}_2(t+\Delta t/2)}e^{(\Delta t/2)\mathcal{H}_1(t+\Delta t/2)} \\ &\quad + O(\Delta t^3),\end{aligned} \tag{125}$$

respectively. Any higher-order decomposition of ordered exponentials can be obtained easily from the decomposition formulas of ordinary exponential operators (Suzuki, 1993b).

9. THEORY OF PHASE TRANSITIONS IN QUANTUM SYSTEMS

To study phase transitions theoretically is one of the most important subjects in statistical mechanics. Concerning conceptual arguments of phase transitions, see the article STATISTICAL MECHANICS, CLASSICAL.

There are two categories of phase transitions in quantum systems. Phase transitions in the first category are called quantum phase transitions, which occur as a result of quantum effects. Typical examples of such quantum phase transitions are superconductivity and superfluidity (or the Bose–Einstein condensation). Phase transitions in the second category are such transitions as occur even in classical systems. The gas–liquid phase transition belongs to the second category.

9.1 Landau's Phenomenological Theory of Phase Transitions

The concept of symmetry is crucial in the theory of phase transitions. Landau (1937) introduced an order parameter, say M, for specifying the symmetry of the relevant system. The phase transition is characterized by symmetry breaking. The Helmholtz free energy F is expanded as

$$F = F_0 + AM^2 + BM^4 + \cdots - HM, \tag{126}$$

because the relevant system is assumed to be symmetric as shown in Fig. 5. The equation of state is obtained by setting the derivative of F equal to zero:

$$2AM + 4BM^3 + \cdots = H. \tag{127}$$

As is easily seen from Fig. 5, the coefficient A may assume the following temperature dependence, namely, $A \simeq a(T - T_c)$ near the critical point T_c, where $a > 0$. Then, the susceptibility $\chi_0(T)$ defined by $\chi_0(T) = \lim_{H\to 0}(M/H)$ shows the following Curie–Weiss law:

$$\chi_0(T) = \frac{1}{2A} \simeq \frac{1}{2a(T - T_c)}. \tag{128}$$

The spontaneous order parameter M_s is given by the solution of the equation $2AM_s + 4BM_s^3 = 0$; namely,

$$M_s = \pm\left(\frac{-A(T)}{2B(T)}\right)^{1/2} \simeq \pm\left(\frac{a(T_c - T)}{2B(T_c)}\right)^{1/2} \tag{129}$$

for $T \leq T_c$, using $B(T_c) > 0$.

The above Landau theory is valid even in

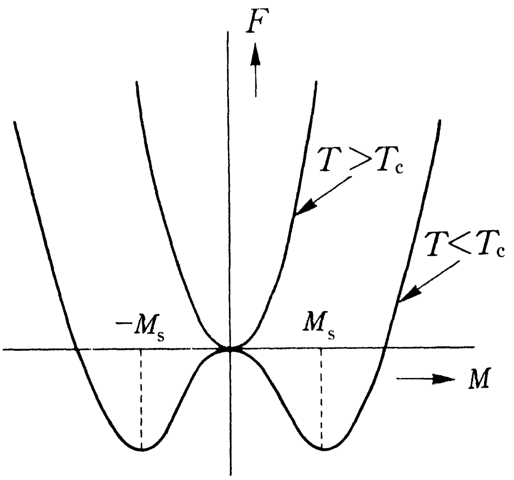

FIG. 5. Landau's free energy as a function of the order parameter M.

quantum phase transitions. His theory has historically played a leading role in finding the mechanism of a new type of phase transitions such as superconductivity, though it is essentially equivalent to the mean-field theory first proposed by P. Weiss (1907).

9.2 Order Parameters in Quantum Phase Transitions

The Bose–Einstein condensation explained in Sec. 5.2 is characterized by the order parameter $b = b_{k=0}$ for the Bose annihilation operator b_k with the momentum k. The eigenstate of the order parameter b is given by the coherent state

$$|\alpha\rangle_c = \mathcal{N}\exp(\alpha b^\dagger)|0\rangle \tag{130}$$

with the normalization factor $\mathcal{N}$. That is, we have

$$b|\alpha\rangle_c = \alpha|\alpha\rangle_c. \tag{131}$$

In Eq. (130), the state $|0\rangle$ denotes the vacuum of the Bose system; namely, $b|0\rangle = 0$, and $b^\dagger b|n\rangle = n|n\rangle$. Thus, the order parameter M of the Bose–Einstein condensation is defined by the average of the annihilation operator b in the coherent state $|\alpha\rangle_c$ as

$$M = {}_c\langle\alpha|b|\alpha\rangle_c = \alpha. \tag{132}$$

Another example of quantum phase transitions is superconductivity, whose order parameter is given by the number of Cooper pairs (Bardeen *et al.*, 1957); namely,

$$\Psi \equiv \sum_k \langle a_{k\uparrow}^\dagger a_{-k\downarrow}^\dagger\rangle \tag{133}$$

for the Fermi operators $\{a_{k\sigma}\}$ with spins $\sigma = \uparrow$ and $\downarrow$. The Cooper pair $b^\dagger \equiv \Sigma_k a_{k\uparrow}^\dagger a_{-k\downarrow}^\dagger$ is essentially a Bose operator, and consequently Ψ denotes the order parameter of the condensation of Cooper pairs.

9.3 Weiss Mean-Field Theory

The simplest theory of phase transition is the Weiss mean-field theory, in which an infinite number of degrees of freedom is replaced by the mean field applied at a specific single spin or particle.

For simplicity, we explain here the mean-field theory of magnetic phase transitions. We consider the Heisenberg model, which is described by the Hamiltonian

$$\mathcal{H} = -J\sum_{\langle ij\rangle} \mathbb{S}_i\cdot\mathbb{S}_j - g\mu_B H\sum_{j=1}^{N} S_j^z, \tag{134}$$

where $\mathbf{H}$ is parallel to z. The mean-field theory replaces the above total Hamiltonian by the following effective Hamiltonian:

$$\mathcal{H}_{\text{mf}} = -(Jz\langle S_i^z\rangle + g\mu_B H)S_j^z, \tag{135}$$

where z denotes the number of nearest neighbors. The average $\langle S_i^z\rangle$ is determined by the self-consistency condition that $\langle S_i^z\rangle = \langle S_j^z\rangle$ because of the uniformity of the system.

The average $\langle S_j^z\rangle$ is easily calculated as

$$\langle S_j^z\rangle = SB_S(\beta g\mu_B SH + \beta Jz\langle S_i^z\rangle S), \tag{136}$$

using the Brillouin function (90). The magnetization M is thus given by

$$\begin{aligned} M &= Ng\mu_{\text{B}}\langle S_j^z\rangle = \beta\frac{N(g\mu_{\text{B}})^2S(S+1)}{3-\beta zJS(S+1)}H \\ &= \frac{N(g\mu_{\text{B}})^2S(S+1)}{3k_{\text{B}}(T-T_c)}H;\ T_c = \frac{zJS(S+1)}{3k_{\text{B}}}, \end{aligned} \tag{137}$$

by expanding the Brillouin function $B_S(x)$ with respect to x, as far as the linear term in H is concerned. Thus, the susceptibility $\chi_0(T)$ is shown to satisfy the Curie law

$$\chi_0(T) = \frac{N(g\mu_{\text{B}})^2S(S+1)}{3k_{\text{B}}}\frac{1}{T-T_c} \tag{138}$$

in the Weiss mean-field approximation.

9.4 Generalized Cluster Mean-Field Approximations

For simplicity, we consider here a ferromagnet. In order to take fluctuations into account, we consider a generalized cluster at whose boundary a mean field H_{mf} is applied, as shown in Fig. 6. We assume that the mean field H_{mf} is proportional to the magnetization m_b at the boundary as $H_{\text{mf}} = k_{\text{mf}}m_b$ with the mean-field coefficient k_{mf}. It is expressed as $k_{\text{mf}} = \bar{z}J$ with the interaction strength J and with the number $\bar{z}$ of nearest neighbors outside of the cluster.

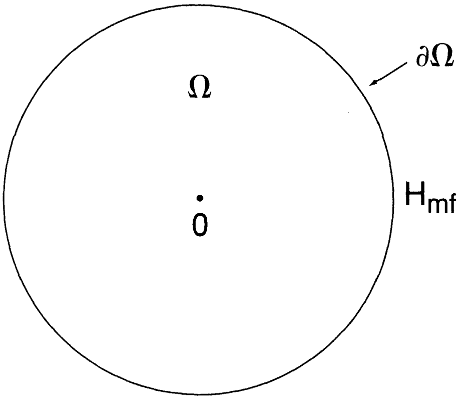

FIG. 6. Generalized cluster Ω with a mean field H_{mf} at the boundary $\partial\Omega$.

Now, the order parameter, namely, the magnetization at the center of the cluster Ω, is expressed in the form

$$m_0 = \chi_L(T)H + \mathscr{F}_L(T)m_b, \tag{139}$$

as far as the terms linear in the external field H and the mean field H_{mf} are concerned. Here L denotes the system size L of the cluster Ω. The cluster susceptibility $\chi_L(T)$ is expressed by the correlation function

$$\chi_L(T) = \beta\mu_{\mathrm{B}}^2\langle S_0^z;S_\Omega^z\rangle, \tag{140}$$

where $S_\Omega^z = \Sigma_{j\in\Omega}S_j^z$ and $\langle A;B\rangle$ denotes the following canonical correlation:

$$\langle A;B\rangle = \frac{1}{\beta}\int_0^\beta \langle AB(i\hbar\lambda)\rangle_\Omega d\lambda. \tag{141}$$

Here $B(z)$ denotes the interaction representation defined by

$$B(z) = e^{it\mathscr{H}_\Omega/\hbar}Be^{-it\mathscr{H}_\Omega/\hbar} \tag{142}$$

with the cluster Hamiltonian $\mathscr{H}_\Omega$ in the absence of a mean field H_{mf}. The average $\langle Q\rangle_\Omega$ denotes the canonical average over the cluster Hamiltonian as

$$\langle Q\rangle_\Omega = \mathrm{Tr}\,Qe^{-\beta\mathscr{H}_\Omega}/\mathrm{Tr}\,e^{-\beta\mathscr{H}_\Omega}. \tag{143}$$

The coefficient $\mathscr{F}_L(T)$ in (139) denotes the feedback function defined by

$$\mathscr{F}_L(T) = \beta k_{\mathrm{mf}}\langle S_0;S_{\partial\Omega}\rangle;\ S_{\partial\Omega} = \sum_{j\in\partial\Omega} S_j^z. \tag{144}$$

Now we impose the self-consistency condition $m_0 \equiv m_b \equiv m$. Then we obtain the magnetization in the form

$$m = \frac{\chi_L(T)}{1 - \mathscr{F}_L(T)}H \equiv \chi_0(T)H. \tag{145}$$

The critical point T_c in this approximation is determined by the solution of the equation $\mathscr{F}_L(T_c) = 1$. Thus, the susceptibility $\chi_0(T)$ is derived to show the following classical anomaly, namely, the Curie-Weiss law:

$$\chi_0(T) \simeq \frac{\bar{\chi}(T_c)}{\epsilon};\ \epsilon = \frac{T - T_c}{T_c}. \tag{146}$$

This is called a "skeletonized susceptibility." The mean-field critical coefficient $\bar{\chi}(T_c)$ is given by

$$\bar{\chi}(T_c) = \chi_L(T_c)/[-T_c\mathscr{F}_L'(T_c)]. \tag{147}$$

This expression is very useful in the coherent-anomaly method (CAM) explained in the succeeding subsection.

There are many other cluster effective-field approximations such as the Bethe-type one (Bethe, 1935) and the double cluster approximation (Oguchi and Kitatani, 1988)

9.5 Coherent-Anomaly Method

As is seen from the preceding subsection, the critical exponent γ of the susceptibility defined in

$$\chi_0(T) \sim 1/(T - T_c^*)^\gamma \tag{148}$$

near the critical point T_c^* is classical; namely, it is given by $\gamma = 1$. However, recent theoretical and experimental results show that $\gamma > 1$. This difference comes from the existence of intrinsic fluctuations in realistic systems.

The main purpose here is to present a general scheme for studying these intrinsic fluctuations and to estimate accurately nonclassical critical exponents by using a systematic series of generalized critical mean-field approximations. The crucial point of the present general scheme, called the coherent-anomaly method (CAM) (Suzuki, 1986), is to note that the mean-field critical coefficient $\bar{\chi}(T_c)$ becomes anomalously large as the approximate critical point T_c approaches the true critical point T_c^*. This is called the coherent anomaly. By "coherent," we mean "systematic." Thus, we have

$$\lim_{T_c \to T_c^*} \bar{\chi}(T_c) = \infty. \tag{149}$$

Then, we may assume the singularity of the mean-field critical coefficient $\bar{\chi}(T_c)$ in the form

$$\bar{\chi}(T_c) \sim 1/(T_c - T_c^*)^{\psi} \tag{150}$$

near the true critical point T_c^*. Then, the critical exponent γ defined in Eq. (148) is shown to be related to the coherent-anomaly exponent ψ estimated through the coherent-anomaly data $(T_c, \bar{\chi})$ in Eq. (150). This situation is explained by the envelope theory shown in Fig. 7.

This CAM theory has been already applied to many classical and quantum systems for evaluating the critical points and critical exponents of such systems (Suzuki *et al.*, 1987). This can be also applied to quantum phase transitions at the ground state (Nonomura and Suzuki, 1992).

9.6 Scaling Law and Renormalization-Group Theory

Critical phenomena are characterized by the scaling law (Fisher, 1964; Widom, 1965), which was justified by the Kadanoff (1966) cell analysis. The scaling law provides the following equation of state:

$$M \simeq t^{\beta} f_{\mathrm{sc}}(H/t^{\Delta}) \tag{151}$$

for the order parameter M and the temperature difference $t = T - T_c^*$. Here, the critical exponent β denotes the singularity of the spontaneous order parameter (namely, the spontaneous magnetization in a ferromagnet) as $M_s \sim (T_c^* - T)^{\beta}$. The exponent Δ is related to β as $\Delta = \beta + \gamma$.

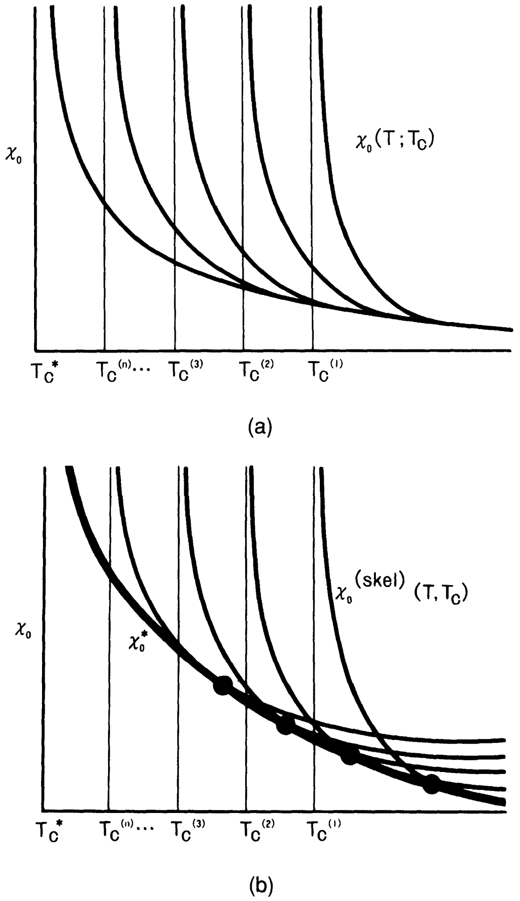

FIG. 7. (a) Susceptibilities obtained in a systematic series of cluster mean-field approximations. (b) Skeletonized susceptibilities of (a) and the envelope χ_0^*. (Figure from Suzuki, 1986.)

The renormalization-group theory (Wilson, 1971) gives microscopic evaluations of critical exponents. In particular, the correlation-length exponent defined in the singularity of the correlation of $\xi \sim t^{-\nu}$ is given by the Wilson formula

$$\nu = (\log b)/(\log \Lambda). \tag{152}$$

Here b denotes the scale factor for the renormalization and Λ the derivative of the renormalized interaction $K' = f_b(K)$ with respect to the original interaction K at the fixed point $K^* = f_b(K^*)$. This renormalization scheme has been used in many systems (see STATISTICAL MECHANICS, CLASSICAL).

For example, in the ferromagnetic Heisenberg model described by the Hamiltonian

$$\mathcal{H} = -J \sum_{\langle ij \rangle} \mathbb{S}_i \cdot \mathbb{S}_j, \tag{153}$$

the renormalized interaction K' is given in the form

$$K' = 2^{d-2} \ln\left(\frac{2e^k + e^{-2k}}{3}\right) \tag{154}$$

for $K = J/2k_BT$ in d dimensions, using the Migdal–Kadanoff approximation (Takano and Suzuki, 1981). The fixed point K^* in three dimensions is calculated easily to give $K^* = 0.68$. However, there exists no fixed point except the trivial one $K^* = 0$ in two dimensions, as is expected.

10. LINEAR RESPONSE THEORY

Up to now, equilibrium statistical mechanics has been presented. In this section, we discuss nonequilibrium statistical mechanics, focusing on Kubo's linear response theory (Kubo, 1957).

Einstein (1905) proposed a theory of Brownian motion, in which a transport coefficient is related to the fluctuation of the corresponding current in equilibrium. For example, the mobility of a particle, μ, is expressed as

$$\mu = \frac{1}{k_BT}\int_0^\infty \langle v(t)v(0)\rangle dt, \tag{155}$$

with $v(t)$ the velocity of the particle. The electric conductivity σ is also given in the form

$$\sigma = \frac{1}{k_BT}\int_0^\infty \langle j(t)j(0)\rangle dt. \tag{156}$$

These expressions are easily derived phenomenologically in the classical approximation.

10.1 Kubo Formula

Now we present here quantum-statistical expressions of transport coefficients. We start from the von Neumann equation

$$i\hbar \frac{\partial}{\partial t} \rho(t) = [\mathcal{H}(t), \rho(t)] \tag{157}$$

for the density matrix $\rho(t)$, where $\mathcal{H}(t)$ is the time-dependent Hamiltonian of the relevant system, and it is assumed to be given in the form

$$\mathcal{H}(t) = \mathcal{H} - AF(t). \tag{158}$$

Here, $F(t)$ denotes an external force and A its conjugate physical quantity operator. The expectation value of any physical quantity B at time t is expressed as

$$\langle B\rangle_t = \mathrm{Tr}\, B\rho(t). \tag{159}$$

We are now interested in a perturbational expansion of $\langle B\rangle_t$ with respect to the external force. To derive it, we study the unitary operator $U(t_1,t_0)$ defined by

$$\rho(t) = U(t,t_0)\rho(t_0)U^\dagger(t,t_0). \tag{160}$$

It satisfies the equation

$$i\hbar \frac{\partial}{\partial t} M(t,t_0) = \mathcal{H}(t)U(t,t_0) \tag{161}$$

with the initial condition $U(t_0,t_0) = 1$. This is also expressed as the product of the following two unitary operators:

$$U(t,t_0) = U_0(t,t_0)\, U_1(t), \tag{162}$$

where $U_0(t,t_0)$ is the unperturbed unitary operator defined by

$$U_0(t,t_0) = \exp[(1/i\hbar)(t - t_0)\mathcal{H}]. \tag{163}$$

Then, the perturbed unitary operator $U_1(t)$ satisfies the following equation:

$$i\hbar \frac{d}{dt} U_1(t) = \mathcal{H}'(t)U_1(t), \tag{164}$$

where $\mathcal{H}'(t)$ denotes the interaction representation

$$\mathcal{H}'(t) = U_0^\dagger(t,t_0)[-AF(t)]U_0(t,t_0). \tag{165}$$

Thus, the expectation value $\langle B\rangle_t$ is expressed as

$$\langle B\rangle_t = \mathrm{Tr}\, \rho(t_0)B - \frac{i}{\hbar}\int_{t_0}^t \mathrm{Tr}\, \rho(t_0)[A, B(t - s)]F(s)ds. \tag{166}$$

Here, we have used the condition that $[\rho(t_0),U_0(t,t_0)] = 0$ and the definition

$$B(t - s) = U_0^{\dagger}(t,s)BU_0(t,s). \tag{167}$$

If we put $\rho(t_0) = \rho_{\text{eq}} \propto \exp(-\beta\mathscr{H})$, the above condition that $[\rho(t_0),U_0(t,t_0)] = 0$ is satisfied. Thus, the first-order deviation or response $\Delta\langle B\rangle_t$ is expressed in the form

$$\Delta\langle B\rangle_t = \text{Re}[\chi_{BA}(\omega)Fe^{i\omega t}], \tag{168}$$

when the external force is given by $F(t) = F \times \cos\omega t$. Here, Re denotes the real part of the relevant quantity, and the complex admittance $\chi_{BA}(\omega)$ is given by

$$\chi_{BA}(\omega) = -\frac{i}{\hbar}\int_{-\infty}^{t} \langle[A, B(t - s)]\rangle_{\text{eq}}e^{i\omega s}ds \tag{169}$$

with the definition (167). When Eq. (169) is divergent, we add the adiabatic factor $e^{\epsilon t}$ as

$$\chi_{BA}(\omega) = -\lim_{\epsilon\to+0}\frac{i}{\hbar}\int_0^{\infty} \langle[A,B(t)]\rangle_{\text{eq}}e^{-i\omega t-\epsilon t}dt. \tag{170}$$

Using Kubo's identity

$$[A,e^{-\beta\mathscr{H}}] = \frac{\hbar}{i}e^{-\beta\mathscr{H}}\int_0^{\beta} \dot{A}(-i\hbar\lambda)d\lambda, \tag{171}$$

we arrive at the expression

$$\chi_{BA}(\omega) = \lim_{\epsilon\to+0}\int_0^{\infty} dte^{-i\omega t-\epsilon t}\int_0^{\beta} d\lambda\langle\dot{A}(-i\hbar\lambda)B(t)\rangle_{\text{eq}}. \tag{172}$$

Now we define a current operator J by $J = \dot{A}$ and we observe the current, namely $B = J$. Then, we may put

$$\langle J\rangle_t = \sigma(\omega)Fe^{i\omega t}. \tag{173}$$

Here, the transport coefficient $\sigma(\omega)$ is expressed as

$$\sigma(\omega) = \int_0^{\infty} dte^{-i\omega t}\int_0^{\beta} d\lambda\langle J(-i\hbar\lambda)J(t)\rangle_{\text{eq}}. \tag{174}$$

If we use the canonical correlation

$$\langle J;J(t)\rangle = \frac{1}{\beta}\int_0^{\beta} \langle J(-i\hbar\lambda)J(t)\rangle_{\text{eq}}d\lambda, \tag{175}$$

then $\sigma(\omega)$ is expressed as

$$\sigma(\omega) = \frac{1}{k_{\text{B}}T}\int_0^{\infty} \langle J;J(t)\rangle e^{-i\omega t}dt. \tag{176}$$

In particular, the static coefficient $\sigma(0)$ is given in the form

$$\sigma(0) = \frac{1}{k_{\text{B}}T}\int_0^{\infty} \langle J;J(t)\rangle dt. \tag{177}$$

In the classical limit $\beta \to 0$, we obtain the result $\langle J;J(t)\rangle \to \langle JJ(t)\rangle_{\text{eq}}$, and consequently we rederive the classical expression (156).

10.2 Fluctuation–Dissipation Theorem and Kubo–Martin–Schwinger Condition

The relaxation function $\Phi_{BA}(t)$ is defined by

$$\Phi_{BA}(t) = \lim_{\epsilon\to+0}\int_t^{\infty} \phi_{BA}(s)e^{-\epsilon s}ds \tag{178}$$

using the response function

$$\phi_{BA}(t) = -(i/\hbar)\langle[A,B(t)]\rangle_{\text{eq}}. \tag{179}$$

The Fourier transform $f_{BA}(\omega)$ of $\Phi_{BA}(t)$ is introduced as

$$\Phi_{BA}(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} f_{BA}(\omega)e^{i\omega t}dw. \tag{180}$$

Next, we introduce the symmetrized time correlation $\Psi_{BA}(t)$ as

$$\Psi_{BA}(t - t') = \tfrac{1}{2}\langle(\Delta A(t)\Delta B(t') + \Delta B(t')\Delta A(t))\rangle_{\text{eq}} \tag{181}$$

with $\Delta A(t) = A(t) - \langle A\rangle_{eq}$. The Fourier form $g_{BA}(\omega)$ of $\Psi_{BA}(t)$ is related to $f_{BA}(\omega)$ as

$$g_{BA}(\omega) = E_{\beta}(\omega)f_{BA}(\omega) \tag{182}$$

with the energy $E_{\beta}(\omega)$ of a harmonic oscillator in equilibrium at temperature T, namely with

$$E_\beta(\omega) = \tfrac{1}{2}\hbar\omega \coth(\tfrac{1}{2}\beta\hbar\omega). \qquad (183)$$

Relation (182) is called the fluctuation–dissipation theorem. This is very important conceptually in nonequilibrium statistical mechanics.

The following relation is also easily derived (Martin and Schwinger, 1959):

$$\langle \Delta A \Delta B(t)\rangle_\omega = e^{\beta\hbar\omega}\langle \Delta B(t)\Delta A\rangle_\omega \qquad (184)$$

concerning the Fourier transform $\langle Q(t)\rangle_\omega$ of a time-dependent operator $Q(t)$.

10.3 Onsager's Reciprocity Theorem

When we consider several external forces $\{F_j(t)\}$ and their conjugate physical quantities $\{A_j\}$, we can define the following response functions $\{\Phi_{ij}(t)\}$:

$$\Phi_{ij}(t) = \beta\langle A_j; A_i(t)\rangle. \qquad (185)$$

If the relevant system (namely, the corresponding Hamiltonian $\mathcal{H}$) is symmetric with respect to time inversion, then we have the Onsager (1931) reciprocity relation

$$\Phi_{ij}(t) = \Phi_{ji}(t). \qquad (186)$$

That is, we have

$$\chi_{ij}(\omega) = \chi_{ji}(\omega). \qquad (187)$$

These symmetry relations are practically very useful, for example, in chemical engineering.

10.4 Exponential Perturbation Theory

If we put $\rho(t) = e^{\eta(t)}$, then the "entropy" operator $\eta(t)$ satisfies the same von Neumann equation as ρ:

$$i\hbar\frac{\partial}{\partial t}\eta(t) = [\mathcal{H}(t), \eta(t)]. \qquad (188)$$

To solve this equation, we put

$$\eta(t) = -\Phi(t) - \beta\mathcal{H} + \Delta\eta(t). \qquad (189)$$

Using the time-dependent Hamiltonian $\mathcal{H}(t) = \mathcal{H} - AF(t)$, we obtain the equation

$$i\hbar\frac{\partial}{\partial t}\Delta\eta(t) = [\mathcal{H} - AF(t), \Delta\eta(t)] + \beta F(t)\dot{A}. \qquad (190)$$

The operator $\Delta\eta(t)$ may be expanded with respect to $F(t)$ as

$$\Delta\eta(t) = \Delta\eta_1(t) + \Delta\eta_2(t) + \cdots, \qquad (191)$$

where

$$\Delta\eta_1(t) = \beta\int_{-\infty}^{0} F(t+s)\dot{A}(s)ds, \qquad (192)$$

$$\Delta\eta_2(t) = \frac{\beta}{i\hbar}\int_{-\infty}^{0} dsF(t+s)\int_0^s F(t+s') \times [A(s'), \dot{A}(s)]ds', \qquad (193)$$

and in general we have

$$\Delta\eta_n(t) = \frac{\beta}{(i\hbar)^{n-1}}\int_{-\infty}^{0} dsF(t+s)\int_0^s dt_1\int_0^{t_1} dt_2 \cdots \int_0^{t_{n-2}} dt_{n-1}F(t+t_1)F(t+t_2) \cdots F(t+t_{n-1}) \times [A(t_1),[A(t_2),\cdots[A(t_{n-1}),\dot{A}(s)]\cdots]. \qquad (194)$$

This scheme is called exponential perturbation theory. The first-order expression

$$\rho_1(t) = \exp[-\Phi(t) - \beta\mathcal{H} + \Delta\eta_1(t)] \qquad (195)$$

gives the Zubarev (1971) statistical operator. This is often used for studying nonlinear relaxation phenomena in many physical systems.

GLOSSARY

Bose–Einstein Condensation: The fact that Bose particles occupy the zero-momentum state macroscopically at low temperatures.

Bose Particle: A particle obeying Bose statistics.

Bose Statistics: Quantum statistics coming from the even symmetry of the many-particle wave function for integer-spin particles, in which any number of particles can occupy the same state simultaneously.

Density Matrix: A statistical operator expressing a statistical-mechanical ensemble such as the canonical or grand canonical ensembles, and having both the probabilistic character of quantum mechanics and statistics of the ensemble theory.

Exponential Product Formula: A formula expressing an exponential operator such as $\exp[x(A + B)]$ for the noncommutating operators A and B as the product of the exponential operators $\exp(xA)$ and $\exp(xB)$.

Fermi Particle: A particle obeying Fermi statistics.

Fermi Statistics: Quantum statistics coming from the odd symmetry of the many-particle wave function for half-integer-spin particles, in which only single particle can occupy each state.

Fluctuation–Dissipation Theorem: A theorem expressing that dissipation is related to fluctuation in equilibrium.

Kubo Formula: A general formula expressing transport coefficients in terms of time-correlation functions in equilibrium.

Kubo–Matrix–Schwinger Condition: A condition regulating an equilibrium state in terms of time-correlation functions.

Linear Response Theory: A theory expressing responses with respect to an external force in its first order, namely, fluctuations in the absence of the external force.

Mean-Field Theory: A theory expressing approximately a system of infinite degrees of freedom in terms of finite degrees of freedom by introducing some effective fields.

Ordered Exponential: An exponential operator prescribed by the Dyson time-ordering operator.

Quantum Monte Carlo Method: A Monte Carlo method for quantum systems based on the Suzuki–Trotter transformation which transforms a d-dimensional quantum system with short-range interactions to a $(d + 1)$-dimensional classical system with short-range interactions.

Quasiparticle: A particle deformed in mass or momentum dependence by the interaction with other particles.

Thermal de Broglie Wavelength: A characteristic length λ_D of a Fermi particle in thermal equilibrium determined by the condition $\lambda_D = h/p$ with $p^2/2m = 3k_BT/2$.

Trotter Formula: A product formula on an exponential operator, namely, $\exp[(A + B)] = \lim_{n\to\infty}[\exp(A/n)\exp(B/n)]^n$

von Neumann Equation: A basic formula that the time-dependent density matrix satisfies.

INTRODUCTION

> "Like gold to ayery thinnesse beate"
> —John Donne, *A Valediction: forbidding mourning*, 1611

In the nineteenth century, Lord Raleigh speculated that oil spread on water could form a layer only one molecule thick. By spreading a known volume of oil on a calm lake and estimating, by observing reflected light, the area that the oil covered, he was able to determine that the layer had a thickness in the range of 10^{-9} m. Today, we know of many examples of thin sheets, networks, and membranes that occur naturally in biological systems or that can be produced by a variety of physical and chemical means. These membranes and networks are very flexible and have small elastic moduli. For example, the volumetric compression resistance of a protein network in a cell may be more than ten million times smaller than that of a typical liquid.

The properties of highly flexible materials are a natural area of application for statistical mechanics. Many interesting characteristics of rubber, such as the observation first made by John Gough in 1805 that natural rubber contracts when heated, arise from the entropic properties of polymeric chains. The chains in such materials are flexible at the molecular level and possess a large number of equal-energy conformations, or equivalently, have substantial conformational entropy. Statistical mechanics explains Gough's observations by demonstrating that a flexible chain behaves like a spring with a spring

constant that increases linearly with temperature.

Viewed as two-dimensional generalizations of one-dimensional chains, membranes show a rich behavior on mesoscopic length scales. Computer simulations argue that *fluid* membranes, with vanishing in-plane shear modulus, exhibit highly convoluted configurations on long length scales, whereas *polymerized* membranes, which resist an in-plane shear, are asymptotically flat. Further, the elastic moduli of membranes are predicted to be wavelength dependent. In their interaction with each other, and with rigid objects such as flat walls, membranes unbind at high temperatures because of thermal undulations.

The study of the elastic and geometrical properties of membranes is a rapidly advancing field with an interplay of experiment, analytical theory, and computer simulation. Insights obtained from each of these physical approaches are contained in the following pages, which also include a short review of some concepts from polymer physics for both comparative and illustrative purposes. Space does not permit the presentation here of the application of statistical mechanics to the phase behavior of surfactant/solvent systems. We describe several of these phases in Sec. 1, where their existence is taken as given, but refer the interested reader to the monographs by Israelachvili (1992), Mouritsen (1988), and Safran (1994) for detailed experimental and theoretical treatments.

1. MEMBRANES AND NETWORKS

1.1 Fluid Membranes

Surface-active agents (or *surfactants*) owe their grease-cutting success to their affinity to both polar and nonpolar solvents. Surfactants are referred to as *amphiphilic*, reflecting their common attraction to otherwise immiscible liquids. Viewed at the molecular level, common soap (sodium stearate) has a long hydrocarbon chain that is attractive to nonpolar liquids such as oil and has a polar carboxylate group at the end of the chain that is attractive to polar liquids such as water; these two interactions are referred to as *hydrophobic* and *hydrophilic*, respectively. The molecular structures of two families of amphiphiles, fatty acids and dual-chain lipids, are illustrated in Fig. 1. Most lipids found in biomembranes have two chains with 16–18 carbon atoms per chain and head groups that are geometrically smaller than the hydrocarbon chains. Some phospholipids, for example, have just a three- or four-segment group (e.g., $-CH_2-CH_2-NH_2$) linked to the carboxylate end of the hydrocarbon chains through a phosphate group ($-PO_4-$) [see Gennis (1989) or Alberts *et al.* (1989) for further details].

While amphiphiles play an important role at interfaces in ternary systems such as oil/water/amphiphile, complex phases are found even in binary systems such as water plus amphiphile. Concentration, temperature, and *p*H are among the conditions that influence the phase structure of binary and ternary systems containing amphiphiles. Among other things, what makes these phases of interest biologically is that the amphiphiles self-assemble into structures with mesoscopic dimensions. Some aspects of the mesoscopic geometry have been interpreted in terms of the molecular geometry of the amphiphile, as we now attempt to demonstrate by example [see Israelachvili (1992) for further details].

Consider first the simple system of water and a single-chain lipid such as a fatty acid. At very low concentrations, the amphiphile dissolves in the conventional manner into the water solvent. In spite of the hydrophobic nature of the amphiphile's hydrocarbon

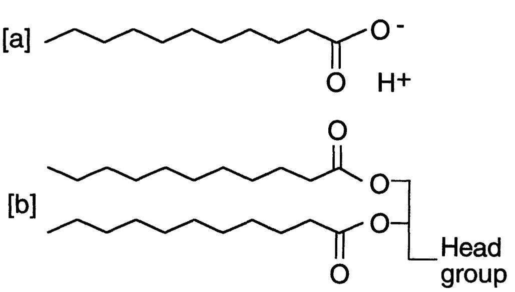

FIG. 1. Molecular structure of two families of amphiphiles. Molecule (a) is a fatty acid, having a single hydrocarbon chain terminating in a carboxylic acid group. Molecule (b) is a dual-chain lipid, with two hydrocarbon chains and a polar head group. In a typical phospholipid, the head group is much smaller than the hydrocarbon chains (e.g., $-PO_4-CH_2-CH_2-NH_2$ for phosphatidyl ethanolamine).

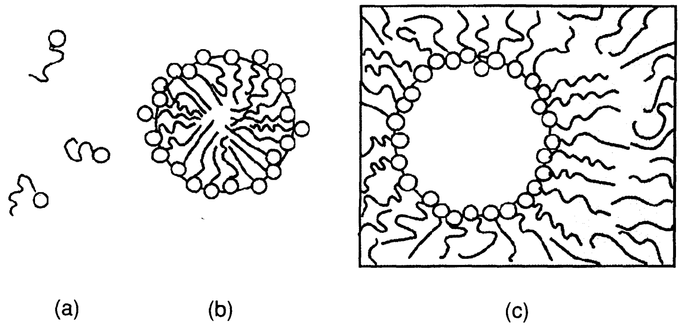

FIG. 2. Sample of phases that may be present in amphiphile/water systems: (a) conventional solution at very low amphiphile concentration, (b) micelle formation for concentrations above the critical micelle concentration (CMC), and (c) inverted micelles at high amphiphile concentrations. Other geometries are possible as well. In the diagram, the polar group of the molecule is indicated by a circle.

chain, the hydrophilic polar group at the head of the chain favors solvation. However, even at very modest concentrations of amphiphile, some fraction of the amphiphilic molecules undergo phase separation into *micelles,* as shown in Fig. 2. The abrupt onset of micelle formation occurs at the *critical micelle concentration* (or CMC). In an aqueous medium, the amphiphiles in a micelle are arranged so that their polar groups are in contact with water, while the nonpolar acyl chains aggregate in the interior of the micelle and are shielded from water. While micelle formation is favored energetically, it does not occur at very low amphiphile concentrations because of the low entropy of mixing compared to a conventional solution. Finally, at large amphiphile concentration, a phase of inverted micelles may form, also as indicated in Fig. 2.

The hydrocarbon chains of the micelle in Fig. 2(b) are packed together rather tightly, surrounded by the polar groups, which form a relatively close-packed array on the micelle surface to minimize the contact between the micelle interior and its aqueous environment. Thus, micelle formation is favored for amphiphiles whose polar head-group area is large compared to the transverse dimension of the hydrocarbon chains. In dual-chain lipids, the chains occupy proportionately more area than the head group does, and other phases, such as the lipid bilayers of Fig. 3, compete with micelle formation. Depending on the molecular geometry of the lipid, the most favored bilayer may be flat or curved. The ability of dual-chain lipids to form bilayers should not be interpreted as meaning that such lipids do not form micelles. In fact, because of the large hydrocarbon areas, the CMC of dual-chain lipids (typically 10^{-8} mol L^{-1}) is orders of magnitude smaller than that of single-chain lipids (typically 10^{-3} mol L^{-1}). Dual-chain lipids also are capable of forming phases of inverted micelles. As discussed further in Sec. 1.2, living cells are bounded by a plasma membrane whose structure includes a fluid lipid bilayer.

It is possible to obtain the elastic properties of biomembranes and related structures by several different techniques. An example of the micropipette aspiration technique is shown in Fig. 4, in which a cell or synthetic vesicle is drawn under pressure into a micropipette with a diameter of about a micron. Elastic moduli can be determined from the strain observed in the membrane when it is subject to a known stress. Another technique for measuring elastic moduli uses the fluctuations in cell geometry (see Sec. 2.4 for a de-

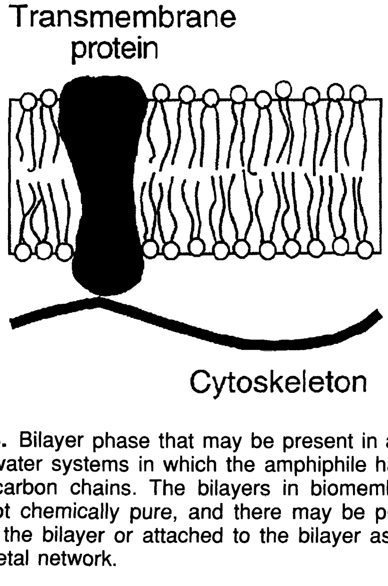

FIG. 3. Bilayer phase that may be present in amphiphile/water systems in which the amphiphile has two hydrocarbon chains. The bilayers in biomembranes are not chemically pure, and there may be proteins within the bilayer or attached to the bilayer as a cytoskeletal network.

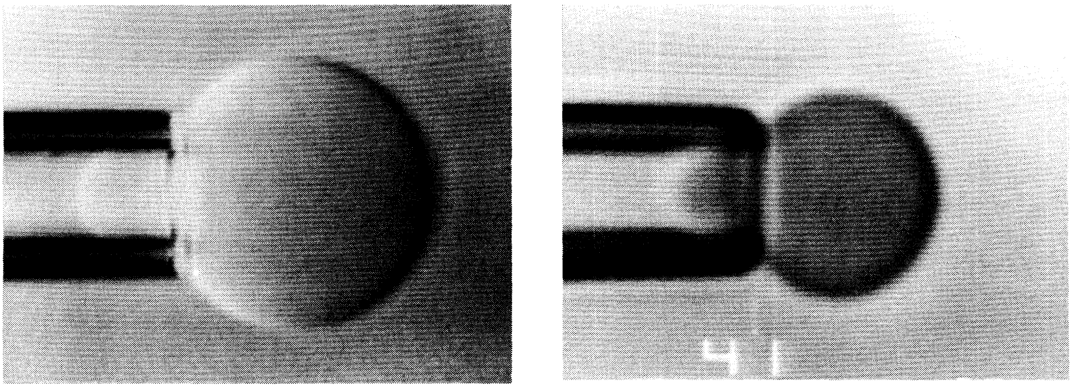

(a) (b)

FIG. 4. Micropipette aspiration of a giant phospholipid bilayer vesicle (left, diameter ~20 μm) and an osmotically preswollen red cell (right, diameter 6 μm). Several of the elastic constants of bilayers can be measured using variations of a technique in which the vesicle is subject to a known stress (from Mohandas and Evans, 1994).

scription of the bulk modulus in terms of volume fluctuations).

The bending moduli (k_b of Sec. 2.3) of phospholipid bilayers of biological importance typically are in the range (3–20) × 10^{-20} J, depending on chemical composition, and is in the same range as that reported for the red blood-cell plasma membrane using different techniques. While small compared to thin inorganic films, this modulus is about an order of magnitude larger than that of surfactant monolayers at an oil–water interface. The two-dimensional area compression modulus of a flat red-cell bilayer is 0.5 J/m^2, which may be more than an order of magnitude smaller than the product of the bilayer thickness and the volume compression modulus of a simple liquid such as water. Since bilayers are fluid, their shear modulus vanishes.

Depending on their geometry and other properties, lipids may form into bilayers that are flat or have a tendency to bend spontaneously (*spontaneous curvature;* see Sec. 2.3). A naturally curved bilayer may form into a closed geometry such as a sphere with no energy penalty. A spherical *vesicle* whose surface energy density depends only on the mean surface curvature has a relatively modest total energy of $8\pi k_b$ independent of the vesicle radius. This means that the deformation energy of the whole vesicle may be just $(250–2000)k_BT$ for the range of moduli quoted above (where k_B is Boltzmann's constant and T is the absolute temperature). The size of the mesoscopic structures adopted by lipid bilayers covers a broad range: Stable vesicular systems that are found in Nature or that can be prepared in the laboratory vary from tens of nanometers to tens of microns.

Ternary mixtures of amphiphiles, oil, and water have very complicated phase diagrams, as one would expect. Micellar phases may be present, of course, and there are structures that can form with amphiphile at the interface between oil and water. Sponge phases also exist, in which oil and water are separated from each other in a labyrinth of three-dimensional channels running throughout the system. In this article, we concentrate on the self-assembled bilayers formed in binary systems.

1.2 Polymerized Membranes and Networks

The lipid bilayers described in Sec. 1.1 are fluid: they do not resist an in-plane shear. However, there are many inorganic monolayers or polymerized organic monolayers and bilayers that can support an in-plane shear (at least on small length scales, see Sec. 4.2). These materials are predicted to have different properties than fluid membranes, so we describe several examples here.

Graphite derives its lubricating properties from its molecular geometry consisting of carbon rings linked together in a planar honeycomb structure. Other examples of planar inorganic monolayers can be obtained by a process known as exfoliation (Divigalpitiya *et al.,* 1989). This is a two-step process in which potentially reactive ions such as lithium are *intercalated* into layered structures such as MoS_2. In a second step, the intercalated material is exposed to water, which reacts strongly with the lithium and forces the monolayers apart. A section of an MoS_2 monolayer is illustrated in Fig. 5. Polymerized organic membranes can be obtained by exposing to ultraviolet radiation monolayers or bilayers of certain reactive organic compounds. The resulting materials are not always uniform, since polymerization may occur in local patches. A variety of materials have shown the ability to polymerize, many examples of which can be found in Ringsdorf (1988).

Two-dimensional networks also are examples of polymerized membranes. These networks need not be "solid" in the chemical sense—they only need to have a two-dimensional structure and fixed connectivity resulting in shear resistance. An example of a polymerized network is the spectrin cytoskeleton of the red blood cell (see Alberts *et al.*, 1989). The erythrocyte plasma membrane consists of three regions: the lipid bilayer forming the cell boundary, the glycocalix exterior to the cell, and the cytoskeleton on the interior or *cytoplasmic* side of the membrane. Tetramers of the spectrin protein (with a contour length of about 200 nm) form a two-dimensional network with largely triangular connectivity at the junction points of the spectrin tetrameres. The network is loose, with a mean separation between the junction complexes of 70 nm. A schematic representation of the cytoskeleton from a computer simulation is shown in Fig. 6, in which view (a) is perpendicular to the bilayer and view (b) is along the bilayer plane. The bilayer lies below the cytoskeleton in view (b). The in-plane shear modulus of this network, as measured by the micropipette experiments, is (6–9) × 10^{-6} J/m^2, although other experiments based on long-wavelength fluctuations have yielded lower values.

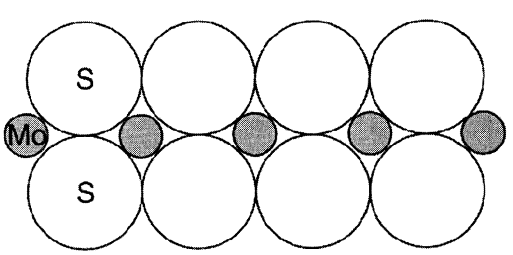

FIG. 5. Schematic drawing of a section through an MoS_2 monolayer. Such monolayers are formed by first intercalating the bulk material with reactive ions such as lithium, and then adding a solvent such as water that undergoes a reaction with the intercalant.

There is no reason to expect that all polymerized membranes or networks have uniform connectivity. For example, the erythrocyte cytoskeleton has approximately sixfold connectivity at its junction vertices, but the fraction of sixfold vertices is not 100%, and the connectivity of a given spectrin tetramer may not be fixed: There may be detachment and reattachment of spectrin, even if the rate is very slow. Further, there are hereditary

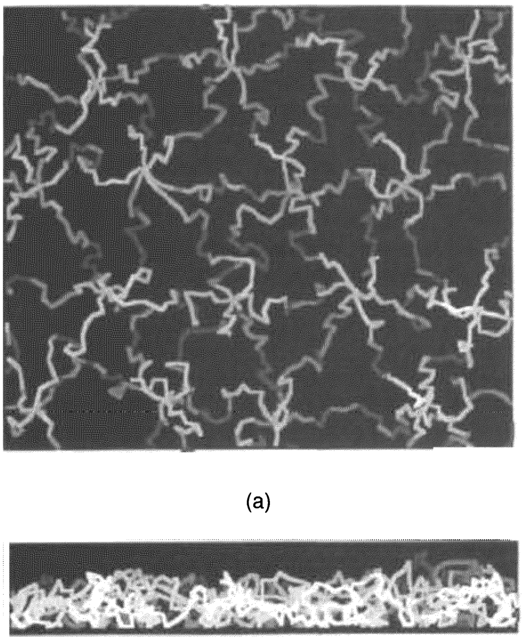

FIG. 6. Computer simulation of the membrane-associated cytoskeleton of the human erythrocyte. (a) The network seen from the cytoplasmic side of the membrane showing the sixfold connectivity of the cytoskeleton. (b) A section through the cytoskeleton. The lipid bilayer, not shown in (b), lies below the cytoskeleton.

diseases in which the spectrin concentration is depleted, resulting in incomplete networks and red cells with reduced elasticity (Mohandas and Evans, 1994).

1.3 Multilamellar Systems

One technique for vesicle production involves the swelling of multilayer (or *multilamellar*) stacks of dried lipid. Similar to, but much slower than, the production of inorganic monolayers by exfoliation described in Sec. 1.2, the invasion of water laterally through the stack forces the individual membranes apart. Not all bilayers in this procedure become separated from each other, and some remain in multilamellar structures. The bilayers in multilamellar systems are not always tightly bound to each other; there may be solvent trapped between lamellae, or several stacks of membranes may be linked by a single membrane. It is also possible to obtain more uniform multiple layers of material through the Langmuir–Blodgett technique (see Gaines, 1966). Small multilamellar stacks of membranes can be produced by the less gentle technique of applying high-frequency mechanical vibrations to lipid/solvent dispersions (sonication—see Fromherz *et al.*, 1986).

Part of the interest in multilamellar systems is the study of adhesion between bilayers. In some systems, thermal fluctuations of a membrane may prevent two membranes from adhering. These phenomena are treated in more detail in Sec. 6.

2. ELASTICITY

2.1 Deformations and the Strain Tensor

In one formulation of continuum mechanics, force is replaced by stress, and displacement is replaced by strain. Stress and strain can be represented by tensors, with the stress tensor having the dimensions of an energy density, while the strain tensor is dimensionless. In the statistical mechanics applications here, we use only the strain tensor; the reader interested in the more general formulation of continuum mechanics is referred to Fung (1994), Landau and Lifshitz (1986), or MECHANICAL PROPERTIES OF SOLIDS.

Consider the deformation of a two-dimensional square as shown in Fig. 7. Two-dimensional deformations are used here for diagrammatic simplicity; the notation is three dimensional. Two positions, marked by a and b on the undeformed square, define a vector $d\mathbf{x}$. A stress is applied to the square to change its shape and the points a and b move to new absolute positions, changing the vector $d\mathbf{x}$ to $d\mathbf{x}'$. Vectors $\mathbf{u}_a$ and $\mathbf{u}_b$ describe the displacement of positions a and b from the undeformed to the deformed state. The coordinate system does not change with the deformation.

Adding a constant displacement $\mathbf{u}$ to all positions on the object simply results in a translation of the object. In Fig. 7, the direction and magnitude of $\mathbf{u}$ vary locally, and the change of $\mathbf{u}$ with $\mathbf{x}$ provides a description of how vectors $\mathbf{x}$ at different locations on the object change with respect to each other. In our example, the vectors $d\mathbf{x}$ and $d\mathbf{x}'$ are related through

$$d\mathbf{x}' = d\mathbf{x} + \mathbf{u}_b - \mathbf{u}_a, \tag{1}$$

which can be written in the infinitesimal limit as

$$dx_i' = dx_i + \sum_j (\partial u_i/\partial x_j)dx_j, \tag{2}$$

where the components of each vector are indicated explicitly by the subscripts i and j.

The square of the length between neighboring points, dl^2, changes under the deformation to

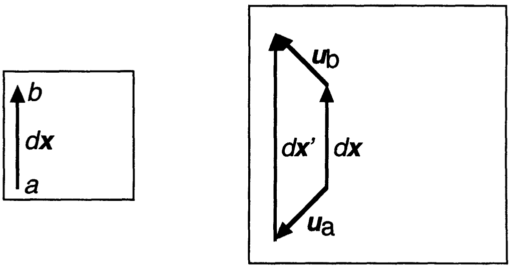

FIG. 7. Change in vector *dx* to *dx'* during a shape-preserving deformation. The initial object is shown on the left, while the deformed object is shown on the right. The initial position vector *dx* is superimposed on the deformed object to show the changes more clearly.

$$dl'^2 = dl^2 + 2\sum_{i,j} \epsilon_{ij} dx_i dx_j, \tag{3}$$

where

$$\epsilon_{ij} = \frac{1}{2}\left[\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} + \sum_k \frac{\partial u_k}{\partial x_i}\frac{\partial u_k}{\partial x_j}\right] \tag{4}$$

is the *strain tensor*. For deformations sufficiently small that terms quadratic in $\partial u_i/\partial x_k$ can be neglected, then the strain tensor can be approximated by

$$\epsilon_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right). \tag{5}$$

2.2 Elastic Moduli

Objects may deform in response to applied forces that, in general, may have complex orientations with respect to the object. For example, while an object may have a simple cubic shape, the forces on the object may be at oblique angles with respect to the surface of the cube. A spatial component of an applied force can be written in terms of the stress tensor σ_{ij} via $\Sigma_i \sigma_{ij} s_j$, where $\mathbf{s}$ is a vector whose magnitude is equal to the surface area to which the force is applied and whose direction is normal to the surface.

A spring is a simple example of a Hooke's-law object in which the strain (the displacement from equilibrium) is proportional to the stress (the applied force). Hooke's law can be generalized to the stress and strain tensors defined above, although the single spring constant must be replaced by more complex proportionality constants. One way of writing Hooke's law is

$$\sigma_{ij} = \sum_{p,q} c_{ijpq}\epsilon_{pq}, \tag{6}$$

where the constants c_{ijpq} are the elastic constants and have units of energy density. In principle, there are 36 elastic constants for three-dimensional materials, but if the elastic energy is a quadratic function of the strain, as it is in Hooke's law, then the maximum number of independent constants is 21. Further, the number of independent constants depends on the symmetry of the system, with isotropic systems having only two elastic constants.

We now consider an isotropic system in more detail. The change in free-energy density of deformation, ΔF, can be expanded in powers of the strain tensor, and the lowest-order terms in the expansion are quadratic in ϵ. Two independent scalar combinations of ϵ are available: the squared sum of the diagonal elements, $(\mathrm{tr}\epsilon)^2$, and the sum of the elements squared, $\Sigma_{i,j}\epsilon_{ij}^2$. If we assume that the deformations are small, then ΔF can be written as

$$\Delta F = (\lambda/2)(\mathrm{tr}\epsilon)^2 + \mu \sum_{i,j} \epsilon_{ij}^2. \tag{7}$$

The constants λ and μ are called the Lamé coefficients, of which μ is the shear modulus. The compression modulus K can be expressed in terms of the Lamé coefficients by

$$K_A = \lambda + \mu \quad \text{(two dimensions)}, \tag{8a}$$

$$K_V = \lambda + 2\mu/3 \quad \text{(three dimensions)}. \tag{8b}$$

Both K and μ must be positive, or else the system could spontaneously deform by a shear or compression mode. The Lamé coefficient λ is not constrained to be positive, and systems are known in which λ is negative.

A further quantity of interest is the Poisson ratio σ_P, which is a measure of how much a material *contracts* in the transverse direction when it is stretched in the longitudinal direction. The geometrical definition of σ_P is then $-\epsilon_{yy}/\epsilon_{xx}$ for a deformation u_x in the x direction that results in a displacement u_y in the y direction. Poisson's ratio can be expressed in terms of elastic constants by

$$\sigma_P = (K_A - \mu)/(K_A + \mu) \quad \text{(two dimensions)}, \tag{9a}$$

$$\sigma_P = (3K_V - 2\mu)/(6K_V + 2\mu) \quad \text{(three dimensions)}. \tag{9b}$$

As an application, we consider a triangular network of springs in two dimensions, as shown in Fig. 8. The elastic moduli can be found by evaluating the energy change of a specific deformation and comparing the result with Eq. (7). At zero temperature, one finds

$$K_A = \sqrt{3}k_{sp}/2 \tag{10}$$

and

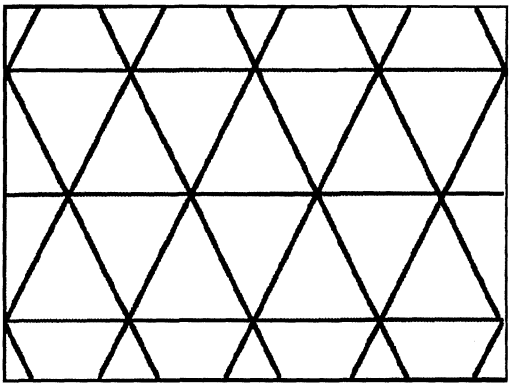

FIG. 8. Triangular network of springs in two dimensions.

$$\mu = \sqrt{3}k_{sp}/4 = K_A/2, \tag{11}$$

where k_{sp} is the spring constant. Note that both moduli are independent of the unstretched spring length. The Poisson ratio for this network is then

$$\sigma_P = \tfrac{1}{3}. \tag{12}$$

This sign of the Poisson ratio indicates that when the network is stretched in one direction, it contracts in the transverse direction. Many solids have a Poisson ratio of about $\frac{1}{3}$ in three dimensions. Some networks under tension are predicted to have a negative Poisson ratio.

2.3 Bending Resistance

The compression modulus is a measure of the free-energy change when the elements of a structure are forced closer together under pressure, or pulled further apart under tension. When the membranes illustrated in Figs. 3 and 5 are forced to bend, say about an axis pointing out of the plane of the diagram, then elements on one side of the midplane are forced closer together, while elements on the other side move farther apart. The free-energy change associated with the bending deformation is a measure of the bending resistance.

Just as with the shear and compression deformations of Secs. 2.1 and 2.2, we first need to develop a geometrical description of the bending of a surface. Following the approach of Safran (1994), we begin by reviewing the description of a curved line. In a coordinate system external to the line, each point on the curve is specified by a vector **R**, as in Fig. 9. The distance in space dl between two points separated by an infinitesimal arc length ds is then

$$dl = \left|\frac{\partial \mathbf{R}(s)}{\partial s}\right| ds, \tag{13}$$

where $|\mathbf{R}|$ represents the length of vector **R**. The unit vector normal to the curve, **n**, is proportional to the second derivative of the position vector:

$$C\mathbf{n}(s) = \frac{d^2\mathbf{R}(s)}{dl^2}, \tag{14}$$

where C is the curvature.

Now, the above description must be generalized for a two-dimensional surface embedded in three dimensions. Consider the surface shown in Fig. 10. Each point on the surface is specified by a height $h(x,y)$, which is a function of the fixed coordinate system x and y. In the figure, there is only one surface element for each (x,y) pair—there are no overhangs, and $h(x,y)$ is single-valued. We assume that the membrane of interest is sufficiently flat that this representation, referred to as the Monge representation, is valid.

The figure also shows vectors **n** normal to the surface. At each point (x,y), the normal has coordinates

$$\mathbf{n}(x,y) = (-\partial_x h, -\partial_y h, 1)/(1 + |\nabla h|^2)^{1/2}, \tag{15}$$

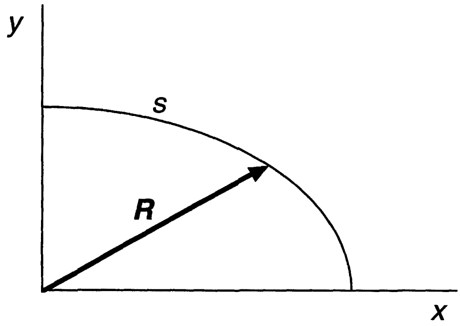

FIG. 9. Coordinates of a curve. The arc length s is the coordinate along the curve, while **R** is the position of a particular point on the curve, as measured with respect to an external coordinate system.

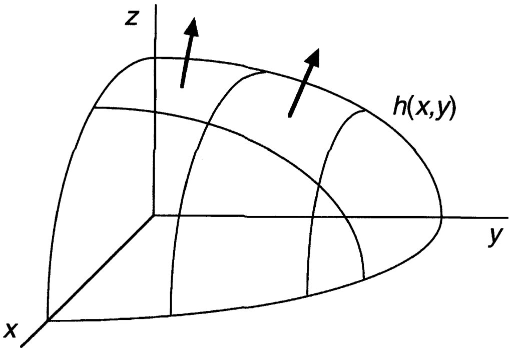

FIG. 10. Coordinates of a surface. Each element on the surface is described by its height $h(x,y)$ above the xy plane. Normals to the surface are indicated by bold arrows.

where ∂_x is $\partial/\partial x$. While there is a unique curvature associated with a given point on a line in Eq. (14), the curvature on a surface has a direction dependence that reflects the orientation of the vector $d\mathbf{R}$ along the surface:

$$C = -(d\mathbf{R}\cdot d\mathbf{n})/(d\mathbf{R}\cdot d\mathbf{R}). \tag{16}$$

Clearly, one has to establish a set of directions along which to evaluate the curvature, and the method of choice is to construct a curvature tensor $\mathbf{C}$ such that

$$d\mathbf{n} = d\mathbf{R}\cdot\mathbf{C}. \tag{17}$$

The eigenvalues of $\mathbf{C}$ are referred to as the principal curvatures, which we denote by C_1 and C_2. Note that there is no requirement that C_1 and C_2 have the same sign: a saddle point, for example, has principal curvatures of opposite sign.

The curvature tensor provides the geometrical description of a bending deformation, much as the strain tensor describes compression and shear in Sec. 2.1. Further, the free energy can be written as a function of the principal curvatures, as is done for the strain tensor in Sec. 2.2. The curvatures are usually written in the combinations $(C_1 + C_2)/2$ and C_1C_2, which are the mean curvature and Gaussian curvature, respectively. Expressed in terms of the principal curvatures, the leading-order terms in the free-energy density for bending, F, are

$$F = (k_b/2)(C_1 + C_2 - 2C_0)^2 + k_gC_1C_2, \tag{18}$$

where k_b is the bending rigidity and k_g is the Gaussian rigidity. The addition of the parameter C_0, referred to as the spontaneous curvature, allows for situations in which the membrane intrinsically bends to one side. The Gaussian rigidity is often omitted from expressions for the free energy in situations where the topology of the surface is closed, since the integral of the Gaussian curvature over a closed surface is a topology-dependent constant. The shapes of closed surfaces subject to bending resistance, as in Eq. (18), are discussed in VESICLES AND BIOMEMBRANES.

2.4 Elasticity and Fluctuations

The elastic moduli are introduced in Sec. 2.2 as terms in an expansion of the free-energy density. This approach is useful in statistical mechanics problems, since the weight accorded to a specific configuration in an ensemble is $\exp(-\beta E)$, where E is the energy of the configuration and β is the inverse temperature $(k_BT)^{-1}$. Statistical mechanics provides a description of the elastic moduli based on ensemble averages.

Consider the isothermal compression modulus, K_V, as an example. The physical definition of K_V is

$$K_V = -\frac{V}{\partial V/\partial P}, \tag{19}$$

where V is the volume of the system and P is the applied pressure. In an alternative approach that emphasizes the fluctuations in the system at nonzero temperature, the Gibbs free energy is expanded about the equilibrium value at a fixed pressure (Reif, 1965):

$$\Delta G = G(V) - G(V_{eq}) = (V - V_{eq})^2/(2V_{eq}K_V), \tag{20}$$

where V_{eq} is the equilibrium value of the volume. The corresponding partition function can be evaluated analytically, since the weight for a given volume V is proportional to $\exp(-\beta\Delta G)$. As a result, the compression modulus also can be expressed as

$$\beta K_V = \langle V\rangle/(\langle V^2\rangle - \langle V\rangle^2), \tag{21}$$

where $\langle V\rangle$ is the ensemble average of V.

A formally identical problem to this is the relation between the fluctuations in the length of a spring and the spring constant k_{sp}. The expression analogous to Eq. (21) is

$$\beta k_{sp} = (\langle l^2 \rangle - \langle l \rangle^2)^{-1}, \tag{22}$$

where l is the length of the spring. Note that Eq. (22) is independent of the unstretched spring length.

3. FLEXIBLE CHAINS

3.1 Ideal Chains

Linear and branched chains provide an intuitive introduction to the geometrical and elastic properties of membranes. We pause to assemble a number of results from polymer physics that will put the behavior of membranes in context.

The simplest geometry of a single polymer chain is one in which a chain element, or monomer, is freely jointed and can assume any orientation irrespective of the orientation of its neighbors. The conformations of the chain are equivalent to a random walk if the chain elements are permitted to intersect each other. Consider the situation in which the elements of the chain are represented by vectors $\mathbf{a}_i$, each of which has the same length a. A chain with N segments has a contour length along the chain of Na. Of interest is the end-to-end displacement vector $\mathbf{r}_{ee}$, illustrated in Fig. 11, which is just the sum of the individual vectors: $\mathbf{r}_{ee} = \Sigma_i \mathbf{a}_i$. The ensemble average over all possible conformations at fixed N yields the well-known result

$$\langle r_{ee}^2 \rangle = Na^2. \tag{23}$$

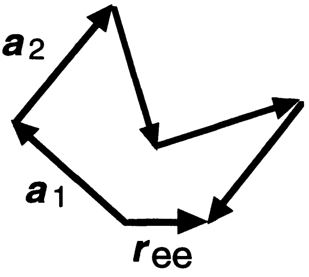

FIG. 11. End-to-end displacement $\mathbf{r}_{ee}$ for a chain whose elements have a common length and random orientation.

Thus, the end-to-end displacement grows with contour length like $N^{1/2}$. Other geometrical quantities, such as the radius of gyration, also scale like $N^{1/2}$.

Consider now the slightly more complicated problem of chains with a fixed polar angle θ between successive segments i and $i + 1$, such that

$$\mathbf{a}_i \cdot \mathbf{a}_{i+1} = -a^2 \cos\theta, \tag{24}$$

where the convention is that $\theta = 0$ if neighboring segment vectors $\mathbf{a}_i$ point in opposite directions. Although the polar angle between segments is fixed, the azimuthal angle is not, and the segments are free to rotate around one another. As shown in Flory (1953), the end-to-end displacement of this chain at large N is

$$\langle r_{ee}^2 \rangle = Na^2(1 - \cos\theta)/(1 + \cos\theta). \tag{25}$$

The important feature to note in Eq. (25) is that the end-to-end displacement scales like $N^{1/2}$, in spite of the restrictions on the chain's conformations. In fact, the $N^{1/2}$ scaling is found for all chains on sufficiently large length scales, so long as the chain path can cross itself. It is then useful to introduce the idea of an effective bond length b which reflects the length scale at which the chains appear to be ideal; that is, $\langle r_{ee}^2 \rangle = Nb^2$. The effective bond length has the same order of magnitude as the persistence length, which measures the length scale over which the spatial orientation of the monomers is correlated [see Eq. (43)]. For the restricted orientation situation of Eq. (25), the effective bond length is

$$b = a[(1 - \cos\theta)/(1 + \cos\theta)]^{1/2}. \tag{26}$$

In alkane chains (the hydrocarbon chains present in soap, for example), θ is close to the tetrahedral angle of 109.5°, and the effective bond length is $\sqrt{2}a$, according to Eq. (26), or about 0.2 nm. Their rigidity and monomer size dictate that protein chains have considerably longer effective bond lengths, several nanometers or more, depending on the protein. Of course, steric interactions prevent physical systems, such as proteins, from intersecting themselves, and so their behavior is not described fully by ideal-chain scaling.

3.2 Self-Avoiding Chains

While the "ideal chains" of Sec. 3.1 may intersect themselves, physical systems have an excluded volume that enforces self-avoidance of the chain. This steric interaction among the chain elements is important for chains in one-, two-, and three-dimensional systems. Consider the simple situation in which a chain lies along the x axis. Self-avoidance forbids the chain from reversing on itself from one step to the next, so that the end-to-end distance must be just the contour length Na. But Eq. (23) shows that $\langle r_{ee} \rangle$ scales like $N^{1/2}$ for ideal chains, *independent of embedding dimension.* Thus, we conclude that in one dimension, self-avoidance of the chain dramatically affects its scaling properties. The same conclusion can be drawn for chains in two and three dimensions.

A simple model for the length-scaling exponent of self-avoiding chains was proposed by Flory (1953). The calculation evaluates the power-law dependence of the free energy on the effective chain size r and number of segments N at both large and small r. Minimizing the free energy yields r as a function of N. Since our goal is to extract the scaling exponent, we do not pay close attention to numerical factors like $4\pi/3$, and we use r to represent the effective size of the chain, as characterized by an end-to-end length or a root mean square radius. Also, our model chains have no explicit energy scale other than the temperature. Following de Gennes (1979), the behavior of the free energy is evaluated in two regimes:

1. Short distances. Steric repulsion between the chain segments causes the chain to swell compared to an ideal chain. The repulsive energy experienced by one segment through its interaction with other segments is proportional to the concentration of segments, roughly N/r^d for a chain in a d-dimensional space. Thus, the total repulsive energy experienced by all N segments is proportional to N^2/r^d. Now, the repulsive energy also will be proportional to the excluded volume of the segment–segment interaction, which we characterize by a parameter v_{ex}. Taking the excluded volume as a hard-core interaction, then the energy scale of the interaction is set by the temperature $k_B T$. Thus, the steric contribution to the free energy should behave like

$$F = k_B T v_{ex} N^2 / r^d, \tag{27}$$

where all constants have been absorbed into v_{ex}.

2. Long distances. As a chain is stretched, the number of configurations that it can adopt at a fixed end-to-end distance decreases rapidly. As shown in Sec. 3.4, the probability of finding a given end-to-end distance r for an ideal chain decays exponentially as $\exp(-dr^2/2Na^2)$, where a is the elementary segment length. Recalling that the entropy S is proportional to the logarithm of the probability, then to within a constant

$$S/k_B = -dr^2/2Na^2. \tag{28}$$

The entropic contribution to the free energy at long distances can be found through $F = E - TS$. Combining Eqs. (27) and (28) and discarding overall normalization constants, the free energy of the self-avoiding chain behaves like

$$F = k_B T v_{ex} N^2 / r^d + k_B T d r^2 / 2Na^2. \tag{29}$$

This expression shows that there is a penalty for pushing the chain elements close together (small r), and there is a penalty for stretching out the chains (large r). The value for r that minimizes F can be found by taking the derivative of Eq. (29) with respect to r, holding other quantities fixed, and this value scales like

$$r \approx N^{3/(2+d)}. \tag{30}$$

The scaling behavior of Eq. (30) is expected for any length scale r that characterizes the linear dimension of the system as a whole, such as the end-to-end distance r_{ee} and the root mean square radius of the system $(\langle r_{ee}^2 \rangle^{1/2}/\sqrt{6})$. The exponent on the right-hand side of Eq. (30) is called the Flory exponent.

The systems discussed thus far in this section are linear chains. Chains with side branches, referred to as branched polymers, have different scaling with system mass N than do linear chains, since branching will add monomers to a given position along the chain. Because a branched polymer has more than two ends, the end-to-end displacement is replaced as a measure of the polymer size by some other quantity such as the radius of gyration R_g, defined by

$$R_g^2 = \sum_i (\mathbf{r}_i - \mathbf{r}_{\text{c.m.}})^2, \tag{31}$$

where $\mathbf{r}_{\text{c.m.}}$ is the center-of-mass position of the chain and the sum is over the positions of the segments. The radius of gyration for branched polymers is found to have a scaling form

$$\langle R_g^2 \rangle \approx N^{2\eta}. \tag{32}$$

The branched-polymer scaling exponents are smaller than the self-avoiding walk exponents, being 0.64 and 0.5 in two and three dimensions respectively, compared to 0.75 and 0.59 for self-avoiding walks. The scaling exponents for linear and branched polymers are summarized in Table 1.

In real polymers, the chains may be rigid because of bond-angle restrictions, and there may be attractive van der Waals interactions between monomers. What effects do these interactions have on scaling behavior? As shown in Sec. 3.1, making chains stiffer only increases the persistence length of the chain; it does not change the scaling behavior in the large-N limit. Of course, for small N the introduction of rigidity may change the appearance of the chain configuration substantially. The situation is different if there is attraction between chain elements. If the attraction is strong enough, then the chains collapse to a dense phase in which the chain size scales like $N^{1/d}$. For example, self-avoiding walks in three dimensions without attractive interactions scale like $N^{3/5}$, but for strong attraction they scale like $N^{1/3}$. The transition between the two scaling regimes is a phase transition and occurs at a temperature (or attraction strength) called the Θ point.

3.3 Self-Avoiding Rings

Let us close our linear chain to form a loop in two dimensions, which will serve as a two-dimensional vesicle. Closing the chain introduces a new characteristic, namely, the enclosed ring area, as well as the conjugate thermodynamic variable of pressure P. The parameter space of the rings then includes bending rigidity, van der Waals attraction, and pressure.

We consider the effects of each parameter in turn, with the others set equal to zero.

Table 1. Scaling exponents η for the scaling law $\langle R_g^2 \rangle \sim N^{2\eta}$ for ideal or random walks, self-avoiding walks, and branched polymers as a function of embedding dimension d.

Configuration	$d = 2$	$d = 3$
Random walk	1/2	1/2
Self-avoiding walk	3/4	0.59
Branched polymer	0.64	1/2

1. Rigidity. The presence of rigidity changes the persistence length, but not the asymptotic scaling behavior at large N, although the scaling behavior at finite N is nontrivial.
2. Pressure. Defining

   $$\Delta P = P_{\text{inside}} - P_{\text{outside}}, \tag{33}$$

   then at $\Delta P > 0$, the ring is always inflated at large N and the scaling behavior is $\langle R_g^2 \rangle \approx N^2$ and $\langle A \rangle \approx N^2$. At zero pressure, the ring should behave like a self-avoiding walk, with $\langle R_g^2 \rangle \approx N^{3/2}$ and $\langle A \rangle \approx N^{3/2}$. When the outside pressure exceeds the inside pressure ($\Delta P < 0$), the ring belongs to the branched polymer family but is not dense. For the ring to look like a branched polymer, it must have little enclosed area, so that $\langle R_g^2 \rangle \approx N^{1.28}$ and $\langle A \rangle \approx N$.
3. Attraction. If the attraction between monomers on the chain is strong enough, then the configurations may become dense, and $\langle R_g^2 \rangle \approx N$ and $\langle A \rangle \approx N$. This is similar to the Θ point of linear polymers.

A summary of the scaling exponents is given in Fig. 12 for two-dimensional rings simultaneously subject to pressure and attraction (Boal, 1991).

3.4 Chain Elasticity

There are comparatively few configurations in which an ideal chain is fully stretched: The most common configurations are ones in which the chain is highly convoluted. Since entropy is proportional to the logarithm of the number of configurations, then another way of stating this observation is that the entropy of the chain is reduced, and the free energy is increased, as a chain is stretched. This implies that the chain has elasticity arising from its entropy.

To find the relationship between the elas-

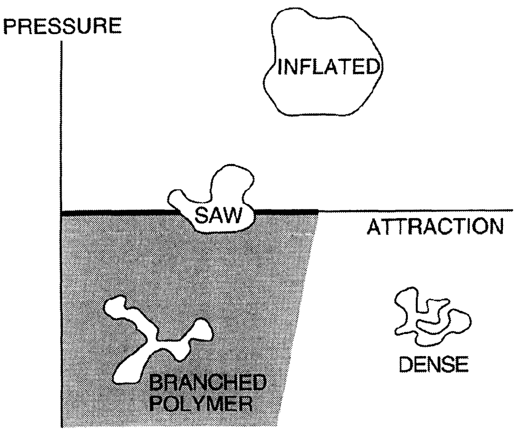

FIG. 12. Phase diagram for two-dimensional self-avoiding rings subject to pressure and attraction. There may be considerable finite-size scaling effects near the phase boundaries.

ticity of an ideal chain and its geometry, we consider the distribution of end-to-end vectors $\mathbf{r}_{ee}$. Let us break up the three-dimensional distribution into three one-dimensional distributions. The x component of the end-to-end displacement, $r_{ee,x}$, is just the sum of the individual monomer segment lengths projected onto the x axis: $r_{ee,x} = \Sigma_i a_{i,x}$. For ideal chains, $a_{i,x}$ is uncorrelated with $a_{i+1,x}$, and the situation is the same as the one-dimensional random walk with steps of variable size. In the continuum limit, the probability of finding a one-dimensional walk with end-to-end displacement between x and $x + dx$ is just

$$\rho(x)dx = (2\pi Na^2/d)^{-1/2}\exp(-dx^2/2Na^2)dx, \tag{34}$$

where $\rho(x)$ is the probability density (probability per unit length) and d is the embedding dimension. This distribution is normalized to unity and has expectations

$$\langle r_{ee,x}\rangle = \int x\rho(x)dx = 0 \tag{35}$$

and

$$\langle r^2_{ee,x}\rangle = \int x^2\rho(x)dx = Na^2/3 \tag{36}$$

for the x component of the end-to-end displacement vector in three dimensions.

Equations (35) and (36) can be used with Eq. (22), which relates the spring constant to the fluctuations in spring length, to obtain an expression for the effective spring constant of the chain:

$$k_{sp} = dk_BT/Na^2. \tag{37}$$

Equation (37) shows that the effective stiffness of the chain increases with d and the temperature T. The elastic behavior of the chain is entropic in origin, since there is no potential-based restoring force at the microscopic level.

4. FLUCTUATING MEMBRANES

4.1 Fluid Membranes

The lipid bilayer component of a cell's plasma membrane is a fluid in the sense that it cannot resist an in-plane shear. In the absence of bending rigidity or in-plane shear resistance, fluid membranes can assume convoluted shapes and are, in a sense, the two-dimensional analogs of freely jointed chains. The geometry of membranes can be described using similar scaling relationships to those used to describe linear and branched chains (see Secs. 3.1–3.3).

Closed configurations, such as spherical or toroidal geometries, have a larger number of scaling observables than do open configurations. An example of a closed fluid membrane with the topology of a sphere is shown in Fig. 13. If the membrane had a sufficiently large value for k_b, then the spherical shape would be obvious, but in fact, the membrane shown in Fig. 13 has $k_b = 0$. The shape is reminiscent of a branched polymer, in that the enclosed volume is proportional to the area, rather than the area to the $\frac{3}{2}$ power expected for a sphere. An analysis performed via computer simulation confirms that closed fluid membranes obey the same branched polymer scaling as self-avoiding surfaces (Kroll and Gompper, 1992):

$$\langle R_g^2\rangle \sim A^1, \tag{38a}$$

$$\langle V\rangle \sim A^1. \tag{38b}$$

The generalized Flory exponent [see Eq. (30)] for self-avoiding surfaces is

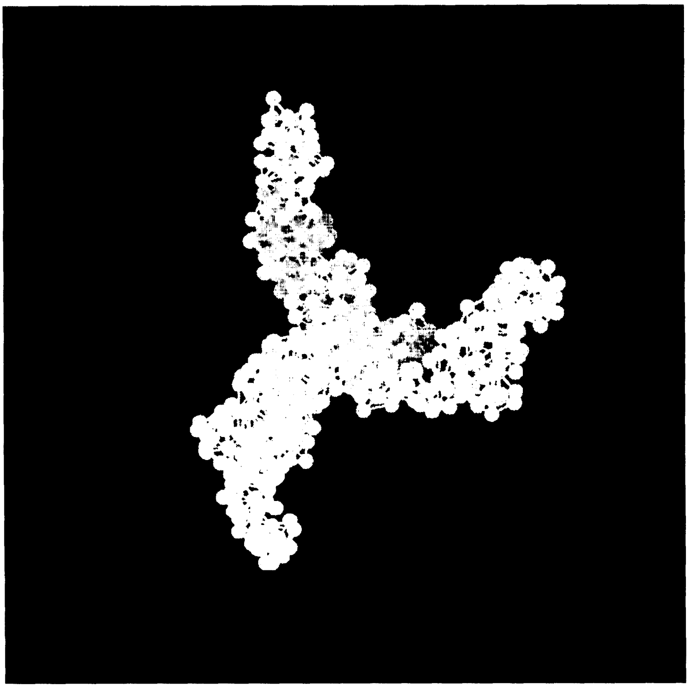

FIG. 13. Sample configuration from a computer simulation of a fluid membrane with spherical topology. The surface, which has no bending resistance, is represented by discrete points: hard beads linked together by tethers of a maximal extension. The beads are not attached to a fixed set of neighbors, but can migrate through the membrane.

$$\nu_F = (2 + D)/(2 + d), \tag{39}$$

where D is the dimension of the surface ($D = 1$ for chains, $D = 2$ for membranes) and d is the embedding dimension (see lectures by Kantor in Nelson *et al.,* 1989). Equation (39) predicts that $\langle R_g^2 \rangle \sim A^{0.8}$ for a fluid membrane in three dimensions, but this scaling behavior has been seen only for moderate system sizes, not large systems. Fluid membranes with bending resistance also belong to the class of branched polymers, although the distance at which the asymptotic scaling behavior becomes apparent increases with k_b. Again, this is like the scaling of chains with bending resistance described in Sec. 3.1.

Fluid-membrane undulations, at distances short compared to the persistence length, can be treated using the Monge representation (see Sec. 2.3). The mean square fluctuation in the height $h(\mathbf{r})$ at position $\mathbf{r}$ is predicted to vary as

$$\langle h(\mathbf{r})^2 \rangle \sim TL^2/k_b, \tag{40}$$

where T is the temperature and L is the linear dimension of the system (see Safran, 1994). This relationship demonstrates that the fluctuations increase with temperature and system size. In contrast, the mean square undulations at an interface dominated by surface tension (between water and air, for example) grow only logarithmically with the system dimension L.

The membrane height can be expressed in terms of its Fourier components $h_\mathbf{q}$ via

$$\langle h(\mathbf{r})^2 \rangle = A^{-1} \sum_\mathbf{q} \langle |h_\mathbf{q}|^2 \rangle \tag{41}$$

where A is the membrane area. The Fourier components corresponding to Eq. (40) scale as

$$\langle |h_\mathbf{q}|^2 \rangle \sim T/k_b q^4. \tag{42}$$

In comparison, the Fourier components of the height of an interface dominated by surface tension scale like $\langle |h_\mathbf{q}|^2 \rangle \sim T/q^2$. Experimental observations of membranes under tension are consistent with the undulation spectrum of Eq. (42) (see references in Mohandas and Evans, 1994).

Because of surface undulations, the normals to the surface $\mathbf{n}(\mathbf{r})$ are correlated only at short distances. That is, the product of two normals decays with displacement $\mathbf{r}$ as

$$\langle \mathbf{n}(0)\cdot\mathbf{n}(\mathbf{r})\rangle \sim \exp(-|\mathbf{r}|/\xi_p), \tag{43}$$

where ξ_p is the persistence length. Perturbation theory can be used to calculate the low-temperature fluctuations of a membrane whose energy is characterized by a bending modulus k_b, as in Eq. (18), yielding a persistence length of (see lectures by Leibler in Nelson *et al.*, 1989)

$$\xi_p \sim a \exp(4\pi\beta k_b/3), \tag{44}$$

where a is a microscopic length scale and β is the inverse temperature $(k_B T)^{-1}$. The numerical factors in the exponential depend on the method used for the calculation. What is important about Eq. (44) is that the persistence length is exponential in the bending rigidity.

The persistence length of a chain sets the length scale above which bending resistance and other geometrical constraints are sufficiently unimportant that the chain conformations are described by a random walk. Another way of saying this is that the effective bending resistance of the chain decreases with the increasing length scale on which the resistance is measured. The behavior of fluid sheets can be viewed in the same way, that the effective bending modulus $k_{b,\mathrm{eff}}$ decreases with the increasing length scale of the system. Again, perturbation theory consistent with Eq. (44) indicates that to leading order, the effective bending resistance has the form

$$k_{b,\mathrm{eff}}(L) = k_b[1 - (3/4\pi\beta k_b)\ln(L/a)], \tag{45}$$

where L is the length scale of interest (see lectures by Leibler in Nelson *et al.*, 1989).

4.2 Polymerized Membranes

Polymerized membranes and networks have fixed connectivity, by which we mean that a given element of the membrane has a fixed set of neighbors, as distinct from fluid membranes in which an element can diffuse through the membrane. The shear rigidity imparted by fixed connectivity results in constraints on the configuration space of the membrane, which, in turn, affect its scaling behavior. The shape of the fluid membrane in Fig. 13 easily can be seen to be different from the shape of the polymerized membrane in Fig. 14: The fluid membrane is convoluted whereas the polymerized membrane is flat.

Scaling analyses of open polymerized membranes show that

$$\langle R_g^2\rangle \sim A^1, \tag{46a}$$

$$\langle h^2\rangle \sim A^\zeta, \tag{46b}$$

where A is the contour area (or mass) of the membrane and ζ is the roughness exponent. The mean square height $\langle h^2\rangle$ in Eq. (46b) measures the thickness of the membrane and is the smallest eigenvalue of the membrane's inertia tensor. First measured to be 0.65 ± 0.05 (Plischke and Boal, 1988), the roughness exponent obtained from recent computer simulations is close to the field-theoretic prediction of 0.59 (Le Doussal and Radzihovsky, 1992).

The polymerized membrane in Fig. 14 is flat in spite of the fact that it has no local bending resistance: $k_b = 0$. The membrane becomes increasingly rigid at long length scales because of geometrical constraints im-

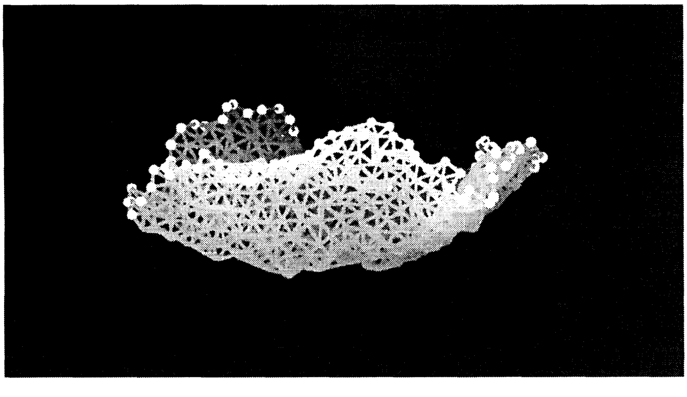

FIG. 14. Sample configuration from a computer simulation of an open polymerized membrane with no local bending resistance. As in Fig. 13, the surface is represented by discrete points; but here, the beads are attached to a fixed set of neighbors.

posed by polymerization. As experimentation with aluminum foil will convince the reader, an initially flat polymerized membrane cannot even approximate the configuration shown for the fluid membrane in Fig. 13 without extensive folding of the surface, and such folding is strongly suppressed by entropy. Thus, the effective bending resistance $k_{b,\mathrm{eff}}$ of a polymerized membrane should increase with length scale L, rather than decrease as found for fluid membranes. Several calculations show that $k_{b,\mathrm{eff}}$ diverges like $L^{2-2\zeta} \sim L^{0.8}$ (see Nelson *et al.*, 1989).

Although the bending resistance of a polymerized membrane increases with L, other in-plane moduli are expected to decrease with L because of undulations. Calculations of the in-plane area compression modulus and shear modulus both show moduli that vanish at large L, as, for example,

$$\mu \sim L^{-(4\zeta-2)} \sim L^{-0.4}. \tag{47}$$

Most of these predictions have been confirmed by computer simulation. Further, the Poisson ratio of polymerized networks is predicted to be universally equal to $-\frac{1}{3}$ (Le Doussal and Radzihovsky, 1992).

Experimental tests of the analytic and simulation results thus far have addressed whether polymerized membranes are flat, and not all of the measurements are in agreement. One set of measurements on the isolated two-dimensional cytoskeleton of the red blood cell indicates that the network is flat on long length scales. Other work on inorganic monolayers does not support this finding.

4.3 Membranes under Stress

The membranes discussed in Secs. 4.1 and 4.2 are isolated, in the sense that they are not subject to external stress nor do they interact with a medium or with other membranes. However, a complete description of physical membrane behavior must include the characteristics of interacting membranes. In this section, the effects of compression and tension on membranes will be described, while interactions between membranes are presented in Sec. 6.

4.3.1 Closed Fluid Membranes Closed fluid membranes with spherical topology (a computational *vesicle*) subject to pressure have been simulated both for surfaces whose elements are plaquettes on a lattice and for triangulated surfaces that are not constrained to lie on a lattice, and whose connectivity can evolve with time (as in Fig. 13). Both rings in two dimensions (Sec. 3.3) and fluid vesicles in three dimensions obey branched-polymer scaling under compression, but only vesicles show branched-polymer scaling at zero pressure. Depending on the vesicle mass, the scaling may remain branched-polymer even if the pressure inside the vesicle moderately exceeds the pressure outside; however, at large pressure differences, there is a transition to an inflated state.

4.3.2 Open Membranes at a Wall The interaction between a membrane and a wall has been investigated for two situations: a sheet forced against a flat surface by pressure and a sheet confined between two flat surfaces. The presence of the wall removes the divergence in the fluctuation spectrum of fluid membranes observed at long wavelengths [Eq. (42), see Safran, 1994]. The behavior of polymerized membranes near walls can be used to determine the roughness exponent.

4.3.3 Planar Membranes under Tension Observed at sufficiently short length scales, membranes under tension, or membranes with bending resistance, are relatively flat. The elasticity of a planar, polymerized network of springs under tension has been investigated by simulation. At zero temperature, the in-plane elastic moduli vary with stress σ as

$$K_A/k_{sp} = (3^{1/2}/2)(1 - \sigma/3^{1/2}k_{sp}), \tag{48a}$$

$$\mu/k_{sp} = (3^{1/2}/4)(1 + 3^{1/2}\sigma/k_{sp}), \tag{48b}$$

where positive σ corresponds to a network under tension and k_{sp} is the spring constant of an individual spring. These expressions, which have Eqs. (10) and (11) as their zero-stress limit, predict that the Poisson ratio of the network becomes negative when $\sigma/k_{sp} > \sqrt{3}/5$. At finite temperature, in-plane fluctuations increase the moduli above their zero-temperature values.

5. SYSTEMS WITH DEFECTS

5.1 Percolation Phenomena

The networks and membranes typically found in Nature are not the ideal, uniform systems that are considered in Sec. 4. Rather, they may be chemically inhomogeneous and/or may contain structural defects. Two examples of defective membranes and networks are mentioned in Sec. 1.2: partially polymerized membranes in which polymerization is random or localized, and spectrin-depleted erythrocyte cytoskeleta in which the coordination of some junction complexes may be much less than sixfold. Further, defects may develop in otherwise regular membranes and networks when they are subject to stress or elevated temperatures, leading ultimately to mechanical failure. These structural aspects of membranes are an active area of study in statistical mechanics, although the investigation of systems with defects dates back more than a century to Maxwell.

One very useful concept that emerged from computational studies of defective systems is that of *percolation.* Consider the two-dimensional triangulated network shown in Fig. 15, in which the light gray "bonds" are fluid (as in Fig. 13), while the white "bonds" are polymerized and connected to a fixed set of vertices (as in Fig. 14). If most or all of the bonds are fluid, then the shear modulus of the network vanishes. There must be a reasonable concentration of polymerized bonds present before the network exhibits shear resistance. Computer simulations of systems such as this have shown that

1. there is a well-defined concentration, referred to as the *rigidity percolation* threshold p_r, above which networks resist shear; and
2. there is a well-defined concentration, referred to as the *connectivity percolation* threshold p_c, above which a connected sequence of polymerized bonds completely traverses the network,

where p may be defined as the fraction of polymerized bonds present in the network compared to the fully polymerized network, for which $p = 1$. In Fig. 15, p is greater than p_c, and uninterrupted paths of polymerized bonds can be seen in both the x and y directions. There are many examples in which the connectivity and rigidity thresholds are different (Thorpe, 1986).

5.2 Defective Two-Dimensional Networks

Connectivity and rigidity percolation occur at the same polymerized bond concentration in the mixed-composition network of

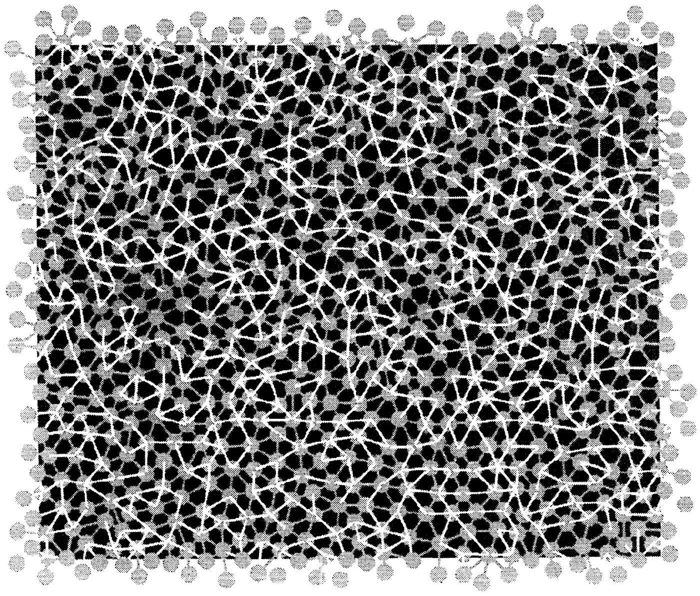

FIG. 15. Sample configuration of partially polymerized membrane with polymer bond fraction p = 0.5, viewed perpendicular to the membrane plane. The fluid bonds are gray, while the polymerized bonds are white.

Fig. 15, namely, $p_r = p_c = 2\sin(\pi/18) = 0.35$ expected for triangulated networks in two dimensions. However, if the fluid bonds of Fig. 15 are completely removed and not replaced by polymerized bonds, thus leaving open holes in the membrane, then the membrane is floppier and p_r increases to about $\frac{2}{3}$, while p_c, of course, remains the same. The mixed-composition (fluid/polymerized) networks with no open holes have higher rigidity at a given polymerized bond concentration than the single-component (polymerized only) networks with holes because of the presence of isolated pockets of fluid that cannot diffuse past the polymerized regions. Single-component bond- or site-diluted networks have been studied in both two and three dimensions, and p_r is typically found to be d times p_c in the systems studied, where d is the embedding dimension (Thorpe, 1986).

Once the rigidity percolation threshold has been crossed from below p_r, the elastic moduli do not rise immediately to their values for a fully connected network. Rather, to a first approximation, the shear modulus rises linearly with $p - p_r$:

$$\begin{aligned} \mu(p)/\mu(p=1) &= (p-p_r)/(1-p_r) \quad \text{for}\, p > p_r, && \text{(49a)} \\ &= 0 \quad \text{for}\, p < p_r, && \text{(49b)} \end{aligned}$$

where, again, $p = 1$ for a fully polymerized network.

Both the mixed-composition and bond-depleted networks may be candidates to describe various partially polymerized networks. Consider the model erythrocyte cytoskeleton of Fig. 6, in which the chains represent the spectrin tetramers of the cytoskeleton and give the model network its elasticity [see Eq. (22)]. In some hereditary blood diseases, the erythrocytes have a lower spectrin concentration and may be examples of bond-diluted, single-component networks (but not mixed polymer/fluid networks since there is no trapped fluid component to the cytoskeleton). The shear modulus of these depleted cytoskeleta is found to decrease linearly as the spectrin content is reduced, as expected qualitatively from Eq. (49a). Although data are not available for highly depleted cytoskeleta (such cells are not viable), the extrapolated value for p_r is much lower than $p_r \sim \frac{2}{3}$ of a bond-depleted triangular network. This does not necessarily indicate that percolation theory is inapplicable to spectrin-depleted erythrocytes; it may be that the coordination of such cytoskeleta is still relatively uniform, but less than sixfold.

5.3 Defective Membranes in Three Dimensions

Bond-depleted networks in two dimensions possess reduced in-plane rigidity, as described in Sec. 5.2. When allowed to fluctuate out of plane into the third dimension, defective networks have fewer geometrical constraints and may adopt configurations in which one region of the membrane passes through a hole in another region. It is known that *phantom* polymerized membranes, in which the surface is free to intersect itself, are not flat but highly crumpled if $k_b = 0$ (see lectures by Nelson in Nelson *et al.*, 1989). Are bond-depleted membranes also crumpled?

The flatness characteristics of two types of bond-depleted (but otherwise self-avoiding) network have been investigated. In one case, bonds are randomly removed from a polymerized triangulated network, as described in the previous section on percolation. This type of network is observed to be flat for any $p > p_c$. In contrast, the geometry of a bond-depleted network known as a Sierpinski gasket is found to be described by the Flory exponent in Eq. (39).

A different defect structure is one in which network connectivity is uniform, but the interactions between junctions are variable. For example, the interaction strength or geometry of the intervertex potential might vary randomly across a network, corresponding to a glassy ground state. Simulation studies of systems with randomly varying interactions are challenging, because the network ground states are difficult to determine uniquely, and because many configurations must be sampled to construct accurate ensemble averages. Thus far, the temperature dependence of the membrane phases between the ground state and high-temperature configurations has not shown novel behavior in the limited studies of inhomogeneous networks with glassy ground states.

6. INTERACTIONS BETWEEN MEMBRANES

6.1 Interactions between Rigid Surfaces

The interactions of flexible membranes, particularly biological systems, involve forces of several different origins. Although this article focuses on effects arising from thermal fluctuations, it is important to appreciate the type and strength of chemical, entropic, and other components of membrane interactions. Here, we briefly review several features of the forces between rigid surfaces, before discussing the effects of undulations in Secs. 6.2 and 6.3. A more extensive treatment of these forces can be found in Israelachvili (1992).

6.1.1 van der Waals Forces Attractive, but relatively weak in strength, van der Waals forces may extend several nanometers away from a surface. The interaction arises from fluctuations in charge distributions at the atomic level: A quantum mechanical fluctuation that results in a dipole moment in one atom induces a dipole moment in a second atom. Thus, an attractive dipole–dipole interaction driven by fluctuations can be present between atoms with no permanent dipole moments. The van der Waals energy per unit surface area between two rigid surfaces with separation s decreases like s^{-2} at modest separations, and like s^{-4} at large separations.

6.1.2 Double-Layer Forces As introduced in Sec. 1.1, fluid membranes typically have a polar headgroup exposed to a polar solvent. Many polar groups can dissociate, leaving a charged region surrounded by counterions in the neighboring solvent, as illustrated in Fig. 16. In other situations, head groups may be capable of adsorbing ions from the solvent. Consequently, the membrane may carry a surface charge, which, together with the counterions in solution, constitute an electric double layer. Double-layer forces, which have been investigated theoretically and experimentally, are longer ranged than van der Waals forces, and are predominantly repulsive. The energy per unit surface area for the interaction between two double layers decays exponentially with separation.

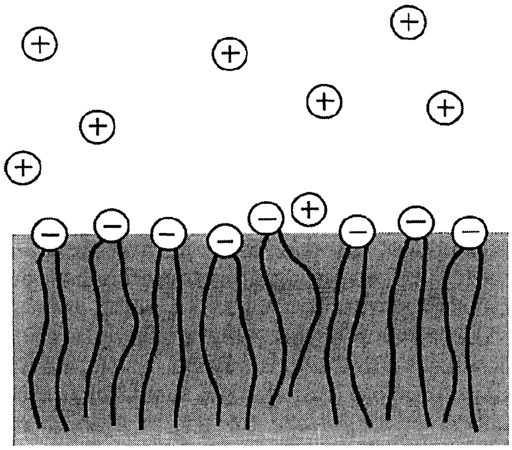

FIG. 16. Double layer at the boundary of a lipid monolayer with a solvent.

6.1.3 Hydration Forces The polar head groups of amphiphiles in a free biomembrane are surrounded by solvent molecules, which may be "bound" in the sense that the amphiphile and solvent have a strong mutual attraction. These solvent molecules must be removed if two membranes are to approach each other closely, suggesting that there is a repulsive hydration force associated with the hydrated amphiphile (the word "hydration" refers to water as a solvent). The pressure required to force bilayers together at small interlayer separation s is approximately exponential, $\exp(-s/s_0)$, and s_0 is found to be in the 1–3-nm range (Rand and Parsegian, 1989). The range of the hydration force is thus of the same magnitude as the attractive van der Waals force or repulsive thermal fluctuations of the bilayer itself.

6.1.4 Steric Interactions All of the above forces may apply to rigid or flexible membranes. However, flexible membranes also may undergo thermal fluctuations, resulting in a repulsive steric interaction between a rigid wall and a membrane or between membranes themselves. Membrane components, such as proteins, that extend into the solvent may give rise to additional steric interactions that are short-ranged compared to undulations but are more repulsive than undulations at small length scales.

The combined van der Waals and double-layer forces comprise the DLVO theory (Derjaguin and Landau, 1941; Verwey and Overbeek, 1948) of colloidal stability. As we have indicated, there may be several short-ranged interactions present in biomembranes in addition to the DLVO forces.

6.2 Entropic Repulsion of Fluctuating Membranes

The idea that membrane fluctuations result in repulsive interactions has support from several experimental observations:

1. vesicles composed of certain lipids show increased binding when their surfaces are under lateral tension;
2. in some situations, repulsion between lipid bilayers is reduced when one of the bilayers is attached to a rigid substrate; and
3. interbilayer repulsion may increase with temperature.

There are several fluctuation modes for a membrane, including out-of-plane undulations and fluctuations in membrane thickness. Here, we consider undulations, whose importance was pointed out by Helfrich (1978), and refer the interested reader to Israelachvili (1992) for a discussion of other fluctuation modes.

Consider a stack of n membranes as shown in Fig. 17, in which each membrane is taken to be parallel to the xy plane on average. A set of n functions is needed to describe the displacement of the membrane stack in the z direction. We label these functions $\psi_n(x,y)$ to show explicitly their x, y, and n dependence, and we assume that they are single valued as in the Monge representation. If the membranes are equally spaced on average, then

$$\int \psi_n(x,y)\, dxdy = ns, \tag{50}$$

where s is the average spacing between successive membranes and where the $n = 1$ membrane has an average height s above the xy plane. One can change the functions to regain a more familiar form by introducing a set of height functions $h_n(x,y)$

$$h_n(x,y) = \psi_n(x,y) - ns, \tag{51}$$

such that $\int h_n(x,y)\, dxdy = 0$. For gentle undulations, the energy density of the membrane stack is

$$H = \int \Big[(B/2) \sum_n (h_{n+1} - h_n)^2 + (k_b/2) \sum_n (h_{n,xx} + h_{n,yy})^2 \Big] dxdy, \tag{52}$$

where $h_{n,xx} + h_{n,yy}$ is the mean curvature of the nth membrane and k_b is the bending modulus [see Eqs. (14) and (18)]. For notational simplicity, the xy arguments have been omitted from Eq. (52).

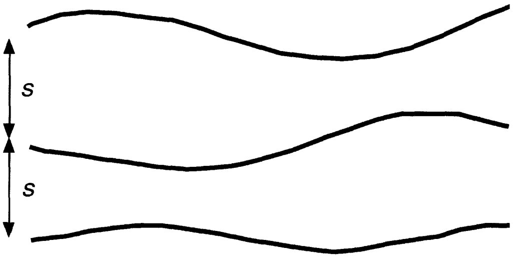

FIG. 17. Cross section through a membrane stack illustrating intermembrane repulsion arising from thermal fluctuations. The average separation between successive membranes is s.

Compared to Eq. (18), the new feature of Eq. (52) is the elastic modulus B, which represents the intermembrane repulsion. Helfrich (1978) uses a self-consistent argument for obtaining B by (1) determining as a function of B the difference in the free energy per unit volume Δf_v between the many-membrane and single-membrane systems, and (2) imposing the elasticity relationship

$$B = s \frac{\partial^2 \Delta f_v}{\partial s^2}, \tag{53}$$

to the free energy found by procedure (1). This method yields (Safran, 1994)

$$B = 36/\pi^2 \beta^2 k_{\mathrm{B}} s^4. \tag{54}$$

and a corresponding difference in the free energy per unit area $\Delta f_A = s \Delta f_v$ of

$$\Delta f_A = 3/\pi^2 \beta^2 k_{\mathrm{B}} s^2. \tag{55}$$

There are two aspects of the free-energy expression in Eq. (55) worth noting. First, the s^{-2} dependence of the entropic repulsion is the same as that of the van der Waals interaction between rigid surfaces at moderate separations. Second, the repulsion increases with temperature. Both of these features are consistent with observations **1** and **2** listed at the beginning of this section. Helfrich (1978) estimates that the repulsion from undulations is about $\frac{1}{4}$ of the van der Waals interaction in magnitude for egg lecithin membranes.

A mean-field approach that avoids the introduction of the modulus B has been used by Evans and Parsegian (1986) to obtain the undulation modes analogous to Eq. (42) and the free-energy density Δf_A. At large separations, their expressions have the same functional forms as those obtained by Helfrich and illustrate the substantial shift in the free-energy density across the 2–3-nm range in s arising from undulations.

6.3 Unbinding Transition

Fluctuations cause membranes to repel each other, and the magnitude of the repulsion increases with temperature. In principle, such fluctuations can overcome an attractive interaction between membranes that might be sufficient to bind them at low temperatures. Indeed, bilayer membranes have been observed to dissociate from a closely bound membrane stack over a very narrow temperature range (see Lipowsky in Lipowsky and Sackmann, 1995).

Since van der Waals interactions decrease more rapidly than s^{-2} at large separation s, then, for the purpose of investigating membrane binding, it is sufficient to use a square-well potential to represent the attractive interaction between two membranes:

$$\begin{aligned} V(s) &= -U \text{ for } 0 < s < s_{\max}, \\ V(s) &= 0 \text{ for } s > s_{\max}, \end{aligned} \tag{56}$$

where U and $s_{\max}$ are positive parameters that set the energy and length scales of the potential. At zero temperature, the membranes are confined to distances less than $s_{\max}$, as dictated by Eq. (56). At temperatures greater than zero, the membranes repel but do not unbind until the transition temperature T^* given by

$$T^* \sim (k_b U s_{\max}^2)^{1/2}, \tag{57}$$

which predicts that the more rigid the membranes or the stronger their attraction, the higher the unbinding temperature.

Systematic calculations have shown that the unbinding transition is continuous and that the mean separation diverges with temperature like $|T - T^*|^{-1}$ as the transition is approached from below T^*. For representative lipid bilayers, the estimated theoretical unbinding temperature varies by 50% about room temperature, depending on the membrane rigidity. Whether the suppression of thermal undulations is responsible for the tension-induced adhesion observed experimentally remains to be seen. Recent calculations, based on a description of the steric interaction that encompasses both the rigidity-dominated and tension-dominated regimes, show that the applied tension must be very large to permit tension-induced adhesion of fluid membranes (Seifert, 1995).

GLOSSARY

Cytoskeleton: A two- or three-dimensional protein network in a cell's interior.

Erythrocyte: A red blood cell; human erythrocytes are structurally simple since they do not have a nucleus and their cytoskeleton is connected only to the plasma membrane.

Fatty Acid: A carboxylic acid (-COOH) with a long hydrocarbon chain, found in natural fats and oils.

Fluid Membrane: Two-dimensional system with no resistance to in-plane shear.

Lipid: A small water-insoluble molecule with one or more hydrocarbon chains.

Lipid Bilayer: A double layer of oriented amphiphilic molecules; in biomembranes, the lipid bilayer is fluid.

Monolayer: A sheetlike structure with a thickness of one molecular unit.

Persistence Length: Length scale at which the relative orientation of chains or surfaces is uncorrelated.

Polymerized Membrane: Two-dimensional system with resistance to in-plane shear.

Protein: A macromolecule composed of one or more polypeptide chains (amino acids linked by peptide bonds); actin, spectrin, and tubulin are examples of proteins that form two- and three-dimensional networks in cells.

INTRODUCTION

Steam engines can trace their lineage to the early 1700s, when the need for a means of pumping water out of English coal mines generated a burst of creative development. In the earliest practical steam engine, patented by Thomas Savery 1698, steam admitted to a cylinder pushed water in the cylinder through a pipe that had a check valve to stop return flow. The steam supply was stopped, and cold water flowing over the cylinder caused a vacuum that in turn allowed water being pumped to be sucked in. In 1712 Thomas Newcomen developed an engine that also condensed steam in a cylinder, but here the vacuum was used to move a piston, which, connected to a beam, in turn moved another piston to pump the water. This engine was used to drive machinery in addition to pumping water and is reported to have been a commercial success. James Watt improved on the Newcomen engine in the 1770s by removing the condensing function from the working cylinder as well as introducing a number of innovations, including pistons that allowed steam to be admitted to both sides of the piston (double-acting pistons) and the concept of allowing the steam to expand after being admitted to the cylinder. In the late 1700s, Richard Trevithick developed engines using steam at pressures above atmospheric and began adapting his designs to steam-driven road vehicles and locomotive propulsion. In 1804 he demonstrated a steam locomotive. A variation of the Trevithick design was applied by George Stephenson in his "Rocket" locomotive in 1829. This launched the practical application of steam for rail propulsion. A practical marine propulsion engine was demonstrated in 1801 by William Symington. In 1838 the *Great Western* crossed the Atlantic ocean powered by steam.

Steam engines have been applied to a variety of other purposes, including farm machinery, electrical-generating plants, and auxiliary drives, as well as propulsion for automobiles, ships, and rail locomotives. There were even steam-powered bicycles in the late 1890s and a steam-powered airplane in the 1930s.

With a few important exceptions, such as electrical-power generation and marine propulsion, the steam engine is of historical significance at this time. The literature of the past two decades includes reports of refurbishing old engines, celebration of centennials or bicentennials of famous developers, and design exercises or experimental applications as part of waste-heat recovery equipment, in solar and geothermal power applications, and in developing countries where indigenous fuels are available.

This article discusses the mechanical manifestation of the Rankine cycle, including the thermodynamic, fluid mechanical, and mechanical design considerations of the overall system and of each of the major components. It also summarizes the characteristics of some of the more notable applications and of efforts to use fluids other than water in a variety of Rankine-cycle applications.

1. SYSTEM CONSIDERATIONS

The ideal Rankine cycle described in HEAT ENGINES AND REFRIGERATORS consists of isentropic compression of a saturated liquid to boiler pressure, followed by isobaric heat addition, first to a saturated liquid, then phase change to a saturated vapor. Work is performed during an isentropic expansion, and heat is rejected in an isobaric phase change (condensation) back to liquid. One reason the Rankine cycle has been so widely applied is that there are many practical ways to approximate this theoretical cycle.

The efficiency of the cycle is the net work divided by the heat added. For a desired amount of work out, the most efficient cycle is the one with the least heat added. On the basis of thermodynamic fundamentals (the Carnot cycle), the cycle efficiency also increases with higher average temperatures for the heat addition.

One commonly applied method of reducing the amount of heat added is to use some form of internal heat transfer between the expander exhaust and the feed water. In large central-station electrical-generating steam plants, feed-water heating usually takes the form of extraction of some steam from the turbine at a number of places along the expansion, using it to heat water on its way to the vapor generator.

One way to increase the average temperature of heat addition is to superheat the vapor, that is, heat the saturated vapor to a higher temperature than the boiling temperature. Another way is to use reheat, that is, to return the partially expanded steam to the vapor generator for further heat addition.

Although ideally it is desirable to have as high a peak temperature as possible in a Rankine cycle, the actual choice is limited by vapor-generator design considerations. Even though combustion-gas temperatures may be on the order of 1400 °C, very few steam power plants have peak steam temperatures as high as 600 °C, with most somewhat lower than 550 °C. Peak pressures are typically on the order of 7 MPa (except for some large central-station plants operating in the supercritical region, where pressures will be on the order of 22 MPa). One reason for this is that boiler tubes must be designed to withstand the pressure on the basis of the properties of materials suitable for use at these high temperatures. Few materials are available that meet the strength criteria. Another limitation on the choice of peak temperature, when a positive-displacement expander is used, is the properties of available lubricants.

At the heat-rejection part of the cycle, in most cases the steam will be condensed. The exceptions are where the expander exhaust steam can economically be discharged directly to the atmosphere, where the steam is usable for other purposes, or where there is no room for a condenser. Although thermodynamic considerations dictate as low a condensing temperature as possible, this temperature is limited by the available heat sink. For large central-station electrical-generating plants, this is usually a large body of water. For surface transportation applications, the heat sink is the ambient air temperature. Marine propulsion engines use the body of water they are traversing.

When considering real engines as compared to ideal cycles, a number of other practical limitations must be taken into account. Each of the subsystems contains a number of auxiliary components. The vapor generator not only includes the heat-transfer components but it also contains the components necessary for combustion: a fuel pump and its drive for liquid fuels or equivalent devices for solid fuels, a combuster, an air blower and its drive, and the controls for these units. It often also contains a heat exchanger that preheats the combustion air and a heat exchanger that uses the exhaust combustion products to heat the water. The expander includes a lubricant pump and its auxiliaries. The condenser usually contains a lubricant separator to remove any lubricant in the expander exhaust so that it does not coat the surfaces of the condenser or get carried over to the boiler, where in either case it would affect the heat transfer. If the condenser is air cooled, there will be some kind of fan drive plus possibly some additional air-flow control such as louvers. If the condenser is water cooled, there will be a cooling-water pump and its controls. If only minimal cooling water is available, a cooling tower may also be employed. The pumping subsystem often includes a boost pump and its drive as well as the main feed pump and its drive. For propulsion applications, a transmission or other speed-changing devices may also be necessary.

There are other factors that differentiate the real steam engine from an ideal Rankine cycle. Expansions and compressions are not isentropic—expanders produce less work on expansion and pumps require more work on compression than the ideal components. Flow through heat exchangers results in pressure drops, increasing the amount of pump work required. Heat is lost through piping and heat-exchanger walls. Some steam leaks past valve stems and piston rings, or turbine shaft seals, doing no work. Also, ideal cycles do not take into account the work that must be provided to drive the numerous auxiliaries. In small plants, these auxiliary loads tend to be a large part of the total work output.

There are further inherent limitations on the overall power-plant design in propulsion applications. One of these is the requirement to operate at part load for major portions of the time. This makes it difficult to optimize component design for high efficiency. Engines for naval combat vessels and for motor vehicle propulsion must also be able to change output rapidly. Probably the most severe limitation for most propulsion applications is the strict limits on the available volume, weight, or frontal area, all of which tend to limit attainable efficiencies.

2. EXPANDERS

There are two fundamental types of expanders: positive displacement and dynamic or turbine expanders. Each has its own advantages and disadvantages.

Positive-displacement expanders have relatively high efficiency at part loads. Countering this advantage is a pressure drop across the valving, a limited volumetric expansion ratio, the friction losses as a piston or other positive-displacement device moves in its chamber, and the difficulty in finding practical lubricants for use with high-temperature superheated steam.

Turbomachinery has the advantage of a potentially higher design-point efficiency than a positive-displacement expander, and the ability of having the highest temperatures in stationary components so that turbine blades and disk and the lubricants are not exposed to these temperatures. Turbines are typically lighter than positive-displacement expanders; however, the inherent high speed of the output shaft often requires gearing to bring shaft speed to a usable range, which may negate any weight and size advantage. Turbines also have poor part-load efficiency, and sealing the high-speed shafting may be difficult.

2.1 Positive Displacement

A pressure–volume (p-V) diagram is helpful in visualizing what happens in a positive-displacement expander. In an ideal positive-displacement expander (Fig. 1), steam is admitted at constant pressure to a point where the ensuing expansion would occur adiabatically to the exhaust pressure. The steam is exhausted to a point where the steam remaining in the cylinder would be compressed adiabatically to just fill the clearance space at the pressure of the incoming steam. No heat losses or friction are assumed to occur.

Real engines, of course, do not follow this ideal cycle exactly. "Good" design would have the steam enter the cylinder when the piston is nearing the top of its stroke, and steam admission would end shortly after the piston began its downward stroke. Similarly, exhaust would begin shortly before the piston reached the bottom of its stroke, and a

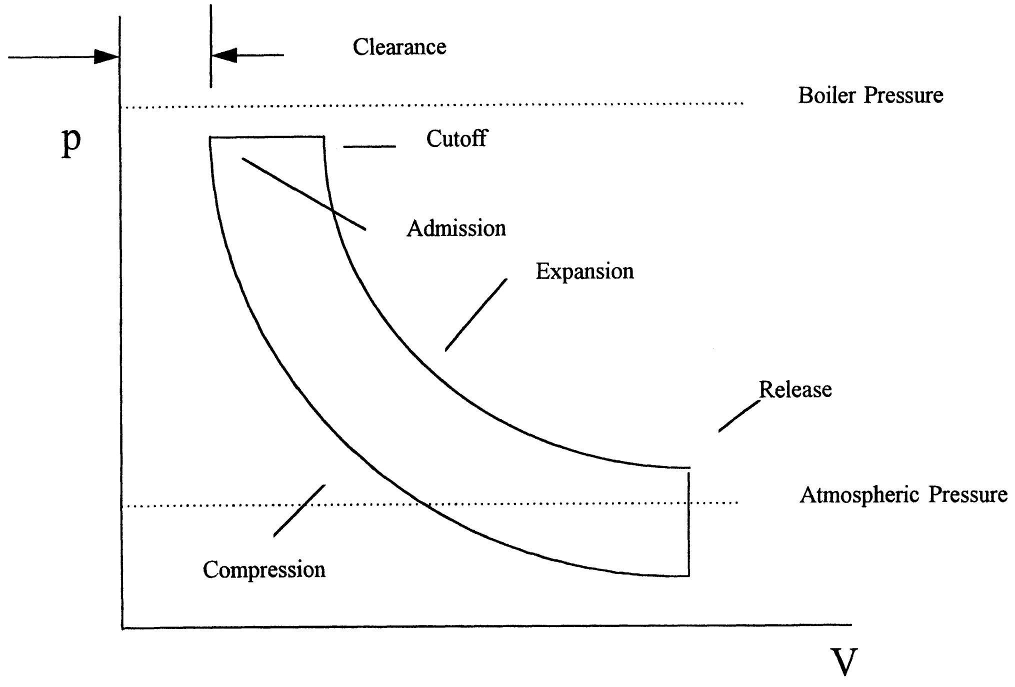

FIG. 1. Schematic pressure–volume diagram of positive-displacement steam engine expander.

minimum of steam would remain in the cylinder to be recompressed.

Although p-V diagrams of operating engines now are obtained by means of electronic pressure transducers, early practice going back to the time of Watt used a great variety of mechanical devices that could provide accurate indications of what was occurring inside the cylinder at the low rotational speeds employed. The "reading" of pressure–volume diagrams (indicator cards) of steam engines developed to a high art, with numerous publications showing how such diagrams could tell the operator where in the cycle the variations from the ideal pressure–volume relationship were occurring. For example, an indicator would show pressure drop in the valving, the cutoff point not at the ideal point, the expansion pressure below the exhaust pressure, or recompression pressure exceeding inlet pressure.

2.1.1 Configurations The simplest positive-displacement expander consists of a piston moving in a cylinder (Fig. 2). A connecting rod is attached to a crank of a drive shaft. A more widely applied design employs a crosshead interposed between the piston and the crankshaft (Fig. 3). The crosshead can be thought of as a sliding bearing. Attached to the crosshead is one end of the connecting rod, the opposite end of which is attached to a crank. This allows the piston rod to move in reciprocating motion with the connecting rod now moving in a complex motion to drive the crank of the output shaft.

Various arrangements of steam flow in the cylinder are possible. In a single-acting engine, steam expands against only one side of the piston, whereas in a double-acting engine, it expands against both sides. An advantage of the double-acting design is that there are two "working strokes" per revolution of the crankshaft. Steam flow into the cylinder can be either uniflow, where it enters at one end and leaves at the other, or counterflow, where it enters and leaves from the same end.

The uniflow concept was first successfully demonstrated by Stumpf in 1908 as a means of reducing the tendency for the incoming steam to condense on the cold cylinder walls. With superheated steam, initial con-

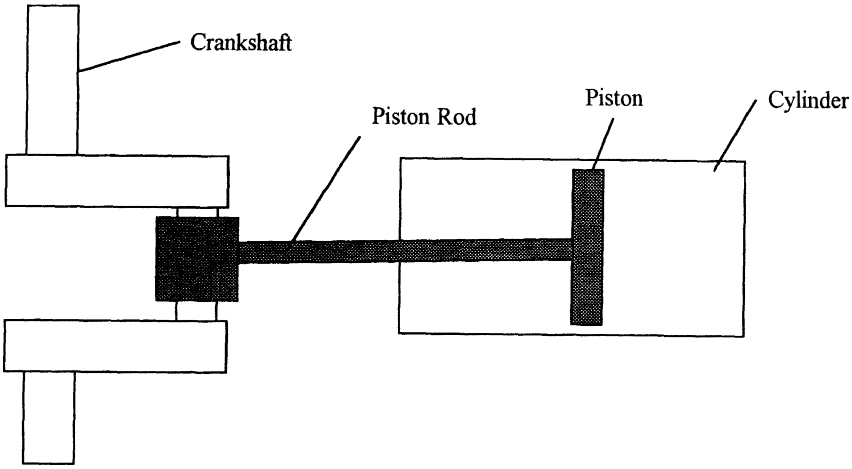

FIG. 2. Diagram of simple expander.

densation is not a significant problem. However, there are other advantages of this expander design. Since in a uniflow expander the exhaust steam exits the cylinder through ports cut into the side of the cylinder, there is no need for exhaust valves, and thermal stresses are reduced by allowing a fairly uniform temperature gradient from the cylinder head down to the crankcase. Another advantage of the uniflow design is that the engine efficiency remains high across the load range, which makes it particularly attractive for applications with widely varying loads.

At higher steam pressure more than one stage of expansion can result in higher overall efficiency as well as a more practical engine design. Engines with two stages of expansion (compound engines) were common in many applications, including some locomotive designs. Triple expansion was widely applied in ship propulsion engines, with some marine engines employing quadruple expansion.

Other positive-displacement expander configurations have been used at low power levels or for auxiliary drives. These include

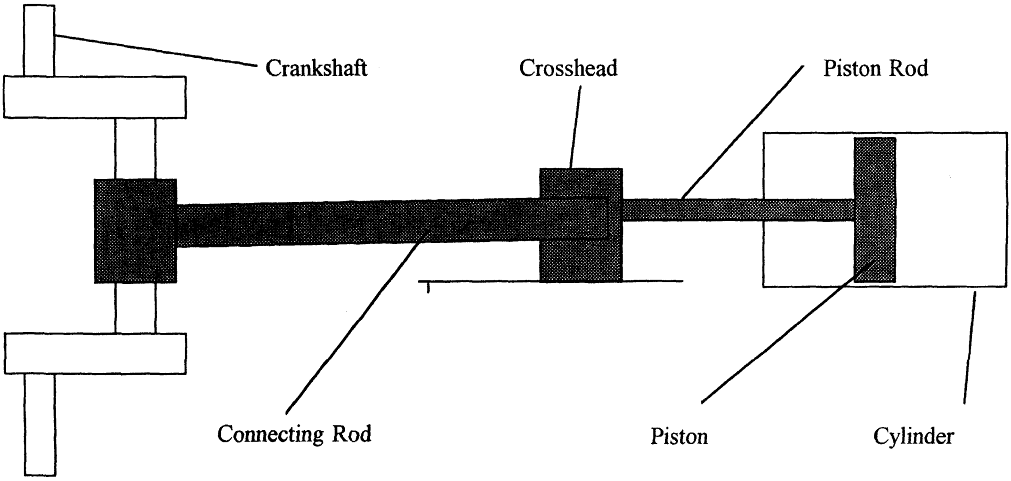

FIG. 3. Diagram of expander with crosshead.

the rotary-vane expander, which has movable vanes in slots of an off-center rotating shaft. As the working fluid expands, it drives the vanes, which, in turn, rotate the shaft. Trochoidal (Wankel) and multiple-cylinder piston designs resembling hydraulic motors have also been applied but not frequently. Considerations of friction and leakage, although present in the piston–crank arrangement, are of greater concern in these other configurations, thus limiting their application. Unless otherwise noted, the remainder of this article considers only the piston–crank arrangement of positive-displacement expanders.

2.1.2 Valving When valves open, steam enters the expansion chamber. Controlling the portion of the cycle during which a valve is open can be used to control the amount of steam admitted and thus the power output of the engine. A cutoff valve remains open to admit steam for a designated portion of the rotation. An early cutoff allows less steam into the cylinder, and thus more of the stroke is available for expansion. A late cutoff allows more steam into the cylinder at the high pressure. This does work, but without expansion. A variable cutoff can be used to change the point where expansion begins.

An alternate approach to controlling engine output is to use a throttling valve at the engine inlet. This valve adjusts the incoming steam pressure and thus the amount of expansion.

For decades, sliding valves were the common design, driven by an eccentric off the main output shaft. Figure 4 shows the principle of operation of this type of valve. As the valve moves down, steam is admitted to the top of the cylinder while it is exhausted from the bottom of the cylinder. As the valve continues to move down, it comes to a point where the openings for both inlet steam and exhaust steam are the greatest. The valve then reverses and closes the steam flow to the top of the piston while allowing exhaust to continue. As the valve continues to move upward, it closes both inlet and exhaust. With further upward motion, steam begins to exhaust from the top of the piston and begins to be admitted to the bottom of the piston. Using a similar principle, cylinder or spool valves were also used in some engines.

A disadvantage of the slide valve is that when the valve plate nears the end of its admission or exhaust positions, there is a loss as the steam has to flow through a small opening. The Corliss valve introduced a quick-acting rotary valve design that reduced the throttling loss significantly. In this design four rotary valves were used. The design was used in many stationary engines and increased the overall efficiency.

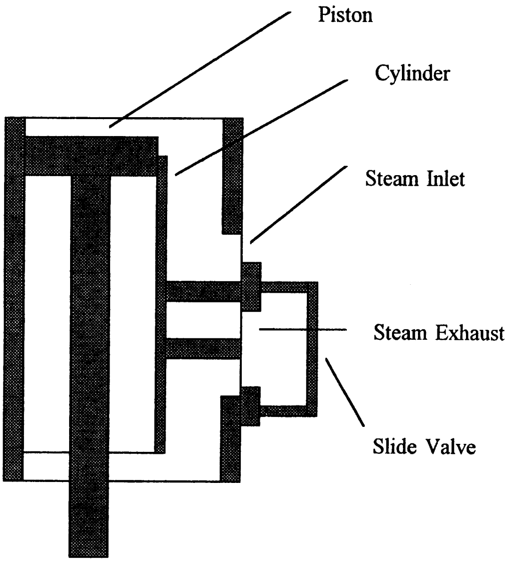

FIG. 4. Diagram of steam engine slide valve.

In a uniflow expander, the piston can be considered to be a valve, as the outlet ports are uncovered when the piston moves to a particular point in the expansion process.

Depending on the details of the expander design, some portion of the entering steam will remain in the cylinder after the exhaust valves or ports have been closed but before the admission valve has been opened. The steam remaining in the cylinder will then be compressed, possibly to a pressure higher than the inlet pressure. To eliminate any problems that may result from overpressure, a recompression valve can be fitted to open at a pressure near the incoming steam pressure.

2.1.3 Pistons The piston is the mechanical interface with the expanding steam. The unbalanced pressure force in the cylinder causes the piston to move, doing work.

Pistons are usually fairly thin disks relative to their diameter. The pistons operate in a hostile environment, with their tops exposed to the highest temperature and pressure.

A critical part of the piston assembly is the rings to seal the pressure. These rings must seal the high pressure in a high-temperature environment against a back pressure that may be close to or possibly below atmospheric. These rings create friction work and must be carefully designed to minimize the loss. Their placement along the axis of the piston must be optimized as well. Rings placed near the top of the piston reduce the overall clearance volume; however, this design puts the rings in the highest-temperature environment. Placing the rings further down on the piston skirt has the reverse effect.

Another limitation on the piston design is the need to meet the dynamic requirements of the engine. Piston mass must be kept low for this reason.

2.1.4 Lubrication When steam engines used saturated steam, the condensing water along the cylinder surface was often sufficient lubricant. For superheated steam, lubricants must retain their lubricating properties in a high-temperature steam environment where many conventional lubricants thermally decompose, losing their lubricating properties. Since some of the lubricant will inevitably become entrained in the working steam, the lubricant must be separable from the steam prior to being returned to the boiler so that the boiler tubes do not become contaminated. The composition of many steam-engine lubricants is proprietary, but it is known that they usually contain additives for extreme pressure operation, as well as rust inhibitors and demulsifiers to assist in separation from the working fluid.

2.1.5 Other Components The cylinder in which the piston slides also must be compatible with the operating conditions. The surface must be smooth and be able to withstand the temperatures and pressures encountered in these engines. In some designs using saturated steam, the cylinders were surrounded by steam jackets in order to minimize the problem of initial condensation.

Cylinder heads are exposed to the highest pressures and temperatures and must be of a material that can withstand those conditions. The gasket between the cylinder head and the expander body is also a critical component, as it too is exposed to the high temperatures of the inlet steam.

Other components, such as connecting rods, crank shafts, bearings, seals, and engine mounts, are designed in a similar manner as any other reciprocating machinery components, taking into account the temperature environment in which they must operate.

2.1.6 Design Considerations Determining the dimensions for most positive-displacement machinery is based largely on very simple fundamental relationships adjusted by empirical factors. The basic relationship is that the power is a function of the mean effective pressure, the displacement, and the number of cycles per unit time. This is useful because the desired power output is the starting point for any design, and the rotational speed is generally known, based on the application.

Mean effective pressure is the integrated average pressure over the cycle. The expansion of the steam can be approximated by a polytropic expansion where pV^n is a constant. The exponent has been found to range from about 0.7 for wet steam to 1.0 for dry steam to 1.5 for superheated steam. Under the assumption that n equals 1.0, the mean effective pressure can be approximated by

$$p_m = p_1(1 + \ln r_e)/r_e - p_3,$$

where p_m is the mean effective pressure, p_1 is the pressure at the cutoff point, p_3 is the pressure at the point of release, and r_e is the ratio of the volume at the release point to the volume at the cutoff point. The cutoff point refers to the point where the steam admission stops, that is, cuts off. The release point is the point at which the steam begins to exhaust from the cylinder. The value of the mean effective pressure found by this equation is modified by a factor that experience has shown to relate this theoretical value to an actual value. The factor varies from about 0.75 to 0.85 depending on the type of valving as well as such factors as the clearance volume, the size of the passageways, and the speed of operation.

The displacement is the volume of the cylinder. In a double-acting engine, the number of cycles is twice the number of rotations per unit time (revolutions per minute or second).

Mechanical design must also take into account several boundary conditions, including cylinder-wall temperature (which limits the choice of cylinder material and available lubricants and contributes to heat losses), and piston sliding velocity (which is correlated with frictional losses).

2.2 Dynamic (Turbomachinery)

Practical steam turbines were developed in the late 19th and early 20th century, even though the principles were demonstrated much earlier—Hero's reaction turbine in 150 B.C. and Branca's impulse turbine in 1629. Today steam turbines are the primary drivers of electrical generators in large central stations, either fossil or nuclear fueled. Small steam turbines have a number of industrial applications, largely for auxiliary drives in process plants where steam is otherwise available.

In a turbine, energy of a fluid is converted into velocity in a nozzle, with the velocity a function of the square root of the enthalpy change. The jet passes across a set of blades, which are attached to a disk, which, in turn, is attached to a shaft, with rotary motion the final result. The most common turbine design has the flow roughly parallel to the shaft center line, although radial-flow turbines are used in some applications. Only axial-flow turbines are considered here. The two main axial-flow turbine types are impulse and reaction.

2.2.1 Impulse Turbines In an impulse turbine the steam expands in a stationary nozzle and is directed through a set of blades. An impulsive force is imparted to the blades as the steam leaves in the opposite direction. Impulse turbines typically have a large pressure drop in the nozzle, with no additional expansion across the moving blades. In a pure impulse turbine the pressure on the downstream side of the blades is the same as on the upstream side. An advantage of the impulse turbine is that the steam expands in a stationary nozzle, lowering its temperature. This allows the turbine disk, which may be highly stressed, to run at a lower temperature. It can be shown theoretically that the best efficiency of an impulse turbine occurs when the blade velocity is half the velocity of the jet exiting from the nozzle. In practice, slightly less than half the velocity is commonly used for turbine design.

There are a number of variations of the impulse turbine. When the steam passes across one set of moving blades and is then redirected by a stationary set of blades to a second set of moving blades, it is called a Curtis or velocity stage. Other variations of the impulse turbine include turbines that have reentry of the steam after passing through the moving blades, and tangential flow types of turbines where the steam "corkscrews" around several blades in the circumference of the disk.

2.2.2 Reaction Turbines In a reaction turbine, part of the expansion occurs in the nozzle and part in the rotating blades. The rotating blades have a different shape than impulse blades. They are designed as nozzles rather than turning vanes. Reaction stages typically have a relatively low pressure drop across each stage. The best efficiency of a reaction turbine occurs when the blade velocity equals the jet velocity. As a result, reaction turbines tend to operate at higher rotational speeds than impulse turbines.

In large multistage turbines, it is common for the first few stages to be impulse stages to reduce the pressure and temperature the blades and disks are exposed to, with the later stages reaction.

2.2.3 Losses In any turbine, there are a number of losses that reduce the actual output below what is theoretically attainable. Some heat is lost through the turbine case. Nozzles, even well-designed ones, do not convert energy adiabatically. Windage losses are the result of the friction of the steam against the rotating disk. Leakage losses occur when some of the steam goes between the blades and the turbine housing. This can be minimized by having a shroud on the outer circumference of the wheel. There is also an exhaust loss, as the steam exiting the turbine has some velocity that was not converted to work.

2.2.4 Control Power-level control of a turbine can be accomplished in a number of ways. Flow into a turbine can be partial admission, wherein steam is directed at only a portion of the blades. As more power is desired, the mass flow is increased by opening additional nozzles. Partial admission reduces the attainable efficiency as only a portion of the blades is doing any work, and the rest of the disk is exposed to windage and other losses. Many small turbines are controlled by partial admission. Full-admission turbines, wherein steam flows across all of the blades, can be controlled by throttling the inlet flow.

2.2.5 Design Considerations The design limitations for turbomachinery are usually the inlet temperature and the turbine tip speed. This can be correlated with the stresses in the turbine disk and blades. Another consideration is the corrosion properties of the working fluid, which can reduce the available material choices. Design charts suitable for preliminary design of single-stage turbines are available in the literature (Baljé, 1962). These charts show a relationship between the turbine tip diameter, volumetric flow rate, rotational speed, enthalpy change, and turbine efficiency. A more detailed presentation of turbine design can be found in Stodola (1927).

3. CONDENSERS

When the steam exhausts from the expander, it flows to the condenser where the cycle heat is removed and the water returns to its liquid state. There are two basic types of condenser: direct contact and surface. As the name implies, in the direct-contact condenser, cooling water is sprayed into the exhaust steam. These condensers are typically suited for smaller plants and were common in early marine steam-propulsion plants. The surface condenser is the type most commonly applied in modern plants. In this design, cooling water flows inside tubes, and the steam condenses on the outside of the tubes. In addition to provision for condensation, some condensers may include provision for cooling the expander exhaust to the saturation temperature (desuperheating) prior to condensation and cooling the condensate to slightly below saturated liquid temperatures (subcooling) in order to take into account pump design considerations. The condensed water collects in the hot well, which is usually at the lowest level of the plant.

Since the pressure in the condenser is generally considerably below atmospheric, there is a chance that air may leak into it, adversely affecting the heat-transfer characteristics. This air is continuously removed by a steam pump or a mechanical pump.

In many stationary applications, the coolant is relatively cold water, which is a good heat-transfer medium. Steam condensing pressures on the order of 10 kPa absolute are common, with temperatures often less than 30 °C. Where cooling water is scarce, cooling towers may be used, with the ambient air becoming the final heat sink. The cooling tower operates on the principle of evaporative cooling, so that the cooling water approaches the wet-bulb temperature of the air.

For smaller plants that use ambient air as the heat sink, the condenser is usually a fin-tube exchanger that resembles an automotive radiator, except that there are a greater number of fins in order to increase the heat-exchanger effectiveness.

Another condenser design consideration is the fact that the heat exchanger may be exposed not only to the subatmospheric pressure during most of the operating envelope but also to the average pressure of the system when it is shut down. This may be greater than atmospheric. As a minimum, this complicates the pressure-vessel aspects of the design.

4. PUMPS

The pump in a steam engine raises the pressure of the condensed water from the condenser pressure to the boiler inlet pressure. Since the pressure at the pump inlet may be below the boiling pressure at that temperature, a separate boost pump may be required between the condenser and the main feed-water pump.

As with expanders, there are two basic kinds of pumps, positive displacement and dynamic. No matter which type of pump, the key characteristics are the pressure rise and flow rate.

4.1 Positive Displacement

As with positive-displacement expanders, there are numerous types, each with its own characteristics. The overall operation can best be visualized by considering a piston moving in a cylinder. As the piston moves away from the head, water flows through the inlet (or suction) valve to fill the cylinder volume. As the piston starts its return stroke, the pressure begins to rise and the inlet valve closes. When the pressure has risen to the value set by the exhaust (or discharge) valve, the valve opens, and the piston forces the water out at the higher pressure. With a piston pump there are pulsations in the flow, and some type of capacitance is often introduced to allow the mean pressure to stabilize.

Other positive-displacement pumps work on the same principle, except that the pressure rise and flow characteristics differ for each pump type. A variety of gear pumps, vane pumps, and screw pumps have been applied to various pumping tasks, but for feed pumps for relatively low–power-level steam engines, the piston pump is the frequent choice.

4.2 Dynamic

The majority of dynamic pumps used in steam engines are centrifugal pumps as they provide the greatest pressure rise per stage. Axial pumps are used in some applications to achieve higher efficiency than possible with the centrifugal type but are rarely applicable to low-power steam engines.

In the centrifugal pump, water enters at or near the center of a vaned disk and flows outward toward the periphery. The velocity thus generated in the flow is converted into pressure in the volute (the space surrounding the disk) or, for higher efficiency, in diffuser vanes. The vanes are carefully shaped on both the rotating disk and the diffuser. The disk is also shaped so that the flow area tends to remain constant as the diameter increases.

Generalized design charts for dynamic pumps, based on similitude considerations, are available in the literature.

5. VAPOR GENERATORS

Vapor generators have two main subsystems: combustion, where fuel is burned to generate a high-temperature gas, and the heat exchanger or "boiler," which transfers the heat from the combustion gas to the water. In small power plants the boiler is usually a combined feed heater, boiler, and superheater. In it the pressurized feed water is heated to saturated-liquid conditions, the mixed water/vapor mixture is heated to saturated-vapor conditions, and additional heat is added to superheat the steam to the desired expander inlet conditions.

5.1 Heat-Transfer Subsystem

The simplest type of boiler is a heated pot with a pipe for the steam to escape—for example, a tea kettle. An advance over the pot boiler is the "fire-tube" design, where the combustion products are on the inside of tubes going through a large container filled with water. In some designs the hot gas makes two passes through the water, going first through a bank of tubes on the bottom of the container and then turning and going through a second set of tubes on the top portion of the boiler. The combustion products then exit through a smokestack. The heat transfer is from the hot gases through the tube walls to the water in the large container. The steam bubbles from around the tubes and rises to the surface of the water and accumulates in the space above the water level. The steam exits from the boiler through a "dry tube," which is designed to minimize the amount of liquid water carried over with the steam.

The fire-tube boiler was the most widely applied design for many years for both stationary and marine propulsion applications. As the desire to utilize steam at higher temperatures and pressures increased, the practical limit of boiler shell fabrication was reached at about 2.0 MPa.

In the "water-tube" design the combustion products are on the outside of the tubes and water is on the inside. A large number of configurations are available, the details of which depend on the intended application. For example, naval boilers must rapidly respond to varying steam demands, whereas merchant-ship boilers are usually designed with economy of operation in mind.

Most water-tube boilers use natural circulation of the water in the tubes, with the steam collecting in drums. Separate banks of tubes are placed relative to the combustion gas and the radiant walls to perform the feed-water heating, boiling, and superheater functions. In the bank of tubes in which boiling occurs, boiling is usually at low quality to minimize the effects of any unevenness in the heating, which could lead to unstable flow oscillations. (Quality is the term describing the proportion of vapor in a vapor/liquid mixture such as occurs during the boiling process.) Some boilers use a monotube design, in which all of the water flows through a single tube, entering as feed water, then boiling and superheating. An advantage of this design is flow stability. Forced-circulation boilers have a circulating pump to increase the velocity of the water in the tubes.

Modern vapor generators also frequently include an air preheater placed in the path of the exhaust combustion products after they flow over the water tubes. This can add to the overall efficiency by removing the need to heat the combustion air with primary fuel. A feed-water heater, called an economizer, may also be in the path of the by then cooler combustion gases.

Most modern boilers use quite pure water. The water chemistry is checked frequently to be sure that no impurities are introduced.

5.2 Combustion Subsystem

There are a number of important design considerations for vapor-generator combustion subsystems. If coal or other solid fuels are used, the concerns are the geometry of the furnace, as both radiant and convective heat transfer are important. The design depends on the type of coal used, as some are more volatile than others. For fire-tube boilers the grate area relative to the combustion-gas flow area becomes an important consideration. For liquid fuels, especially when low emissions are desired, the approach that has been found to satisfy the myriad requirements best is to have a premixed, prevaporized air–fuel mixture, with a lean fuel/air ratio.

6. APPLICATIONS

6.1 Electric-Power Generation

Large electrical-generating plants are individually designed taking into account the available fuel, the climate, and the economic conditions in the service area as well as numerous technical details. Design decisions are usually based on thorough economic analysis to insure that any additional increase in efficiency is worth the investment. Only the rudiments of this application of steam power are presented here, as a comprehensive treatment is beyond the scope of the article.

Boilers of central stations are designed to extract as much of the thermal energy in the combustion products as possible. The feed water enters the boiler at close to the boiling point, as it already has been heated in several stages of feed-water heating. Boiling usually takes place at low quality in order to assure stable flow. The steam collects in drums. Separate tube sections for superheat and reheat are placed in an appropriate place to insure efficient heat transfer. An air preheater is commonly applied in order to preheat the combustion air.

The expander is a multistage turbine. Some of the steam is extracted at different portions of the expansion and used to heat the feed water on its way to the boiler. Care is also taken to extract any water droplets that form as the steam expands and cools, as they can cause erosion of the blades.

Condensers for large, steam power plants are of the surface type and are typically placed directly below the turbine.

Feed pumps are multistage centrifugal pumps. Since the water exiting from the condenser is below atmospheric pressure, a boost pump is placed ahead of the main feed pump. This pump brings the pressure to a point where the water can enter the main feed pump without vapor bubbles forming.

Many large plants are usually designed to operate at a fixed power level. In large systems comprising many generating plants, there are usually specially designed plants to take care of the varying load.

An application that is increasingly widespread is the cogeneration concept. In these plants the exhaust from a gas turbine supplies the heat source for a steam vapor generator. The steam is then used either for process heat or for generation of electricity. Although there is a significant capital investment required because there are essentially two power plants, the overall efficiency has often been found to be high enough to warrant the extra expense.

6.2 Stationary Power Plants

Stationary power plants are often designed using commercially available components. The design is based on the power-level needs, the need for steam in the plant process, the available fuel, and whether the plant will be operating seasonally such as in some agricultural processing applications or full time as in a manufacturing facility. Historically, many local plants produced shaft power that was transmitted throughout the factory via leather belts. This has been largely replaced by electrical power being distributed with local motors.

6.3 Motor-Vehicle Propulsion

The earliest propulsion application of steam occurred in 1770, when Cugnot in France designed a steam-powered vehicle intended to haul artillery. Steam-powered road vehicles were built in the early 1800s. By the early 1900s, steam-powered automobiles were being produced in significant numbers. Serpollet in France and Stanley and White in the United States developed sophisticated engines operating at high temperatures with complex expanders. Serpollet claimed success in lubricating his expanders at 500 °C. The Stanley vehicles used a two-cylinder, double-acting, piston expander and a fire-tube boiler. The White vehicles used a two-cylinder, compound-expansion, double-acting, piston expander and a monotube boiler. Steam conditions at the vapor generator outlet of both the Stanley and White engines were in the 370 °C, 4.1-MPa range. Production of the Stanley Steamer ended in 1925. Some efforts continued into the 1930s, with designs by Doble, who built passenger cars with four-cylinder, compound-expansion, double-acting, piston expanders and monotube boilers. The expander inlet conditions were typically 400 °C, 5.2 MPa. Although there were some further efforts at steam-powered vehicles, interest waned as internal-combustion engine design matured.

Another burst of activity in steam engine development began in the late 1960s, when concerns over air pollution became a significant issue. Programs sponsored by the U.S. Environmental Protection Agency, the State of California, General Motors, and many others culminated in the demonstration of several sophisticated engine designs in both automobiles and busses. Very compact vapor generators with very low emissions were demonstrated, with peak conditions of 590 °C and 6.9 MPa in several designs.

Fuels for automotive steam engines have included kerosene, diesel fuel, and gasoline. Fuel atomization to about 10 μm is necessary for low emissions, as large droplets have a "wake" that burns at stoichiometric conditions. The mixture must be uniformly prepared, and there must be good flame stabilization, sufficient time for completion of combustion, and precise control during transients.

Although most early steam vehicles did not employ condensation, in order to be competitive with modern spark ignition engines, the experimental steam engines of the 1970s were designed with condensers. Unfortunately, the air neither is a good heat-transfer medium nor is it necessarily very cold. In addition, the frontal area of the vehicle may be the limitation that determines the condenser size and thus what the condensing-state point will be. These practical limitations often mean that the condensing pressure is above atmospheric, on the order of 140 kPa absolute, with temperatures on the order of 100 °C. These conditions have a major effect on the attainable cycle efficiency.

Although Rankine-cycle engines can attain very high efficiencies, requiring such an engine to fit within the available volume required for automotive propulsion, and with weight similar to current internal-combustion engines, severely limits the attainable efficiency and thus fuel economy.

When fuel economy became an important issue in the mid-1970s, interest in steam engine power for automobiles ceased. There was a short-lived interest in using the heat remaining in the exhaust of large over-the-road diesel engines as the heat source for a Rankine-cycle waste-heat recovery plant (bottoming cycle). Demonstration devices were built but were not commercialized.

6.4 Rail Propulsion

The basic design of the locomotive steam engine remained very much the same from its inception in the 1830s until it was largely replaced by diesel engines in the post World

War II era. The details of the design varied from country to country, taking into account local conditions, such as fuel availability, the type of terrain the locomotive would traverse, the limitations on width and height due to existing structures, and the type of loads it would carry.

Except for a few experimental locomotives, locomotive boilers were of the fire-tube design, with pressures in the neighborhood of 1.4 to 2.0 MPa. Early boilers were designed to produce saturated steam. In the early 1900s a practical superheater design was developed, and its application became widespread by the 1920s. In this superheater design, saturated steam was led through small-diameter U-shaped pipes placed in enlarged fire tubes. The usual diameter for the ordinary fire tubes was about 5 cm, whereas the tubes in which the superheater elements were placed were about 12 cm in diameter. The use of superheated steam eliminated the problems with condensation of the saturated steam as it entered the cylinder (initial condensation) as well as providing an increase in cycle efficiency.

An interesting feature of the steam locomotive is the close coupling between the combustion and steam expansion processes. The steam exhausted from the working cylinders goes to a blast pipe and thence out through the smokestack. This flow tends to act as a pump for the combustion products, with increased steam flow creating additional draft that is a reduced pressure at the outlet end of the fire tubes. This in turn draws more air through the combustion region of the boiler, which increases the thermal output of the furnace and increases the amount of steam being produced.

Until very late in its history, the primary fuel for steam locomotives was coal. Wood was used on some locomotives, and toward the end of their active usage, some locomotives used oil.

The most common locomotive expander configuration employed two double-acting simple expansion cylinders. Some three- and four-cylinder locomotives saw service. Some engines with two stages of expansion were used, but the increased efficiency did not prove attractive.

Early steam locomotives used slide valves. With the advent of superheated steam, these were generally replaced by cylindrical valves, which were easier to lubricate in the dry-steam environment. Toward the end of the steam era, some locomotives used poppet valves.

In order to turn the reciprocating motion of the piston into rotary motion of the wheels, the piston was attached to a crosshead, which in turn had a connecting rod to the drive wheel. The drive wheel was connected to the remaining wheels with coupling rods.

Although steam locomotives reigned supreme for more than 100 years, and were economically viable, they never were very efficient in the thermodynamic sense. The reason for this is that the noncondensing basic cycle with quite moderate temperatures and pressures were not more than about 5% efficient in converting the thermal energy in the fuel to work at the wheel. There were some experimental locomotives that used water tube boilers, some that condensed the steam, some that used turbine expanders, and some with exotic variants of the basic Rankine cycle; however, these engines did not prove practical.

6.5 Ship Propulsion

In 1785, James Fitch built a 10-m steam-powered boat propelled by vertical oars. The first steam-powered vessel that can be considered the progenitor of modern design was demonstrated in 1801 by William Symington. His vessel had a single, double-acting horizontal engine directly driving the crankshaft of a stern paddle wheel. The cylinder was 0.56 m in diameter and had a 1.2-m stroke.

Early marine steam engines used saltwater as the working fluid with the pressure at the vapor generator outlet in the range of about 13–20 kPa above atmospheric. The boiler had to be cleaned periodically as deposits built up as a result of the use of saltwater. A remedy to this was found by replacing a small portion of the water every few hours. Superheat was introduced in 1856. Direct-acting condensers were the usual design in the earlier applications, and surface condensers came into service in the 1870s.

Boilers in the early days of marine propulsion by steam were flue boilers; that is, the combustion products followed a tortuous path around walls filled with water. These walls were about 13 cm thick. It was not long before fire-tube boilers came into use, eventually followed by water-tube boilers. Very compact designs of water-tube boilers were developed. Boilers for naval combat vessels were developed so that rapid changes in steam rates were possible.

Triple-expansion reciprocating expanders were the most common design until the steam turbine became the expander of choice. Some of the triple-expansion expanders had three cylinders, and some had four. In either case, the intermediate- and low-pressure cylinders were larger in diameter than the high-pressure cylinder to accommodate the increased volume of the steam as it expanded.

7. OTHER WORKING FLUIDS

Water is not the only possible fluid to use in a Rankine-cycle power plant. There are a number of reasons to consider alternatives. Water freezes at a temperature commonly encountered during part of the year in many parts of the world, whereas other fluids can remain liquid at subzero temperatures. The properties of water are not especially attractive for low–power-level Rankine-cycle engines, as the high enthalpy change per unit mass results in relatively low overall flow rates. Efficient expanders may be difficult to design at these flow rates. Probably the most intriguing reason for considering other fluids is that, at least theoretically, it is possible to design a fluid for a particular application.

On the other hand, many fluids that would be desirable from a thermodynamic, heat-transfer, or expander design viewpoint are toxic, flammable, or with poor thermal stability, and in some cases very costly. Another problem with alternative working fluids is that at the higher molecular weights, the saturated-vapor line has a positive slope on the temperature–entropy diagram. This means that expander exhaust goes far into the superheat region, and thus a considerable amount of superheat must be removed prior to condensing. In practice this can mean that a large heat exchanger would be required, possibly negating any other weight or size advantages the fluid might show.

As the molecular weight of a fluid increases, the enthalpy change per unit mass decreases, which for turbomachinery design means that the nozzle velocity (but not necessarily the Mach number) will decrease, since it is proportional to the square root of the enthalpy change. The result is that turbomachinery with higher molecular-weight fluids can be designed to operate at slower rotational velocities. For the same power level, however, there will tend to be greater mass flow, which will tend to increase the size of the system heat exchangers.

Designing for fluids other than water can be difficult because the thermodynamic and fluid-mechanical properties may not be known with the same degree of precision. However, assuming a perfect gas for the expansion can provide a preliminary idea of the dimensions and rotational velocity for a given power level if a turbine expander is being considered.

A closer approximation to the thermodynamic properties of the working fluid can be obtained by using the principle of corresponding states. Rather than the usual expression relating the pressure, specific volume, and temperature of a perfect gas, the equation

$$pv = ZRT$$

can be used, where Z is the compressibility factor, usually defined as the ratio of the actual fluid volume to the volume that the same fluid would occupy at the same temperature and pressure if it were an ideal gas; p is pressure; v is specific volume; R is the gas constant for the particular gas; and T is the absolute temperature. Z is a highly nonlinear function of the temperature and pressure. Generalized charts of Z are available based on the reduced pressure and temperature, that is, the ratio of the actual pressure and temperature to the critical pressure and temperature. Even if there are meager data on the particular fluid, the critical point is generally known.

A vast number of fluids other than water have been demonstrated in Rankine-cycle plants. Mercury was demonstrated in an experimental central station. Mercury and other liquid metals were also demonstrated in space-power applications. A variety of other fluids were demonstrated or at least considered, including toluene, mixtures of trifluoroethanol and water, hexaflourobenzene and mixtures of hexaflourobenzene and perflourotoluene, and dichlorobenzene, as well as proprietary fluids. The choice was typically made on the basis of the thermal decomposition and corrosion properties of the fluid in contact with the materials that would be used for the mechanical parts of the system.

8. OTHER CYCLES

Depending on where the compression, heat addition, expansion, and heat rejection occur with respect to a fluid's vapor dome, a number of cycle variations are possible (Angelino and Moroni, 1973). One variant would have the entire cycle take place in the supercritical region. In another, heat addition would take place in the supercritical region, but expansion and condensation as in the conventional Rankine cycle. The cycle can also take place entirely in the superheat region, which in the case of air would be the nearly perfect gas region. This cycle is actually the Brayton cycle (see HEAT ENGINES AND REFRIGERATORS) applicable to gas turbine engines. If the compression takes place close to the saturated vapor curve, large real-gas effects may be introduced. An even more exotic cycle can take place when the properties of the working fluid change with temperature and pressure. The thermally dissociating cycle is an example of this type of cycle.

GLOSSARY

Boiler: The device in which combustion products vaporize the steam. This may also include superheat and reheat.

Compound Engine: An engine with two stages of expansion.

Condenser: The device in which heat is removed from the steam after expansion, and the steam returns to a liquid state.

Connecting Rod: The shaft that transmits the force from the crosshead or the piston rod to the crankshaft.

Counterflow Expander: An expander in which the steam enters the cylinder at one end of the cylinder and exhausts at the same end. (See **Uniflow.**)

Crankshaft: A shaft upon which cranks are placed. The action of the connecting rod against the cranks causes the shaft to move in rotary motion.

Crosshead: A sliding bearing that is intermediate between the piston rod and the crank arm of the crankshaft. The crosshead allows the piston rod to move in reciprocating motion while it executes the complex motion required to transmit the force generated by the piston to the crankshaft.

Cutoff: The point where steam admission into the cylinder ceases. Some engines have variable cutoff as a means of controlling power output.

Cylinder: The component in which the steam expansion takes place in a positive-displacement expander.

Enthalpy: A property of a substance equal to the sum of the substance's internal energy and the product of its pressure and specific volume. Changes in enthalpy are governed by the initial and final states rather than by the path between the states.

Expander: The device in which the steam transforms thermal energy into work. In a positive-displacement expander, the work is the result of an unbalanced pressure across a piston, vane, or other similar component. In a dynamic expander, the work is the result of a momentum change as steam exits a nozzle at high velocity and impinges upon movable blades.

Feed-Water Heater: A heat exchanger in which heat is added to the pressurized water prior to boiling.

Fire-Tube Boiler: A vapor generator in which the products of combustion flow through tubes surrounded by water. (See **Water-Tube Boiler.**)

Full Admission: The design of dynamic expander wherein steam flows through all of the stationary nozzles. (See **Partial Admission.**)

Impulse Turbine: A dynamic expander in which the steam expands in a stationary nozzle and impinges on a set of blades, transferring momentum. (See **Reaction Turbine.**)

Indicator Card: A pressure–volume diagram of the process within a positive-displacement steam expander.

Partial Admission: The design of a dynamic expander in which steam is admitted to only a subset of the full circumference of the turbine blades. Partial admission can be used as a power-level control by having more than one set of blades available for admitting steam to the rotating turbine disk. (See **Full Admission.**)

Piston: A disk upon which the steam acts in a positive-displacement expander. The steam exerts a force on one side of a single-acting piston and on both sides of a double-acting piston.

Piston Rod: The shaft that is connected at one end to the piston and at the other end to the crank or crosshead.

Pump: A device that raises the pressure of the water. A circulating pump causes a fluid to flow through a heat exchanger—for example, the cooling water through the tubes of a condenser. A feed pump raises the pressure of the water prior to heat addition. A boost pump raises the pressure of the water from the condenser to the main feed-pump inlet.

Reaction Turbine: A dynamic expander in which the steam expands in stationary nozzles and continues to expand in rotating blades. (See **Impulse Turbine.**)

Reheat: Steam that has been partially expanded and returned to the vapor generator for further heat addition.

Superheat: The state of the steam when it is heated to a temperature greater than its saturation temperature.

Superheater: The portion of the vapor generator in which additional heat is added to saturated steam in order to raise its temperature.

Triple-Expansion Engine: An engine with three stages of expansion. Three-cylinder and four-cylinder versions of this engine type were used. This engine type was commonly used in marine propulsion applications.

Uniflow Expander: An expander in which steam enters the cylinder at one end of the cylinder and flows in one direction toward exhaust ports. This design minimizes initial condensation. This type of engine also has a fairly constant part-load efficiency. (See **Counterflow Expander.**)

Valve: A mechanical device that opens or closes a flow path. Slide valves slide back and forth over slots in the cylinder, allowing steam to enter the cylinder or to be exhausted from it. They are usually D shaped, with the flat side of the D sliding across the cylinder and the round part of the D in communication with the steam inlet and exhaust. Cylindrical valves have a similar action to slide valves, except they are cylindrical. Corliss valves are rotary quick-acting valves of a unique design. Poppet valves are mushroom-shaped valves that move up and down to allow steam into or out of the cylinder. This is the common design found in internal-combustion engines.

Vapor Generator: The device in which water is heated, boiled, and superheated by combustion products. The term boiler is often used as a synonym. The complete vapor generator includes the furnace in which the fuel is burned, blowers and fuel admission components, and other heat exchangers that may be present such as air preheaters and economizers, as well as controls for the various subcomponents.

Water-Tube Boiler: A vapor generator in which the products of combustion flow across water or vapor-filled tubes.

INTRODUCTION

Iron is the chemical element Fe, but the word is also used for an alloy of Fe with low contents of Mn, Ni, and Cr. Iron has a strength slightly above that of copper. By addition of carbon up to 2 wt% and other elements, the strength can be increased by a factor of 10; this is the range of steels that can be hot and cold deformed. With carbon contents above about 2 wt%, hot and cold deformation is nearly impossible; this is the range of cast iron that in general is used in the cast state (Elliott, 1992).

Native meteoric iron has been used for at least 5000 years. Reduction from iron ores has been feasible for about 4000 years, but because of the high melting point of iron

(about 1500 °C), iron and steel could only be produced in the solid state. This was very time consuming, and the volume of steel that could be produced was limited. With improved techniques using water power in the 13th century, temperatures about 1200 °C could be reached, giving liquid pig iron with 2.5–5 wt% C from a blast furnace with a higher capacity than earlier processes. Furnace plates or cannon balls could be cast directly, but on the extraction of carbon by oxidation to the range of forgeable steel, i.e., to below 2 wt% C, the melting point still increases above the temperature that could be realized at that time, and steel production was possible only in the solid state. Iron production at that time in Europe was about 25 000 tonnes per annum. Today one blast furnace produces about 10 000 tonnes per day. People knew nothing about crystal structure, phase transformation, or mechanisms of hardenability. So much the more admirable in retrospect is what was made of steel. One example is the pattern of the Damascus swords (Fig. 1). The striation was realized by welding and forging together steel plates with high and low carbon contents, giving different reflectivity after etching (Sachse, 1994). Patterns such as that shown in Fig. 1 were reproducible; they were not a matter of chance. Such swords are—from today's point of view—composites built up by hard and soft layers of steels giving an excellent combination of high strength, high hardness, and good toughness. Very modern methods such as the creation of compressive residual stresses at the surface were already realized with the finishing of such swords.

With the invention of air refining in a converter and air preheating, i.e., regenerative heating, about 1860 temperature within the furnaces could be raised to produce steel in the liquid state. By combination of this with steam power, producing sufficient energy, the production of steel was enlarged, among other things, one of the requirements for the development of railways. Starting with that time, up to today as a result of investigations of the processes of steel production and heat treatment, not only the quality of steels was improved but also the reproducibility of a defined steel grade. Today more than 2000 different steel grades are available, giving a wide range of applications as structural steels, corrosion-resistant steels, tool steels, or materials with special physical properties. Today the worldwide production of steel is about 700 million tonnes per annum, about 30 000 times more than in the 13th century.

In the following, starting with the properties of pure iron and an introduction to some alloy systems, the strengthening mechanisms of steel and the basic microstructures are discussed. A discussion of the principles of the transformation of steels is followed by a short description of steel production and heat treatment. Engineering steels, tool steels, and stainless steels are taken as examples to give some information on special steel grades. In all cases only basic information about steel production and properties is given. Excellent books are available describing details, and are listed in Further Reading.

1. SOME PROPERTIES OF PURE IRON

Except on a laboratory scale, it is not possible to produce an alloy with 99.999% iron. A typical analysis of commercial pure iron is given in Table 1. The interpretation of such an analysis is not easy, for today we know that a content of 15 ppm B is already a boron-alloyed steel. But such a low level could not be analyzed 50 years ago. Therefore, the values given below and elsewhere refer to an iron as pure as available at the time; experiments are done or are extrapolated from alloyed steels to an alloy content of zero.

Iron forms two crystal structures, the body-centered cubic (bcc) and the face-centered cubic (fcc) (see CRYSTALLOGRAPHY). The bcc α phase is stable at room tempera-

ture and ferromagnetic up to the Curie temperature of 768 °C. The transition of the ferromagnetic state to the paramagnetic state at the Curie temperature often is referred to as the A_2 temperature, but it is a transformation of second order; see MAGNETS; MAGNETIC MATERIALS; and PARAMAGNETISM. At 911 °C, the A_3 temperature, the bcc α iron changes to the fcc γ iron. At 1392 °C, the A_4 temperature, the fcc γ iron changes to the bcc δ iron, which is stable up to the melting point of 1536 °C. The bcc lattice has two atoms per unit cell; the fcc lattice, four atoms per unit cell. Therefore, the lattice constants of α iron and γ iron are very different; see Table 2, which also gives values for the density. The atomic volume of iron (Fig. 2) indicates the change of the structure with temperature. The heat capacity shown in Fig. 3 has a maximum at the Curie temperature T_c. The heat of transformation is 820 J/mol for the α–γ transformation and 850 J/mol for the γ–δ transformation. The heat of melting is about 14 000 J/mol.

Values for the thermal expansion are given in Table 2. The magnetization curve for single crystals at room temperature has the same saturation polarization of 2.16 T at 20 °C for all directions, but below saturation there are differences by a factor of 2 between the (100) and (111) orientation. This effect is used in the production of textured steels for electric machines. The electrical resistance is 10 $\mu\Omega\cdot$cm at 20 °C. The ratio of the resistivity at 273 K to that at 4.2 K is 5000 for iron with 99.999 wt% Fe. This value is used to describe the purity of iron. The thermal conductivity is about 70 J/ms·K at 20 °C. In the visible spectrum the optical reflectivity of iron is about 0.55. The value depends on the quality of the surface. For mechanical properties, see Sec. 3.

The physical properties of pure iron are changed severely by alloying elements. So, fcc γ iron may be stable at room temperature, or bcc α iron may be stable up to the melting point (see Sec. 2), giving ferromagnetic as well as nonmagnetizable steels. In an iron–nickel alloy with about 35% Ni, the thermal expansion coefficient is extremely low, about 1×10^{-6} K^{-1}. In this case magnetostriction compensates thermal expansion. On the other hand, an alloy with 0.6 wt% C, 1 wt% Si, 6 wt% Mn, and 15 wt% Ni has a thermal expansion coefficient as high as 20×10^{-6} K^{-1} at room temperature. Any value in between can be produced (Pepperhoff, 1992; Stäblein and Arntz, 1993; Weßling and Heimann, 1993).

2. PHASE DIAGRAMS WITH IRON

Steels are alloys of iron with elements such as C, Mn, Si, Cr, Ni, Mo, W, etc. For the understanding of the kinetic processes, the knowledge of the phase equilibria is a necessary basis. For the principles of phase diagrams and solid solutions, see THERMODYNAMICS, EQUILIBRIUM and PHASE EQUILIBRIA. Figure 4 shows the system Fe–Mn as an example for alloying elements such as Ni, C, and Mn, which widen the temperature range where γ iron is the stable phase. The

Table 2. Some physical data of pure iron. The coefficient of thermal expansion is the average for the temperature range given in the same row.

Temperature (°C)	Structure	Number of atoms per unit cell	Lattice constant (nm)	Density, calculated (g/cm^3)	Coefficient of thermal expansion (K^{-1})

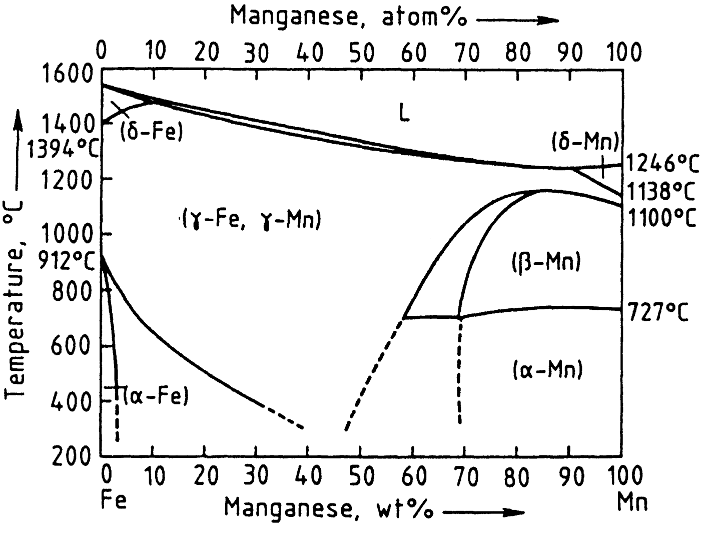

FIG. 4. Iron–manganese phase diagram (Massalski, 1990).

opposite effect is produced by elements like Cr and Si, which extend the temperature range where α iron is the stable phase (Fig. 5). In iron with more than 13 wt% Cr, ferrite is stable between room temperature and the solidus temperature. However, the effects of the alloying elements are not additive. As an example, in a steel containing 18 wt% chromium and 10 wt% nickel, γ iron is stable from room temperature to the melting point. Phase diagrams can be calculated from thermodynamic data (Predel, 1993). Compilations of the most important two- and three-component systems are published (Massalski, 1990; Petzow and Effenberg, 1991; Raghavan, 1987–1992).

In plain carbon steels, the metastable phase Fe_3C, called cementite, is of great im-

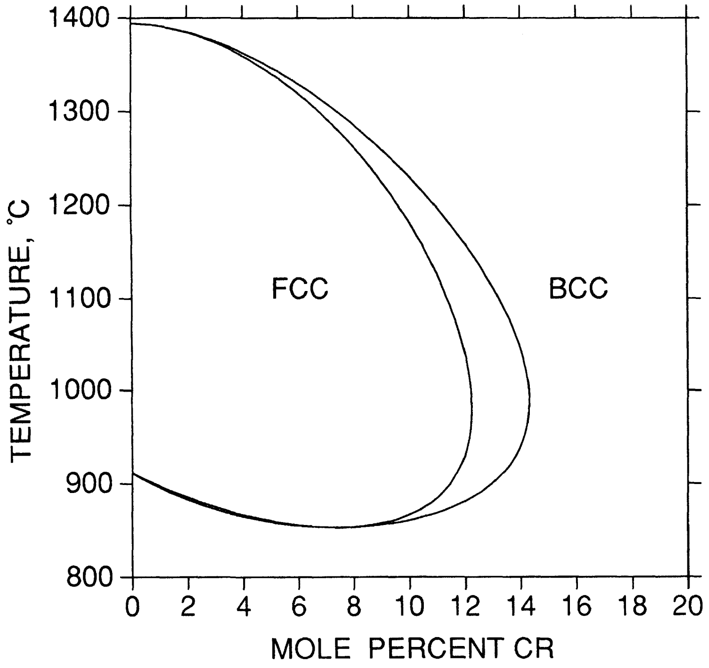

FIG. 5. Section of the iron–chromium phase diagram calculated with the program Thermocalc (Franke, 1995).

portance (Fig. 6). In the system Fe–C, the stable phase is graphite, formed in gray cast iron. These are alloys of Fe, e.g., with carbon contents of 4 wt% C, 1 wt% Mn, and 2 wt% Si. Under technical conditions of heating and cooling in steels, cementite is stable, especially if a solid solution $(Fe,Mn)_3C$ is formed in the presence of the usual manganese content in steels (see Solubility, Alloys). In Fe-Cr-C systems, $(Fe,Cr)_3C$ is stable if more than about 0.7 wt% chromium is present. Figure 7 shows a quasibinary section through an Fe-M-M_3C system, where M represents a metal. For technical applications, the temperature limits of the phase fields are measured during heating with 3 °C/min. For these temperature limits the technical term "Ac temperature" is used. The relationship of the Ac temperatures to the boundaries of the phase fields can be seen from Fig. 7. Alloy steels, which are multicomponent systems containing Fe and C, may contain not only M_3C but also the carbides M_7C_3, $M_{23}C_6$, M_6C, M_2C, MC, and intermetallic phases. In these cases, the simple scheme shown in Fig. 7 is not valid (Pitsch and Sauthoff, 1992).

3. FACTORS THAT DETERMINE PROPERTIES OF STEELS

3.1 Yield Stress

3.1.1 Definitions. In a uniaxial tension test, with increasing load first there is a reversible, linear, elastic deformation with $\sigma = E\epsilon$ N/mm^2 (see Fig. 8). E is the Young's modulus, which for α iron is in the range of 210 000 N/mm^2. The stress σ is defined by $\sigma = K/F_0$, if K is the load and F_0 the initial cross section of the cylindrical specimen. If l_0 is the initial length and Δl the elongation under load, then the strain is defined as $\epsilon = \Delta l/l_0$. At loads higher than the so-called yield stress, the correlation between stress and strain is no longer linear, and plastic deformation starts with irreversible glide of dislocations; see Point and Extended Defects in Crystals. During deloading from point a in Fig. 8, the strain goes back following the dotted line. Point b represents the plastic deformation. The slope of the line a–b is E. Loading again, the material deforms elasti-

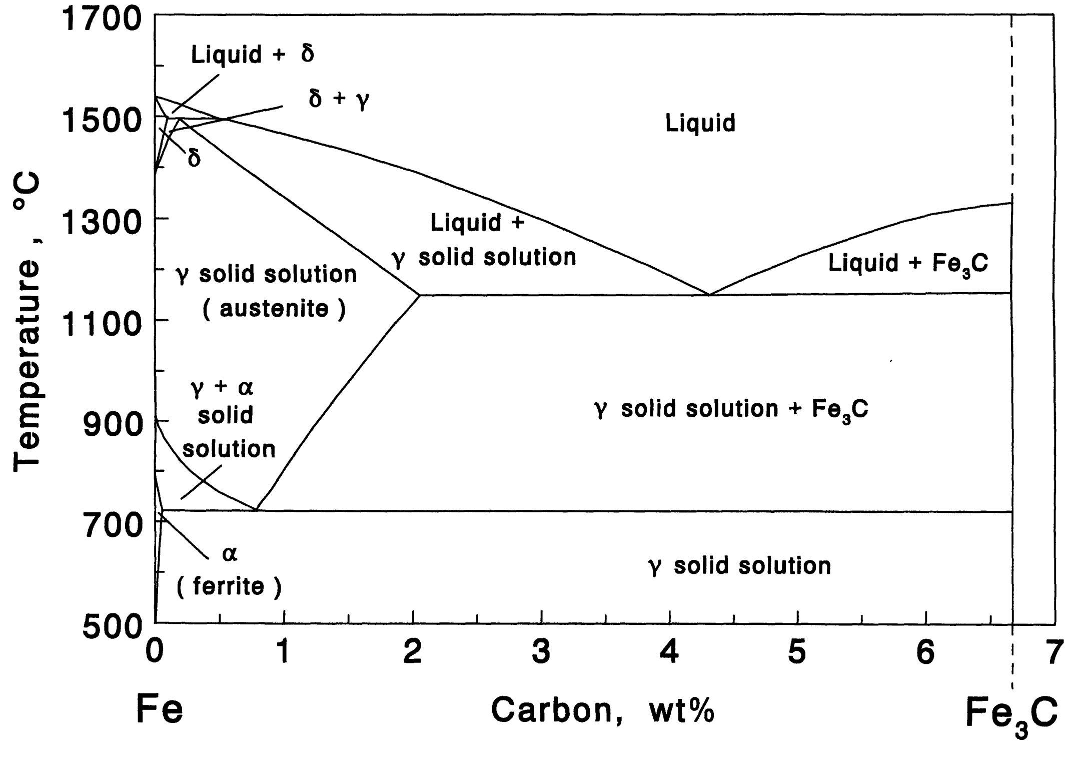

FIG. 6. Phase diagram of the metastable equilibrium iron cementite (Massalski, 1990).

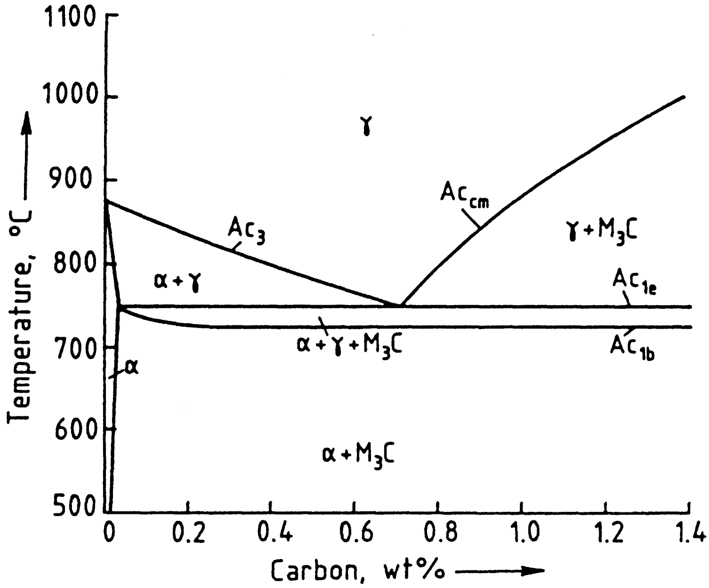

FIG. 7. Quasibinary section of a ternary phase diagram Fe-*M*-M_3C, where *M* represents a metal like Cr, Mn, etc., and M_3C stands for (Fe,*M*)$_3$C (Hougardy, 1990).

cally following the line *b–a*. At loads greater than *a* the stress–strain behavior follows the original curve. For many steels the yield stress cannot be measured with sufficient accuracy. Therefore, the stress giving 0.2% permanent deformation is taken as proof stress, $R_{p0.2}$ in Fig. 8. The increase of yield stress *a* above $R_{p0.2}$ is called work hardening. In iron, dislocations have a density of about 10^8 cm^{-2}; this is the total length of dislocations in cm/cm^3. After plastic deformation the density may go up to 10^{12} cm^{-2}. With increasing load, the cross section of the test specimen decreases; therefore, the true strain ϵ_W must

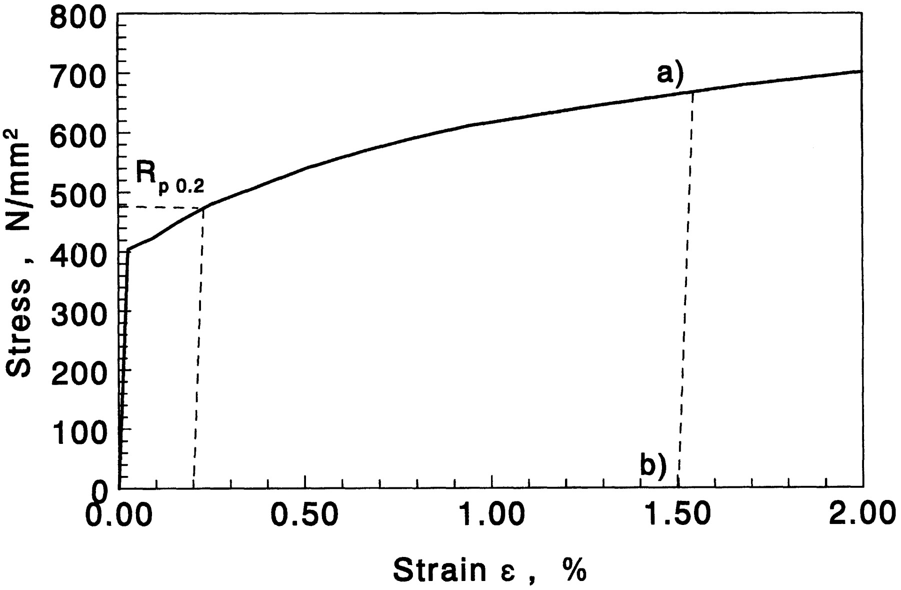

FIG. 8. Initial part of a stress-strain diagram of a steel as obtained by a tensile test.

be calculated by $\epsilon_W = \ln(F_0/F)$, if F is the actual cross section. The subscript denotes the true strain and the true stress, which is defined as $\sigma_W = K/F$. At a stress above $R_{p0.2}$, a first approximation yields $\sigma_W = \sigma_0 + K\epsilon_W^n$. At $\sigma_W = d\sigma_W/d\epsilon_W$ necking of the specimen starts, and the strain increases with decreasing load until rupture; see Fig. 9. After rupture of the specimen there is a reduction of area described by Z, with $Z = (F_0 - F_E)/F_0$, if F_E is the cross section at the fracture surface, and an elongation after fracture $A = (L - L_0)/L_0$, if L is the length after fracture. The maximum stress in the σ-ϵ curve before necking starts is called tensile strength (Fig. 9).

Since the plastic deformation is caused by the movement of dislocations, the yield stress and the exponent n depend on temperature and loading rate. Figure 10 shows the stress–strain curves for a plain carbon steel with 0.45 wt% C for various temperatures. Increasing the strain rate from $\dot{\epsilon} = 10^{-4}\ \text{s}^{-1}$ up to $\dot{\epsilon} = 10^2\ \text{s}^{-1}$ may raise the yield stress by a factor of 1.8.

Pure iron has a yield stress at room temperature of about 100 N/mm^2. The yield stress of high-purity iron with 99.999 wt% Fe is about 50 N/mm^2 at 273 K but about 600 N/mm^2 at 4.2 K, measured with a strain rate of $8 \times 10^{-5}\ \text{s}^{-1}$. For technical applications, steels often should have higher strength to reduce the necessary cross section in constructions or to increase wear resistance. There are four ways of increasing the strength of pure iron. Theoretically the increase of a shear stress is calculated, but in the following this is transposed to an increase in the yield stress measured in a uniaxial tensile test (Dahl, 1992; Mughrabi, 1993; Cahn and Haasen, 1996).

3.1.2 Influence of Grain Size. If d is the average diameter of ferrite grains in the microstructure, the yield stress R_{el} is increased by $\Delta R_{el} = K_y d^{-0.5}$. Here K_y is the grain-boundary resistance. In technical steels d can be varied between 0.5 and 100 μm. K_y is in the range of 20 N/mm$^{3/2}$. For grain sizes in the range of nanometers, see NANOPHASE MATERIALS.

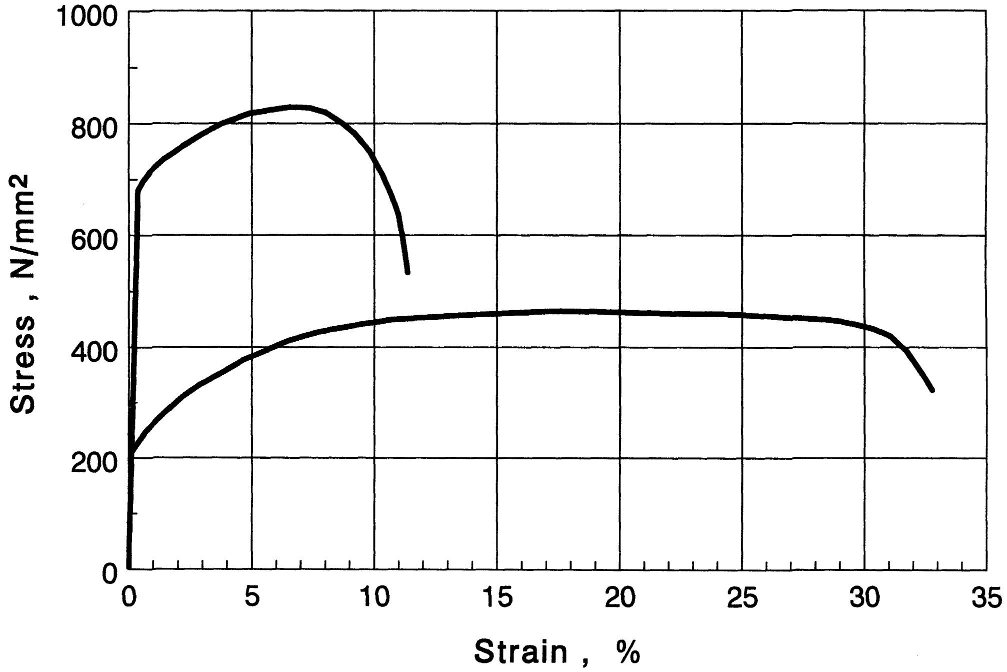

FIG. 9. Stress-strain diagram of two different steels. Strain rate after passing $R_{p0.2}$: $\dot{\epsilon} = 10^{-4}\ \text{s}^{-1}$. Upper curve, steel with a yield stress of 690 N/mm^2 and a tensile strength of 825 N/mm^2; lower curve, steel with a yield stress of 200 N/mm^2 and a tensile strength of 475 N/mm^2.

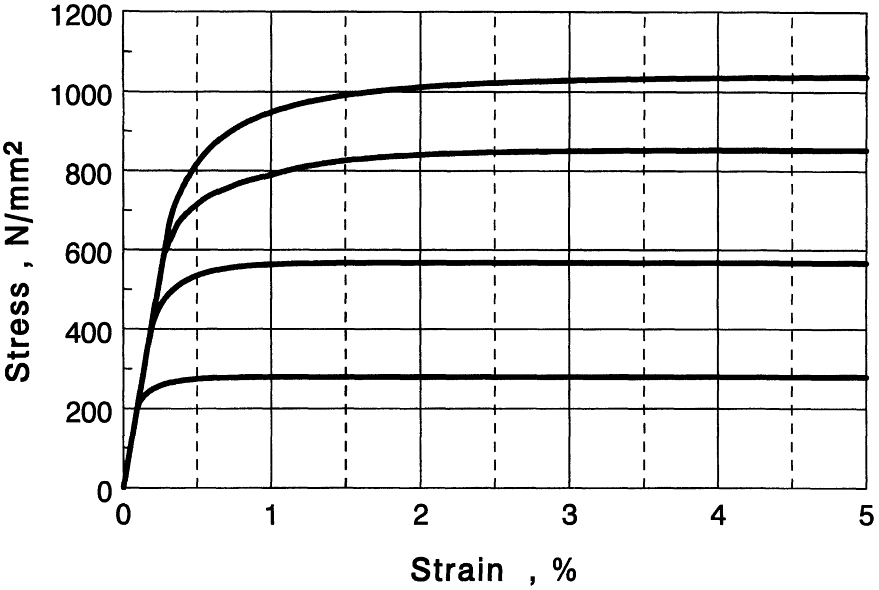

FIG. 10. Stress-strain curves for four temperatures. Steel Ck 45 isothermally transformed to bainite at 425 °C. Testing temperature from top to bottom: 20 °C, 400 °C, 500 °C, and 650 °C.

3.1.3 Influence of Solid Solution. Atoms of alloying elements, such as Mn, Cr, or Si, form a solid solution with iron, at least up to contents of 2 at.%; see Sec. 2. But the lattice of the iron atoms is disturbed by local strain fields around the atoms of the alloying elements. This gives a higher force necessary for the movement of dislocations. The yield stress is increased by $\Delta R_{el} = M\sqrt{c}$, where c is the weight percentage of the foreign atoms. In steels up to about 2 wt% of alloy content yields $\Delta R_{el} = Kc$. For an iron alloyed with Ni, K is 1 N/mm^2; an alloy of iron with Si yields $K = 125$ N/mm^2. Carbon and nitrogen have maximum values of $K = 300$ N/mm^2; they form interstitial solid solutions but have a solubility limited to a few parts per million.

3.1.4 Influence of Particles. Particles are obstacles for the movement of dislocations. For a uniform distribution of particles with a constant diameter d_p and a volume fraction V_v, the increase in yield stress is given by $\Delta R_{el} = KV_V{}^{1/3}/d_p$. The coefficient K is in the range of 0.027 N/mm. There are different equations for nonrandom arrangement and size distribution of particles as well as the kind of particles. If the particles giving an increase in yield stress are produced by precipitation, it is called precipitation hardening.

3.1.5 Influence of Dislocation Density. With increasing plastic deformation the density of dislocations increases. After loading to a stress of a in Fig. 8 and reducing the stress to zero, the steel deforms elastically. Loading again gives a yield stress of a because of the increased density of dislocations ρ by the first load. This increase in yield stress is given by $\Delta R_{el} = K\sqrt{\rho}$. For pure α iron one has $K = 155$ cm·N/mm^2; in steels K depends on the alloying content and the microstructure.

In Table 3 an approximation is given for the maximum yield stress that can be got by

Table 3. Estimation of the maximum increase in yield stress ΔR_{el} and direction of change in toughness of pure iron by different mechanisms. Grain size of the reference pure iron is about 50 μm.

Mechanism	ΔR_{el} (N/mm^2)	Toughness
Solid solution	500	↓
Precipitation	3000	↓
Grain size	500	↑
Dislocation density	1500	↓
Sum of all effects	5500	
Available	3700	

the four mechanisms of increasing the strength of steels. The maximum yield stress got in steel cord wires is about 3500 N/mm^2, less than the sum given in Table 3. The reason is that there is no microstructure combining all elements giving the maximum increase of strength given in Table 3 simultaneously. Above all, steels with the maximum strength possible would have no toughness.

3.2 Toughness

If a steel component is loaded beyond its yield stress or proof stress, it does not break immediately. The plastic deformation and the associated work hardening, see Fig. 8, provide safety against catastrophic fracture of steel constructions. At the end of plastic deformation, ductile fracture takes place, giving a reduction in area of the tensile specimen up to 60%, sometimes even more. If the conditions for superplasticity are met, the elongation after fracture reaches values of 200% or more. The toughness, which can be described qualitatively as resistance to fracture, is reduced with increasing yield stress. There is an upper limit, the microscopic cleavage fracture stress σ^*, where transcrystalline separation of crystal faces by brittle crack propagation or separation of grain boundaries occurs, giving a brittle fracture; see Fig. 11. The temperature where the curve for the yield stress crosses the curve for the microscopic cleavage fracture stress is the transition temperature between ductile and brittle fracture. If the strength of iron is increased by particles, alloying elements, or dislocation density (see Table 3), the transition temperature is raised (line 3). Only refinement of grain size increases the microscopic cleavage fracture stress. As a consequence, only grain refining gives an increase in strength of steel combined with a shift of the transition temperature to lower values (line 2 in Fig. 11). This makes evident the importance of producing fine-grained steels.

The rupture of the specimen is induced by cracks. In ductile fracture the propagation of cracks is accompanied by large plastic deformations with large energies necessary to produce the fracture. In brittle fracture, cracks grow with only very limited plastic deformation and hence limited energy of the mate-

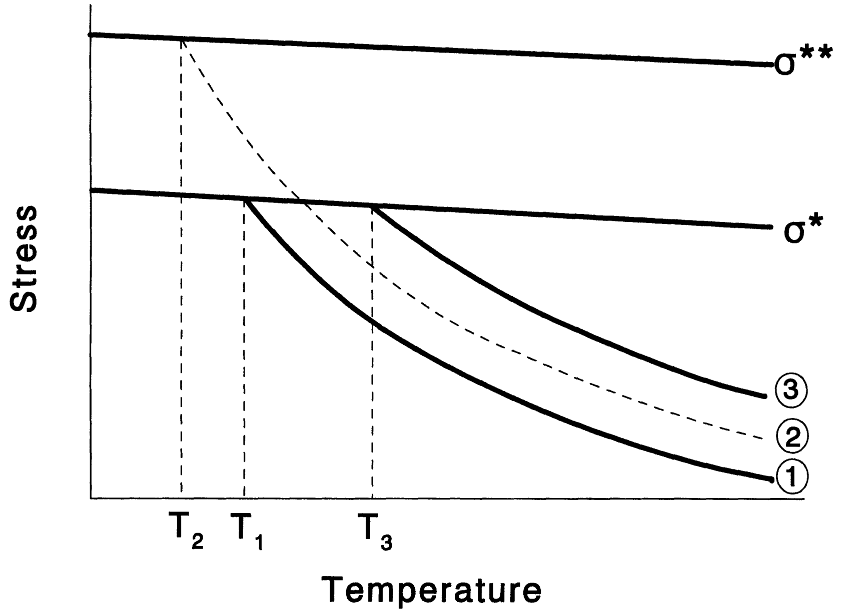

FIG. 11. Effect of hardening mechanisms on the brittle–ductile transition temperature *T*. Microscopic cleavage fracture stress of pure iron σ^*, of fine grained steel σ^{**}. rial. This is described quantitatively by fracture mechanics (Atluri *et al.*, 1992; Ernst *et al.*, 1992; Mughrabi, 1993; Flügge, 1996).

3.3 Creep Resistance

At high temperatures, at a constant load below the yield stress, the strain increases time dependently. After an initial phase I (Fig. 12), the creep rate is constant, state II. In the last state, III, the creep rate increases, and internally voids are formed until rupture is initiated. In state II the creep rate $\dot{\epsilon}$ is given by $\dot{\epsilon}\ (\sigma,T) = K\sigma^n$. The creep rate increases for a given load with increasing temperature. Diagrams as given in Fig. 12 for a defined steel are used for the design of components in industrial applications working under elevated temperature. Ferritic steels are designed to be used up to temperatures about 600 °C, austenitic steels up to about 800 °C, depending on the operating conditions. Ni-based alloys may be used up to 1100 °C, e.g., for turbine blades (Gemmil, 1992; Evans and Wilshire, 1993; Fabritius *et al.*, 1993).

3.4 Fatigue Strength

During cyclic loading the applied stress σ is varied with time t with $\sigma = \sigma_m + \Delta\sigma \times \sin\omega t$. Thus $\sigma_m + \Delta\sigma$ is the maximum and $\sigma_m - \Delta\sigma$ the minimum load. Also if $\sigma_m + \Delta\sigma$ is below the yield stress, after n cycles cracks with length a are formed, which grow with $da/dn = c\Delta K^m$. Here da/dn is the crack propagation rate, ΔK the stress intensity amplitude, and c and m are constants. According to Fig. 13, there is a stress level below which no damage occurs. This level must be known for technical applications; as a first approximation it is correlated to the yield stress. The stress level below which no damage occurs is influenced by residual stresses (Boller and Seeger, 1987; Löhe, 1996; Mitchell and Landgraft, 1993).

3.5 Corrosion and Oxidation Resistance

In aqueous electrolytes iron is dissolved as $Fe \rightarrow Fe^{++} + 2e^-$ (anodic reaction) with $2H^+ + 2e^- \rightarrow H_2$ (cathodic reaction). If oxygen is dissolved there results, in a neutral electrolyte, $O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$. The flow of the electrons e^- is the anodic and cathodic current, respectively. In a system of steel and a liquid corrosive environment, a potential is built up, giving the same current for the cathodic and the anodic reaction. If iron goes into solution as Fe^{++}, the corrosion loss L is given as $L = Ki_a$ mm/a (mm

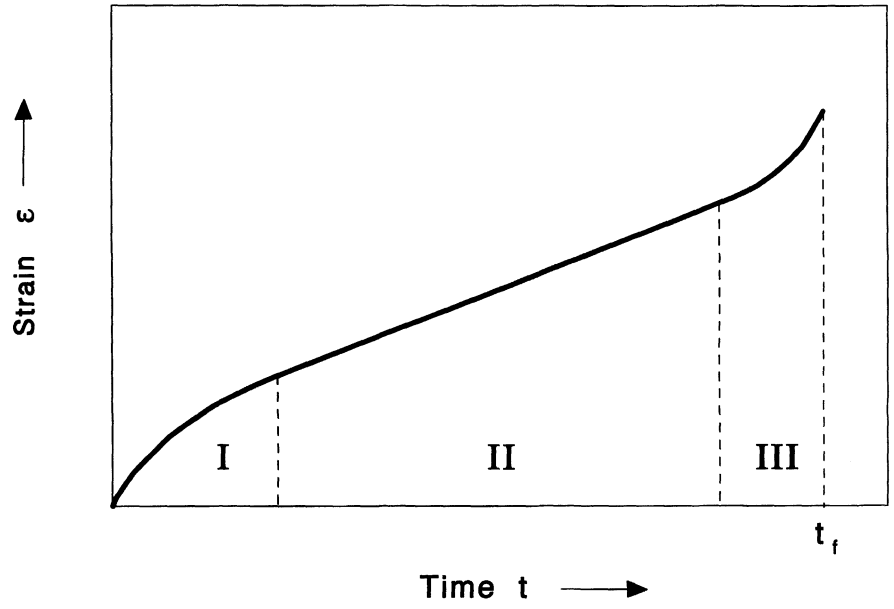

FIG. 12. Strain–time diagram for a constant load measured at elevated temperatures showing three stages of creep.

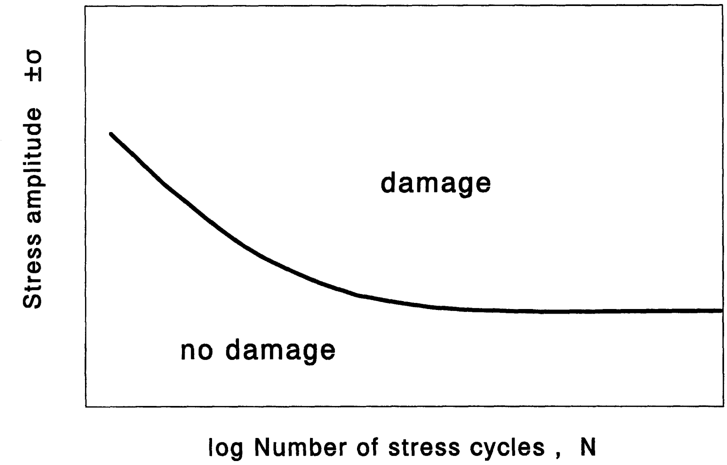

FIG. 13. Influence of cyclic loading with $\sigma < R_{p0.2}$ on lifetime.

per year); i_a is the anodic current density in μA/cm^2 (see Fig. 14), and $K = 0.01$ mm·cm^2/a·μA. In neutral water, dissolution of iron is very low, but in neutral water saturated with oxygen, the corrosion rate is about a factor of 1000 higher, giving a corrosion loss of 1.5 mm per year. In air, the corrosion loss is less because oxyhydrates and oxides are precipitated at the surface, forming rust. The corrosion rate increases with the number of dry/wet cycles at the surface and the presence of other molecules such as SO_2 in the air. As rust does not adhere, unprotected iron gets in repeated contact with the atmosphere, accelerating the corrosion rate. With addition of more than 12 wt% Cr, the steel forms a thin, adherent oxidic layer, which gives passivation against corrosion when oxygen is present. But as described above for water with and without oxygen, the corrosion rate and passivation depend strongly on the chemical composition

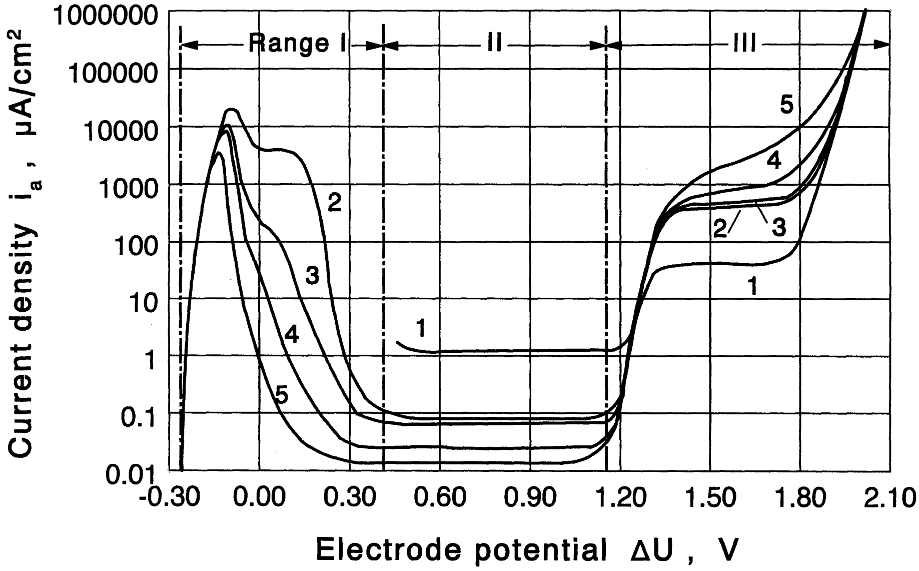

FIG. 14. Influence of Cr on the anodic current density i_a as a function of electrode potential with passivation in range II (Engell and Grabke, 1992). Weight percentages of Cr: Curve 1, 2.8; curve 2, 9.5; curve 3, 12; curve 4, 14; curve 5, 18.

of the steel and the corrosive environment. Figure 14 shows that for steels with high chromium content there is a range of a potential between 0.5 and 1.1 V over which the current density i_a is very low. In weak oxidizing agents such as water, this potential is built up, giving passivation. For this condition, a mechanically damaged passivation layer will heal immediately. For other combinations of steel and corrosive environment, passivation may be metastable, and damage of the passivation layer will start corrosion. In acid solutions without oxygen the potential may be at lower values, and, therefore, other steels must be used; see Sec. 9.4. In sulfuric and phosphoric acid, there is no passivation, but with choice of an appropriate steel the corrosion loss may be no more than 0.3 mm per year.

At high temperatures unalloyed steel is oxidized by an atmospheric environment, forming scale. At temperatures above 550 °C, the growth rate of the scale is high, because of the high diffusivity of vacancies and cations. In ferritic steels with more than 13 wt% Cr, a protective layer of $(Fe,Cr)_2O_3$ is formed, growing only slowly, for the diffusivity of oxygen, cations, and vacancies is much lower than in steels without Cr. Adding about 7 wt% Al gives, at temperatures above 900 °C, a similar protection by the formation of an Al_2O_3 coating. Ferritic steels with 25 wt% Cr, 1.5 wt% Al, and 1 wt% Si or austenitic steels with 25 wt% Cr, 20 wt% Ni, and 2.5 wt% Si can be used up to temperatures of 1150 °C in air. Again, if there are still other gases present containing S, CO, or H_2, the composition of steels must be adapted. Heat-resisting steels are used for such parts as radiation tubes, furnace equipment, and devices for dust cleaning at elevated temperatures. The steel used must be adapted not only to the temperature but also to the environmental gases (Engell and Grabke, 1992; Weßling and Oppenheim, 1993; Craig and Anderson, 1994).

4. MICROSTRUCTURES OF STEELS WITH α–γ–α TRANSFORMATION

4.1 Definitions

Steels are polycrystalline materials. A crystallite is a region of a phase with uniform crystal orientation separated from others by grain boundaries (*q.v.*). In addition, the microstructure includes lattice defects, such as vacancies and dislocations (see POINT AND EXTENDED DEFECTS IN CRYSTALS). For a quantitative calculation of properties according to Sec. 3, the microstructure must be described quantitatively by parameters given in Fig. 15 for each crystallite and each defect. Describing a crystallite, a typical example for a lattice structure is α iron; its chemical composition is the content of Mn, Cr, Si, and so on, which sometimes must be given as a function of location. Volume fraction, shape, and size distribution of the α-iron grains, combined with their arrangement and—except for spheres—the orientation distribution define the spatial distribution of α iron in the material. If the orientation of the lattices of the α-iron grains is not random, the crystallographic texture must be described additionally. Microstructures with texture are produced—among other applications—to optimize the properties of sheets for deep drawing. For a complete characterization, this description ac-

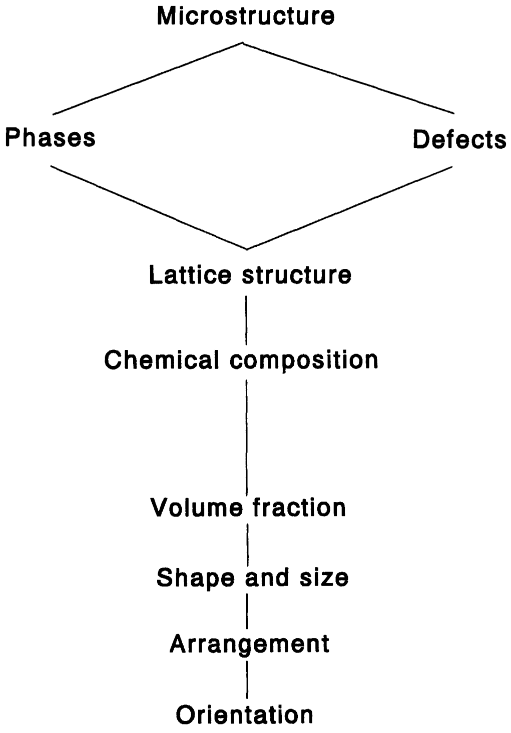

FIG. 15. Parameters for a quantitative description of microstructures.

cording to Fig. 15 must be realized for all phases and defects building up the microstructure of a material. This is quite impossible with the methods we have today. Therefore, for example, the properties of α iron or that of pearlite are measured as given by its alloy content, its density of dislocations, and the interlamellar distance of ferrite and carbide within the pearlite (see Sec. 4.3). The change of properties of a ferritic–pearlitic steel can then be described by the different volume fractions of ferrite and pearlite. The compromise is thus to measure only that detail of the microstructure, in this case the volume fraction of ferrite and pearlite, that has the decisive influence on the property under investigation (Exner and Hougardy, 1988; Diaz, 1994; Hatherley and Hutchinson, 1994).

In steel microstructures, γ iron is referred to as austenite and α iron as ferrite. The term cementite only is used for the carbide $(Fe,M)_3C$. M stands for Mn or Cr, or another metal. Induced by the metallurgical processes—see Sec. 8.1—steel contains some nonmetallic inclusions. These are small particles of sulfides as (Fe,Mn)S and oxides such as SiO_2 or Al_2O_3 (Cubberly *et al.*, 1985; Nicholson and Thornton, 1992; Hougardy, 1994, pp. 231–236).

4.2 Austenite

The microstructure of austenite is characterized by annealing twins that form parallel lines within the grains; see Fig. 16. The curved black lines are the grain boundaries. The picture is taken of an austenitic steel. In plain carbon steels austenite is not stable at room temperature; see Fig. 6.

4.3 Ferrite and Pearlite

In pure iron, austenite, cooled from 1000 °C to room temperature (see Fig. 6), transforms to ferrite by nucleation and growth, which are diffusion-controlled processes; see SOLIDS, DIFFUSION IN. Ferrite has a more irregular shape of grains than austenite; see Fig. 17. The grains may be pure iron or a solid solution of iron with alloying elements such as Cr, Mn, Si, etc. In any case, the carbon concentration within the ferrite is in the range of a few ppm. Figure 17 may also be the microstructure of a ferritic steel.

In a plain carbon steel with 0.5 wt% C at 600 °C, according to Fig. 6, ferrite and the carbide Fe_3C are in equilibrium. The driving force for the transformation is proportional to the free energy of the transformation ΔG with $\Delta G = G_A - (G_p + G_b)$. Here G_A is the free energy of the austenite, G_p that of the mixture of ferrite and carbide, and G_b is the energy stored in the phase boundaries. According to thermodynamics, in equilibrium there is a minimum of grain-boundary energy; i.e., there exist only one grain of ferrite and one grain of cementite. But under technical conditions with high cooling rates, this equilibrium is not established. Instead a lamellar arrangement of ferrite and cementite, called pearlite, is formed, which gives the highest transformation rate from austenite, Fig. 18. The maximum growth rate is found if $\lambda(T) = 4\gamma/[\Delta S_V(T_E)(T_E - T)]$, where λ is the interlamellar distance, γ is the phase-

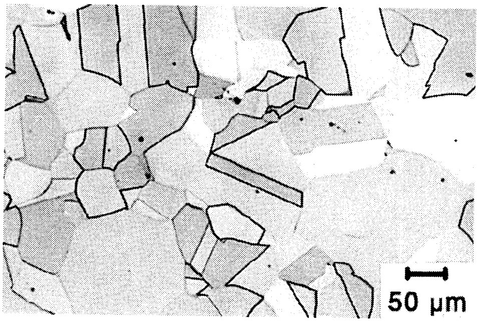

FIG. 16. Microstructure of austenite in an austenitic steel.

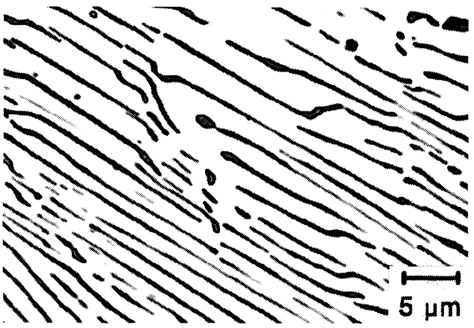

FIG. 18. Pearlite, a mixture of ferrite (white) and cementite (black). Plain carbon steel with 0.7 wt% C, austenitized 800 °C 15 min, cooling with $t_{8/5}$ = 10 000 s (see Sec. 7.2) etched with sodium picrate (for the etching, see Petzow, 1994).

boundary energy between ferrite and cementite, ΔS_V is the entropy change per mol iron at the equilibrium temperature T_E, and T is the actual temperature.

4.4 Martensite

At very high cooling rates, and at temperatures in general below 400 °C, martensite is formed from austenite without diffusion by an ordered movement of atoms over short distances. This movement is defined by the crystal structures of γ iron and α iron. The transformation propagates with the speed of sound. The carbon dissolved in the austenite remains in solution during martensite formation, which leads to very marked lattice distortions, i.e., solution hardening. Therefore, the hardness of martensite increases with the carbon content (see Fig. 19, line *a*). Of all possible microstructures of any steel, martensite has the highest hardness and yield stress. The transformation of austenite to martensite starts if the temperature goes below the martensite start temperature M_s at which ΔG is increased to a value sufficient to allow lattice distortion induced by the formation of martensite. At a given temperature, the energy available for lattice distortion is limited. Therefore, martensite formation is incomplete; its volume fraction is time independent. Depending on the alloy content, the temperature M_s varies between

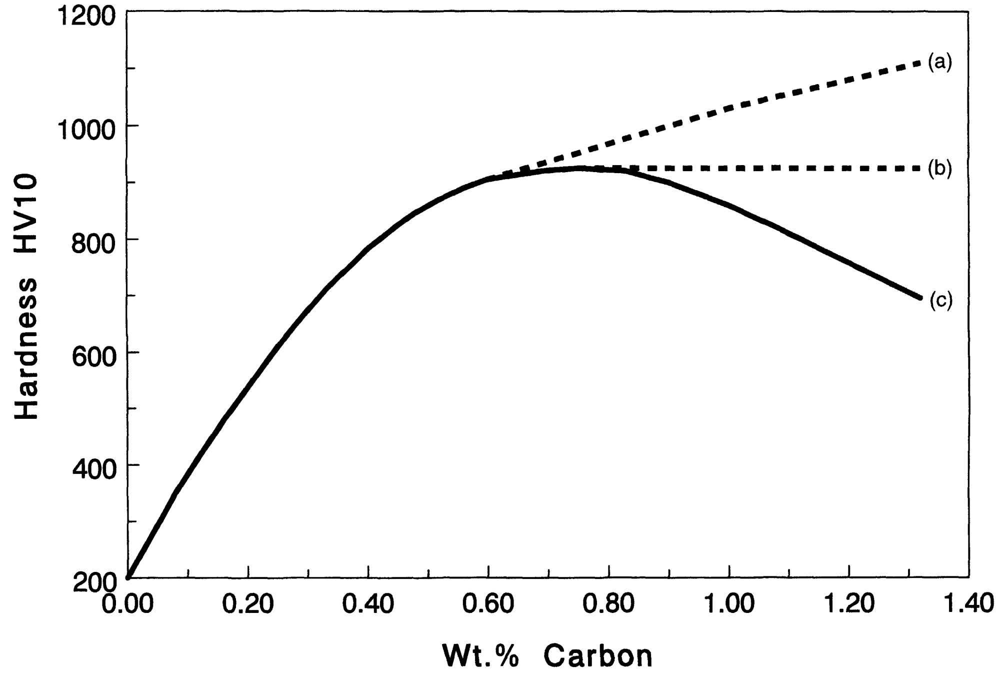

FIG. 19. Hardness of martensite as a function of carbon content of steels. Curve a, pure martensite (estimate); curve b, martensite and undissolved carbides; curve c, martensite and retained austenite. For details, see text.

450 and ~ −100 °C. Steel must be cooled down to approximately 250 °C below M_s to transform 99% of the austenite to martensite. The temperature M_s decreases with carbon content. A first approximation yields $M_s = 550 - 350c_c - 40c_{Mn} - 20c_{Cr}$, the alloy content being in wt%. If the martensite finish temperature M_f is below room temperature, after quenching there is some retained austenite. In plain carbon steels with more than ~0.7 wt% C, the hardness after quenching decreases with increasing carbon content according to the increasing volume fraction of soft retained austenite coexisting with the hard martensite (Fig. 19, line *c*). The transformation of austenite to martensite is associated with a volume increase of 0.5%–1%, depending on the alloy content. In steels with a carbon content >0.2 wt%, martensite forms mainly plates with a high density of twins, which appear needlelike in the polished section. Figure 20 shows a microstructure that is unusual for steels but makes evident the shape of the martensite. This plate martensite has a low toughness relative to its yield stress. In steels with a carbon content <0.2 wt%, a different morphology, lath martensite, is formed with a high density of dislocations. This kind of martensite has very good toughness properties (Schulz-Beenken and Hougardy, 1989; Olson and Owen, 1991; Wayman and Perkins, 1993).

4.5 Bainite

Bainite is formed by nucleation and growth at a temperature between that of the transformation of austenite to ferrite and pearlite and that of its transformation to martensite. The transformation is partly diffusion controlled and partly proceeds by a lattice-shearing mechanism similar to that for martensite. By the combination of these mechanisms, at a temperature just above M_s, the transformation of austenite to bainite is much more rapid than the transformation to pearlite at the same temperature. Below M_s, of course the formation of martensite is the fastest reaction, but after the formation of martensite, transformation may continue with the formation of bainite. Bainite is an arrangement of ferrite and carbides detectable by optical microscopy only, if formed at high transformation temperatures (Fig. 21). The ferrite within the bainite is supersaturated in respect to carbon and has a high dislocation density. After formation just above M_s, the bainite is very fine (Fig. 22)

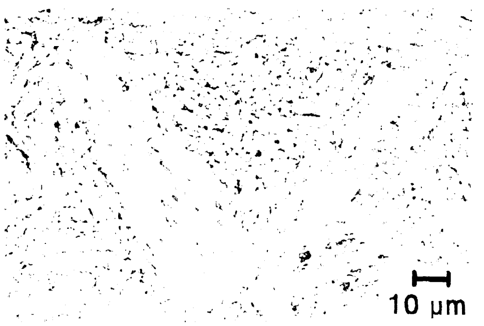

FIG. 21. Coarse bainite, formed at 500 °C. Steel with 0.2 wt% C and 2 wt% Mo, austenitized 950 °C 15 min, etched with nital.

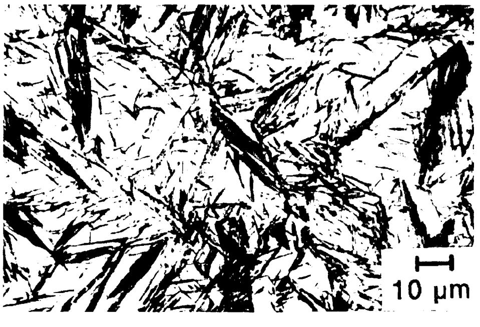

FIG. 20. Martensite (needles and plates) and retained austenite (gray) in a plain carbon steel with 1.0 wt% C. Austenitized 850 °C 15 min, water quench. Etched with nital.

and cannot be distinguished from tempered martensite; see below (Bhadeshia, 1992).

4.6 Microstructures after Tempering

The carbon held in solution within the lattice on martensite formation can form carbide precipitates by diffusion, if the temperature is increased above the temperature at which martensite is formed. Precipitation takes place more rapidly and to a greater extent as the annealing temperature is increased. The microstructure is very similar to that of bainite formed at low temperatures (Fig. 22). In alloyed steels, carbides like *M*C and M_7C_3 as described in Sec. 2 may precipitate from a supersaturated solid solution during tempering. These carbides or carbonitrides have a size ranging from a few nanometers to 100 nm, giving a precipitation hardening; see Fig. 23. The mechanisms of microstructure formation described above also apply to alloy steels, which may have several carbide phases and precipitations during cooling (Schrader and Rose, 1989; Speich, 1992).

5. GRAIN SIZE AND RECRYSTALLIZATION

During the production process, steels are deformed to get the final shape by rolling or forging in the austenite range, according to Fig. 6 between about 850 °C and 1200 °C. At least for plain carbon steels, above 900 °C, recrystallization of austenite is often so rapid that it can take place during the deformation process. This is referred to as dynamic recrystallization (see RECRYSTALLIZATION, DYNAMIC), in contrast to static recrystallization, which only occurs after deformation ceases (see RECRYSTALLIZATION, STATIC). Figure 24 shows, as an example, the fundamental influence of the grain size before deformation, deformation temperature, and degree of deformation on the final austenite grain size. The addition of alloying elements, e.g., Nb and Ti, which form carbonitrides, can cause recrystallization in the austenite domain to be slowed down so much that, after the deformation by rolling, the steel can be transformed during cooling without recrystallization. This is called thermomechanical treatment (TMT). It requires very precise control of the temperature–time curve, especially at the end of a rolling operation. The

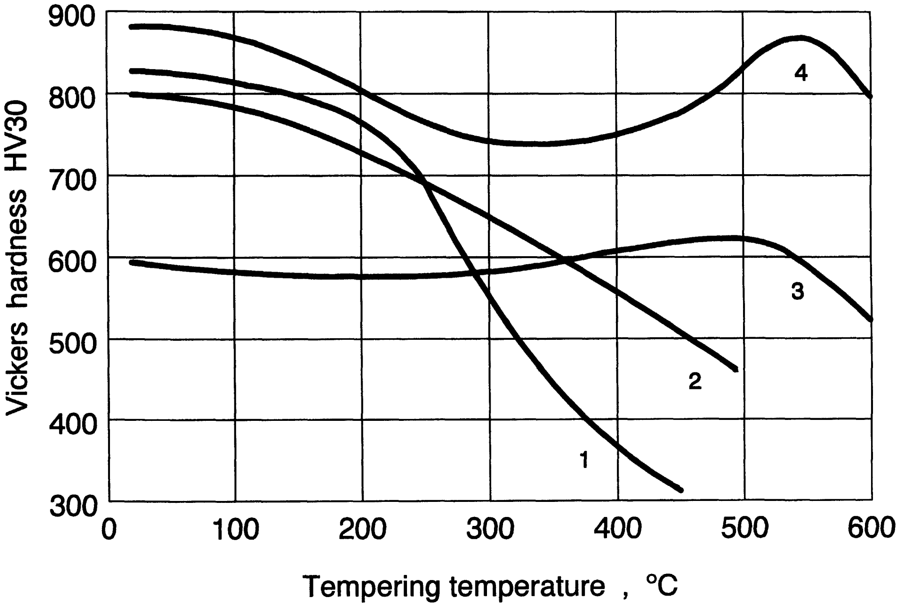

FIG. 23. Hardness as a function of temperature of tempered martensite. Curve 1, plain carbon steel with 0.80 wt% C; curve 2, steel with 0.8 wt% C, 0.6 wt% Cr, and 0.2 wt% V; curve 3, steel with 0.4 wt% C, 5 wt% Cr, 1.5 wt% Mo, and 1.0 wt% V; curve 4, steel with 0.9 wt% C, 4 wt% Cr, 5 wt% Mo, 2.0 wt% V, and 6.5 wt% W.

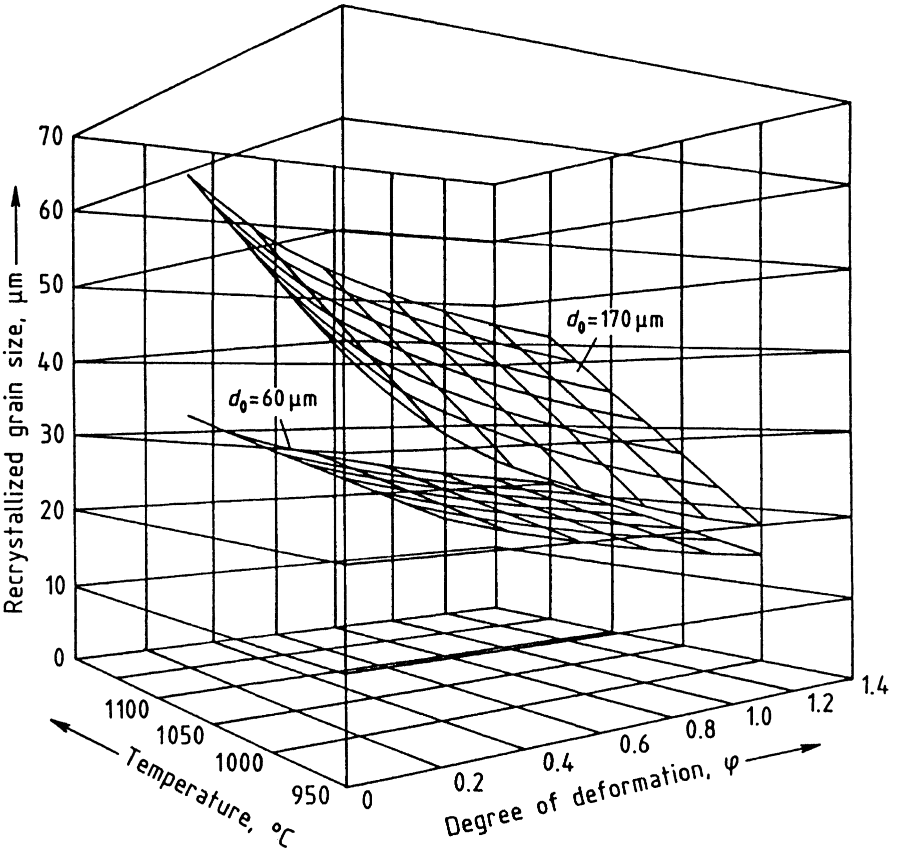

FIG. 24. Grain size of austenite as a function of deformation and initial grain size d_0. Steel with 0.038 wt% C, 1.8 wt% Mn, 0.28 wt% Mo, 0.07 wt% Nb, and 0.009 wt% N. $\varphi = \ln(h_0/h)$, h_0 initial thickness (Kaspar and Pawelski, 1985).

transformation of an unrecrystallized austenite proceeds more quickly than that of a recrystallized austenite, giving extreme fine-grained microstructures. The chemical compositions of the steels must be adapted to the parameters of the available equipment, which determines feasible cooling rate and degree of deformation (Kozasu, 1992).

Lathes and plates of martensite grow across the whole austenite grain. Therefore, the needle length of martensite is defined by the austenite grain size. The grain size of the other microstructures decreases the lower the transformation temperature. Additionally, by repeated austenitization and transformation, the average grain size of the microstructures can be reduced. This is not possible for ferritic and austenitic steels, which have no transformation. In these steels grain refining can be realized only by recrystallization.

6. CORRELATIONS BETWEEN MICROSTRUCTURES AND PROPERTIES

From Sec. 3 it follows that a fine-grained, homogeneous microstructure gives a high ratio of toughness to strength. If the yield stress is increased by precipitation of particles (see Sec. 3.1.4), and the arrangement of particles is not homogeneous, plastic deformation starts locally where particle distances are greatest, giving inhomogeneous gliding. In general, all elements influencing the mechanical properties (see Table 3) must be as homogeneous as possible. The best microstructure in this sense is tempered martensite. Plate martensite has a yield stress very close to the microscopic cleavage fracture stress (see Fig. 11) and, therefore, an insufficient toughness. With increasing tempering temperature, hardness and yield stress steadily decrease (see Fig. 23) and the toughness increases, and this enables any desired intermediate stage to be produced between the properties of martensite and that of a soft-annealed microstructure with a uniform carbide distribution; see Sec. 4.6. Bainite formed at temperatures just above M_s has a similar microstructure and, therefore, similar properties as tempered martensite. Compared with the very fine distribution of carbides in tempered martensite, the carbide distribution in bainite formed at high temperatures or in pearlite is much more inhomogeneous, and therefore the toughness-to-strength ratio of those microstructures is much less than for tempered martensite. For pearlite itself, toughness is improved with decreasing interlamellar distance. Ferrite has excellent toughness but limited strength. Unfortunately, in technical production, microstructures containing ferrite and pearlite are the cheapest ones. Therefore, for practical applications the microstructure is chosen that for a defined level of yield stress gives a sufficient toughness for the purpose in mind. These often are ferritic–pearlitic microstructures, especially if additional properties as weldability must be guaranteed. Other properties are also improved by a homogeneous microstructure. If by a heat treatment or a welding process of a steel with 13 wt% Cr locally a carbide $(Fe,Cr)_3C$ or $(Fe,Cr)_7\ C_3$ is precipitated, the Cr concentration in the surrounding matrix may be lowered below 10 wt% Cr, causing local corrosion, while farther away the matrix has 13 wt% Cr and is corrosion resistant; see Fig. 14. By adding elements such as Nb, carbon is precipitated as NbC, and the steel is stabilized against corrosion induced by precipitation of carbides containing Cr (Tenckhoff and Vöhringer, 1990; Dahl, 1992; Hougardy, 1992, pp. 461–503; Pickering, 1992, pp. 41–94).

7. DESCRIPTION OF THE α–γ–α TRANSFORMATION

If it is intended to produce microstructures such as ferrite, pearlite, bainite, or martensite by a heat treatment, first austenite is formed, which is cooled, typically by quenching, to get the desired microstructure.

7.1 Austenitization

During heating, austenite forms by nucleation and diffusion-controlled growth. Figure 25 illustrates how austenite is formed isothermally from an arrangement of ferrite and cementite in a plain carbon steel with 0.45 wt% C. The first line Ac_{1b} (see also Fig. 7), which is reached at 800 °C after 0.4 s, represents the formation of 1 vol% γ iron (austenite). The last line Ac_3, reached at 800 °C after 2000 s, represents the formation of 99 vol% γ iron. The area $\alpha + \gamma + M_3C$ corresponds to the three-phase equilibrium in Fig. 7. After a short annealing time, the carbon is still enriched in positions where carbides have gone into solution; away from these positions the carbon concentration is

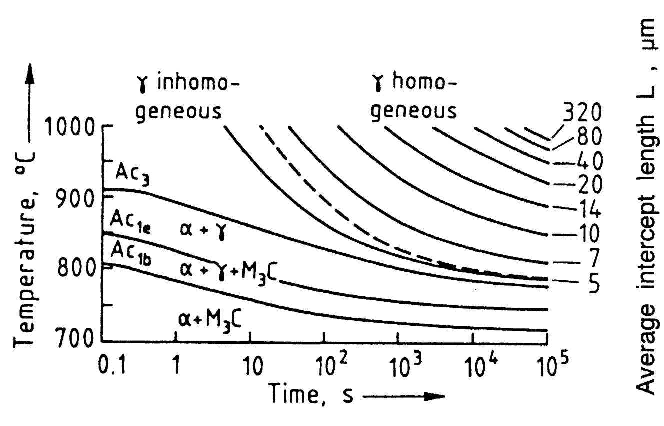

FIG. 25. Diagram for isothermal austenitization for a plain carbon steel with 0.45 wt% C including lines for equal grain size of austenite (Hougardy, 1990).

less than the average value of the steel, giving insufficient or inhomogeneous hardness after quenching (see Fig. 19). With increasing temperature and annealing time, the austenite becomes homogeneous (dotted line in Fig. 25), but the grain size, given as average intercept length, increases (see Fig. 25). In practice, austenitization is carried out at a temperature 30–50 °C above the temperature Ac₃, as defined in the relevant standards; see Sec. 10 (Orlich and Rose, 1973; Orlich and Pietrzeniuk, 1976; Hougardy, 1992, pp. 167–200; Ohtani, 1992).

7.2 Transformation during Cooling

On cooling austenite, the microstructures ferrite, pearlite, bainite, and martensite are formed as described in Sec. 4. A diagram such as that presented in Fig. 26 is called a time–temperature transformation diagram for isothermal transformation (TTT diagram). It shows the time for the beginning and the end of the transformation of austenite in the pearlite and the bainite range as a function of temperature. Thus, at 550 °C, the transformation begins after 1 s, with formation of ferrite. It ends with the transformation to pearlite and is complete after 6 s. Below 480 °C, the transformation of austenite to bainite is superseded by a transformation to pearlite. The maximum in the transformation rate to pearlite at 550 °C occurs because the nucleation rate passes through a maximum as the temperature decreases, while the growth rate, as only diffusion-controlled process, continuously decreases with decreasing temperature. At 300 °C, 50 vol% martensite is formed followed by a transformation to bainite.

Industrial heat-treating processes to produce a microstructure usually involve continuous cooling, for cost reasons. Figure 27(a) shows the time–temperature transformation diagram for continuous cooling (CCT diagram) of a plain carbon steel. As the cooling curves are all similar, they may be characterized by quoting the duration of the cooling between 800 and 500 °C ($t_{8/5}$) or the cooling time to 500 °C [Fig. 27(b)]. For each cooling curve the temperatures and times can be read off for the start of the formation of fer-

rite, pearlite, bainite, or martensite and also for the end of the transformation process.

Figure 27 shows that with $t_{8/5} = 2 \times 10^4$ s first ferrite forms, with carbon content fairly close to that predicted from the phase diagram. This ferrite forms either as a film on the austenite grain boundaries or—in steels with low carbon content—as separate grains (Fig. 28). Its properties mainly correspond to those of pure iron. After the formation of ferrite, pearlite is formed (Fig. 27). The volume ratio of ferrite to cementite in the pearlite can fluctuate over a wide range, as can be seen from the volume fractions [Fig. 27(b)]. As the volume fraction of carbide is constant, with decreasing volume fraction of ferrite precipitated first, the volume fraction of ferrite within the pearlite must increase. Nevertheless, pearlite in Fig. 28 is so fine that the ferrite-cementite lamellae are below the resolution. Figure 27 shows that $t_{8/5}$ must be <1.2 s to get martensite alone. CCT diagrams are valid only for the time–temperature sequence given in the diagram. But nevertheless, the time–temperature sequence for a technical heat treatment of a steel, to get a desired microstructure, can at least be estimated. For a more detailed calculation see Sec. 8.3.10. Collections of transformation diagrams for different steels are available (Rose and Hougardy, 1972; Van der Voort, 1991).

8. TECHNICAL STEEL PRODUCTION AND TREATING

8.1 Steelmaking

Steelmaking starts with the reduction of iron ores, which contain oxides (Fe_2O_3 or Fe_3O_4), e.g., by the reaction $2Fe_2O_3 + 3C = 4Fe + 3CO_2$. Instead of carbon also CO or H_2 is used, derived from coke, oil, or gases. Additional C is used to produce the high temperature necessary to get liquid iron by $C + 2O \rightarrow CO_2$. But depending on the costs of energy, a lot of process variants have been developed working between the liquid and the solid state of iron. Reduction with coke in the blast furnaces at present has the highest capacity. It produces hot iron or, after solidification, pig iron with about 4 wt% C. In the steelmaking process this carbon content is reduced to the desired level in the steel, between 1 and 0.01 wt%, by injection of pure oxygen in a vessel containing 200–400 *t*. The oxygen is forced into the melt with a Mach number about 2 causing a high turbulence. Hence a large contact surface is achieved giving a high reaction rate. In this vessel also 40%–60% scrap is added—the correct figure depends on details of the process—giving the excellent recycling of steel. In this process the combustion of accompanying elements such as C and Si in the iron, coming from the blast furnace, produces the necessary heat. In electric steel process the heat required for the process is obtained from an electric arc or a plasma. In electric arc furnaces only scrap or a mixture of scrap, hot iron, and pig iron can be melted. Hot and pig irons contain more or less phosphorus and sulfur that must be removed to a level less than 0.1 wt%. This is realized by slags containing CaO, SiO_2, MnO, and FeO. Volume, temperature, and composition of the slag are decisive for the level of sulfur and phosphorus achieved. If the carbon is blown down to the desired level, the oxygen content of the melt is reduced by reactions such as $xM + yO \rightarrow M_xO_y$, where M stands for Mn, Si, Al. This deoxidation reaction may be combined with vacuum degassing. After deoxidation, alloying elements such as chromium are added, which are highly sensitive for oxidation. This treatment is generally realized in a ladle outside the steelmaking furnace, called secondary metallurgy. Using slags with special compositions combined with the vacuum metallurgy, carbon contents down to 10 ppm, sulfur contents of 10 ppm, and contents of phosphorus down to 20 ppm including levels of oxygen < 10 ppm, nitrogen < 20 ppm, and hydrogen < 0.8 ppm can be achieved. Of course these low levels of clean steels are very expensive and realized

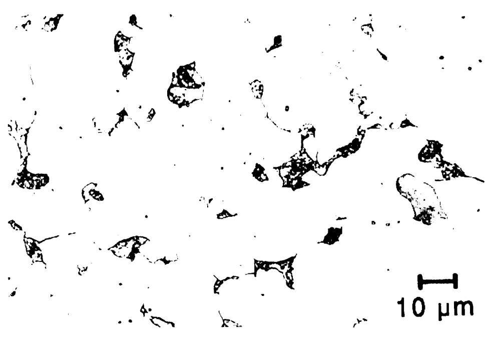

FIG. 28. Ferrite (white) and pearlite (dark). Plain carbon steel with 0.15 wt% C. Austenitization 950 °C 15 min. Cooling with $t_{8/5} = 100$ s.

only as far as really necessary for the steel quality (Nilles, 1992; Nicholson and Thornton, 1992; Deo and Boom, 1993; Oeters, 1994).

The result of steelmaking is—ideally—a liquid, homogenous solution of iron with the alloying elements. In practice, before pouring, steel contains more or less small (<1 μm) nonmetallic inclusions like (Fe,Mn) S, Al_2O_3, or SiO_2 from the desulfurization and the deoxidation reactions. On casting, the homogeneous nature of the liquid steel should be maintained in the solid solution. The aim of casting is the production of a dense, homogeneous ingot without discontinuities and with a smooth surface. But during solidification the density of steel increases; i.e., the specific volume decreases. This and the formation of dendrites, growing into the melt like lances, favor the formation of holes. Because of the change of equilibria with temperature during solidification, segregation occurs; see SOLUBILITY, ALLOYS. In equilibrium, these differences are equalized by diffusion in the solid state, but under technical conditions the time necessary for this diffusion is by far too small. In the solid steel the chemical composition may differ locally from a minimum value, e.g., of 0.7 wt% Cr to a maximum value of 1.5 wt% Cr. In the final microstructure this may be seen as banded structure.

For solidification, steel is poured into ingot molds via a refractory-lined ladle. During solidification the solubility of oxygen in steel decreases, and by reaction with the carbon in solution, CO gas bubbles are formed, partly entrapped between the growing dendrites, partly ascending, forming bubbles at the rim that gave the name "rimming steel." No CO bubbles arise after the content of oxygen is lowered by deoxidation below the solubility in the solid state, giving "killed steels." Today continuous casting is used for a wide range of steel grades and dimensions. In this process, steel is cast in an oscillating mold, and the strand is withdrawn continuously from the mold. Near net shape casting is in development. The limitation is that in casting the final dimension, the surface has not such a high quality as after rolling, internal discontinuities are not closed, and the microstructure is "as cast" concerning local segregation. All these disadvantages can be eliminated by rolling, but this should be reduced to a minimum to save costs (Schrewe, 1989; Hiebler, 1992; Hammerschmid, 1993; Irving, 1993).

8.2 Rolling

By rolling, the cast slab dimension is reduced to the final dimension, e.g., of a sheet. Internal discontinuities are closed, and a smooth surface is produced. Before starting, the slabs are heated in a furnace to reduce temperature gradients remaining from casting and to establish a unique temperature across the whole section. This is done under air as an environmental gas, which produces oxidation of the steel at the surface. Before rolling, the scale, with thickness up to 1 mm, is removed and with it all casting defects on the surface. The starting temperature of hot rolling is between 1150 and 1250 °C; the finishing temperature depends on the final dimension and on the desired state of recrystallization. To get sufficient reproducibility in dimensions below about 2 mm final thickness, cold rolling is used, e.g., for deep drawing sheets used for car bodies with a final thickness about 0.7 mm (Täffner, 1993; Wiegels, 1994).

8.3 Heat Treating

8.3.1 Influences on Transformation. In technical heat treatments temperature–time cycles are often used that do not follow isothermal or continuous cooling as implied in the TTT or CCT diagrams. Therefore, a general representation of transformation behavior is possible only by computer simulation of the transformations (see Sec. 8.3.10). The following treatment is mainly restricted to the principles of a continuous cooling process, as in Fig. 27.

The addition of alloying elements enables the temperature M_s as well as the time required for a transformation in the pearlite and bainite ranges to be shifted within wide limits. In a plain carbon steel, 25 vol % ferrite and 75 vol % pearlite are formed during a cooling from 800 to 500 °C within 30 s; see Fig. 27. By addition of alloying elements such as Mn, Cr, Ni, but also C, the diffusion-controlled transformation to ferrite, pearlite, and bainite becomes much slower. This effect is used to design tool steels, which on air cooling of sections of up to 30 mm diameter form only martensite. However, in any given application, steels with the lowest possible alloy contents are used for reasons of cost (Davis, 1991; Hougardy, 1992, pp. 461–503; Othani, 1992; Vöge, 1993).

8.3.2 Austenitization. The industrial austenitization of heat-treated engineering steels 30–50 °C above Ac_3 usually leads to the formation of a homogeneous austenite with small grain size; see Fig. 25. Special treatments are necessary for tool steels (see Sec. 9.3).

8.3.3 Effect of Dimensions. Industrial cooling operations are usually carried out continuously in air or liquid media. Figure 29 shows the comparison of temperature–time curves for the outer and inner zones of two cylinders with different diameters. The temperature differences between the zones

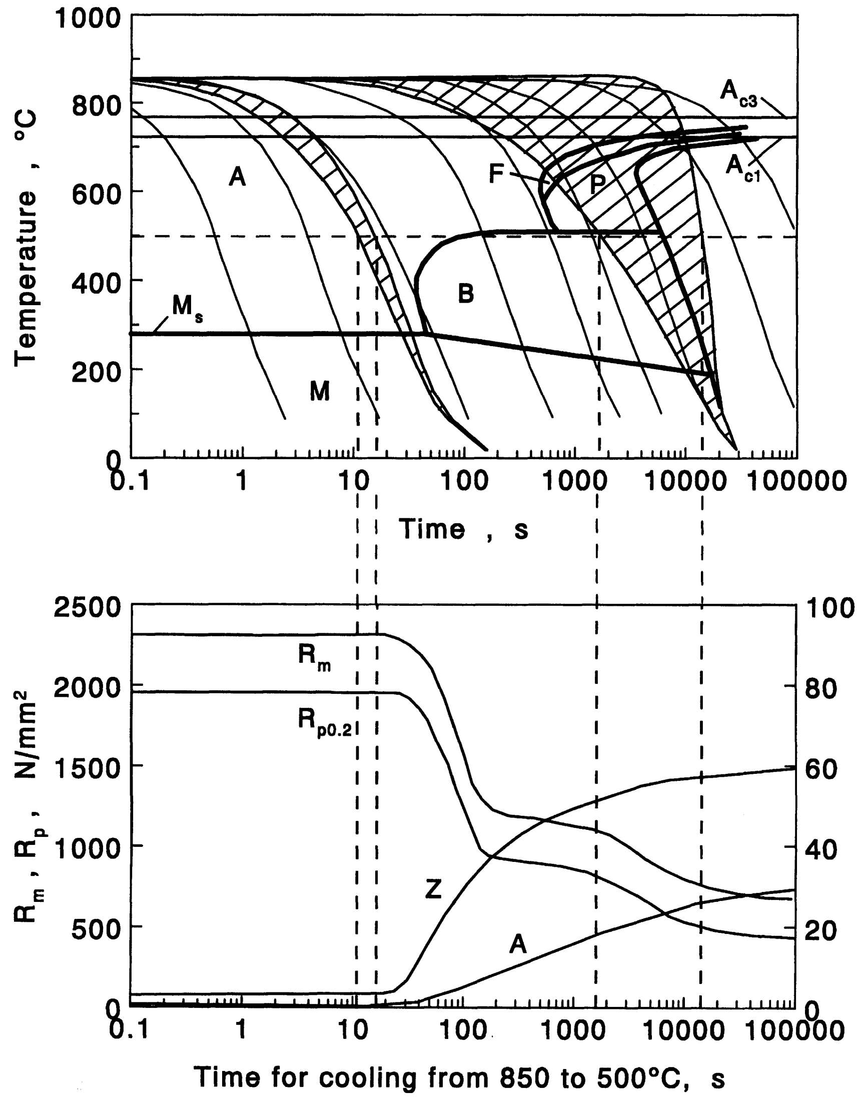

FIG. 29. Upper: Transformation diagram for continuous cooling of a steel with 0.5 wt% C, 1 wt% Cr, and 0.25 wt% Mo. Dashed area: cooling curves for surface (left line) and core (right line) of cylinders with 20 (left area) and 1000 (right area) mm diameter, respectively, during oil quenching. Lower: results of tensile tests (see Sec. 3.1) for different microstructures plotted as function of the cooling time $t_{8/5}$ (Hougardy, 1990).

can be very great, especially during quenching. This leads to the formation of different microstructures in the outer and inner zones. An increase in the cooling time $t_{8/5}$ decreases the proof stress $R_{p0.2}$ and increases the elongation after fracture A and reduction in area after fracture Z (Fig. 29). Figure 30 shows how the hardness varies over the cross section of cylinders of different steels. For an oil-quenched plain carbon steel, maximum hardness is not reached, even near the surface. Maximum hardness with a purely martensitic microstructure can be obtained only near the outer surface for steel *c*. This effect limits the generation of only one microstructure across a whole section (Hougardy, 1992, pp. 461–503; Liscic *et al.*, 1992).

8.3.4 Transformation in the Pearlite Range. A transformation in the lower region of the pearlite range is used in wire patenting. This forms pearlite with very small interlamellar distances, which has very good wire-drawing properties. As the diameter is small, the transformation can be carried out isothermally. Other applications include the production of rails, in which pearlite is formed at low temperatures from the heat of rolling. In plain carbon steels, a ferritic–pearlitic microstructure can be produced by air cooling (Fig. 27). The corresponding heat treatment is known as normalization. Delayed cooling is necessary with alloy steels, especially in thin sections, if a ferritic–pearlitic microstructure is desired (Othani, 1992; Williams, 1992).

8.3.5 Transformation in the Bainite Range. In bainitization, a microstructure consisting only of bainite is produced by an isothermal transformation (Fig. 26). Continuous cooling cannot in principle give a 100% bainitic microstructure; see Fig. 27. The fine microstructures formed in the lower region of the bainite range (see Fig. 22), have a favorable combination of toughness and yield stress, often matching the properties of tempered martensite (Pickering, 1992, pp. 41–94).

8.3.6 Transformation in the Martensite Range. Martensite can be obtained by cooling so rapidly that the formation of microstructures of the pearlite and bainite range is suppressed, and this is simply called hardening. Plain carbon steels must usually be water-quenched to achieve martensite at

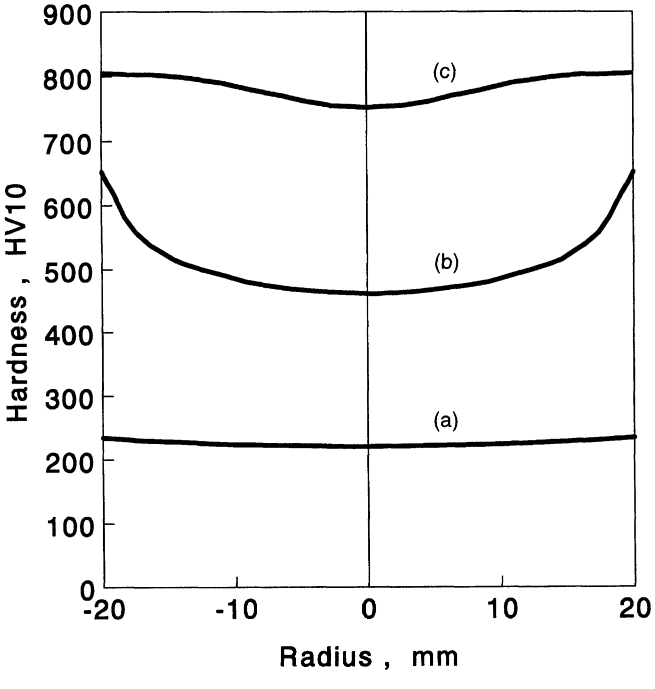

FIG. 30. Variation of hardness across the diameter for three steels, after oil quenching of cylinders with 40 mm diameter. Curve a, plain carbon steel with 0.45 wt% C; curve b, steel with 0.41 wt% C and 1 wt% Cr; curve c, steel with 0.50 wt% C, 1 wt% Cr, and 0.25 wt% Mo.

least at the surface. Alloyed steels may be cooled more slowly by quenching in oil or cooling in air. Because of the high rates of cooling obtained by water quench, large temperature differences between the outer and inner regions of large workpieces occur (see Fig. 29), so that stresses and residual stresses are produced that can induce cracking and distortion. These hardening cracks impose a limit to heat-treatment processes involving rapid cooling of large or complex workpieces (Fletcher, 1989; Totten, 1992; Hauk *et al.*, 1993).

8.3.7 Quenching and Tempering. In general, quenching and tempering consists of hardening followed by annealing, which can give any yield stress between that of martensite and that of a soft-annealed microstructure; see Fig. 23. The relationship between tempering temperature and yield stress is known for many grades of steel. After tempering of martensite, the arrangement of carbides in the ferrite is very uniform and homogeneous; therefore, this process gives very good toughness properties for a given yield stress (Pickering, 1992, pp. 41–94; Speich, 1992).

8.3.8 Annealing for Spheroidization. In components of small dimensions fabricated of high-alloy steels, microstructures of appreciable hardness are produced even with air cooling, which can give machining problems. To get a microstructure suitably weak for machining and to get a standardization of shape and size of carbides before the final heat treatment of tool steels, the carbides are often spheroidized by means of a prolonged annealing process at temperatures just below Ac_1; i.e., coarse carbides are formed in the ferrite (Fig. 31). This process, annealing for spheroidizing, can be accelerated by an imposed temperature oscillation around A_1 or by a prior deformation process (Gasterich *et al.*, 1993).

8.3.9 Surface Hardening. For technical applications, it is often desired that the surface of a workpiece should be hard, in order to provide wear resistance. However, as the load is comparatively small, the average yield stress across the total section can be low. Therefore, often only the surface zone is hardened by two methods (Stevens and Davies, 1992; Tacke *et al.*, 1993; Grosch *et al.*, 1994):

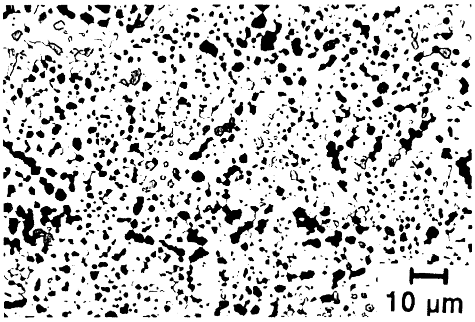

FIG. 31. Microstructure after spheroidize annealing. Plain carbon steel with 1.3 wt% C. White, ferrite; black, carbide. After austenitization 850 °C 15 min and water quench annealed at 720 °C for 8 h. Etched with sodium picrate.

1. Only the surface zone of a workpiece is austenized and hardened by quenching; the interior temperature does not exceed Ac_1. After tempering at about 150 °C, a hardened and tempered high-strength surface zone is produced, surrounding a comparatively ductile core. A process of this kind currently used is induction hardening.
2. In case hardening, steels with about 0.15 wt% C are placed in a carbon-containing medium at 900–950 °C, and carbon diffuses into the surface. The most common technique is gas carburization, which is very easy to control to get a carbon content of about 0.8 wt% at the surface, giving maximum hardness after quenching (see Fig. 19). This treatment is used for gear wheels for motor vehicles and sometimes for roller bearings. Surface hardening in very thin layers can be produced by nitriding, chromizing, and boronizing.

By such treatments, residual compressive stresses are usually produced at the surface, and this also improves fatigue resistance. Because of the internal stresses, the properties of the workpiece can no longer be described by the properties of the material only (Hauk *et al.*, 1993).

8.3.10 Simulation of Heat Treatment. For transformable steels, there are limitless possibilities for transforming austenite in the pearlite, bainite, or martensite range, using controlled temperature–time regimes. Finding an optimum temperature–time regime to produce a desired microstructure, and hence the specified properties, requires long-time experience or a very large number of experiments. Models based on empirical equations or equations based on physical principles have been developed that can be used to calculate the progress of transformation (SteCal 2.0; Hougardy and Yamazaki, 1986; Denis *et al.*, 1992; Bodin and Segerberg, 1992; Inden *et al.*, 1992; Kirkaldy, 1993). Similarly, knowing the temperature and degree of deformation, grain sizes of the austenite after heat treatment of particular grades of steel can be calculated (Kern and Schriever, 1993). If the mechanical properties of the individual microstructure of a steel are known, the final properties produced by a given process can also be calculated (Degenkolbe *et al.*, 1992). In this way, a proposed process can be simulated in advance. Some models are now available but must still be improved. For defined conditions, the properties can be calculated from the chemical composition (Pickering, 1992, pp. 41–94). Additionally, the residual stresses arising during a heat treatment can be estimated (Fletcher, 1989; Hougardy, 1991).

9. STEEL GRADES

Besides mechanical properties, cold workability, weldability, resistance to corrosion, or machining properties may be important for an application. The classification of steels is not simple, for one steel may be used for different applications. Therefore, one classification focuses on the chemical composition, another on the application (e.g., tool steels), and a third on the microstructure (as example, ferritic or austenitic steels). Compilations can be found in standards, or in the general literature. In the following only some examples are given, to have an impression of the range of chemical compositions used and the variety of properties achieved (Pickering, 1992, pp. 41–94; Jäniche *et al.*, 1993; Kalla, 1994).

9.1 Low-Alloy Steels

Low-alloy steels are used as structural steels with a yield stress <355 N/mm^2. If the yield stress is >355 N/mm^2, the steels are often called high-strength low-alloy steel. These steels are supplied with the mechanical properties as standardized; they are not heat treated by the customer. In most cases these steels are designed for welding (Hougardy, 1992, pp. 504–534; Houldcroft, 1992; Olson *et al.*, 1993). Levels of yield stress up to about 500 N/mm^2 can be achieved with ferritic–pearlitic or bainitic microstructures by normalizing or thermomechanical treatment. The chemical analysis is in the range <0.2 wt% C, 0.1–0.6 wt% Si, and 0.5–1.8 wt% Mn. For a yield stress up to 900 N/mm^2, steels have additions of Cr, Ni, and Mo and are delivered in a quenched and tempered condition. Especially sheets from these steels are protected during the production process by different coatings against corrosion (Stevens and Davies, 1992; Tenhaven *et al.*, 1992; Müsgen *et al.*, 1993).

9.2 Heat-Treated Engineering Steels

The main characteristic of heat-treated steels is the chemical composition, which is a decisive factor for the formation of austenite and its transformation during cooling. The first point is the grain size of austenite during austenitization that can be controlled by precipitation of AlN and/or Ti(C,N). These fine-grained steels allow complete austenitization of parts with great thickness without formation of a coarse grain. As described in Sec. 6, for a defined yield stress the optimal ratio of toughness to strength is achieved by quenching to martensite and tempering. But to produce martensite across the whole section of a part has two limitations. One is the finite thermal conductivity, the other is the presence of stresses arising during quenching in water. Therefore, if the maximum toughness must be achieved in thick cross sections, the ferrite, pearlite, and bainite transformation must be shifted to long times by appropriate alloying. In this case, martensite is produced even at modest cooling rates in the center of the part. As far as it is allowed by the desired combination of toughness and strength necessary for an application, steels with a ferritic–pearlitic or bainitic microstructure are taken or surface hardening is used. Therefore, the chemical analysis ranges from 0.45 wt% C and 0.7 wt% Mn for small dimensions to a steel with 0.35 wt% C, 0.5 wt% Mn, 2 wt% Cr, 0.4 wt% Mo, and 4 wt%

Ni for heavy parts and case-hardening steels with <0.2 wt% C, <1 wt% Mn, 1.8 wt% Cr, 0–0.5 wt% Mo, and 0–3.5 wt% Ni (Naylor and Cook, 1992; Schauwinhold, 1994).

9.3 Tool Steels

Tool steels have a wide range of applications such as cold and hot forming and cutting as well as die casting of metals and polymers. Therefore, their strength and hardness must be above that of the materials being formed or cut. Besides a high wear resistance, a minimum of toughness must be realized. For the selection of chemical analyses, the same principles are valid as for steels designed for heat treatment. The transformation characteristic must be adapted to the diameter to get the formation of martensite through the desired part of the diameter. A further aspect used in design of one subset of tool steels is to increase the content of carbides from maximal 11 vol% in eutectoid steels up to 30 vol%, to improve the abrasive resistance including the formation of hard carbides such as WC. Carbides such as $(Fe,Cr)_7C_3$, $(Fe,Cr)_{23}C_6$, MoC, and VC precipitate at higher temperatures than Fe_3C (see Fig. 23), giving better high-temperature strength. Nevertheless, according to the application the hardness of tool steels varies from about 200 HV 10 for glass-mold steels to about 900 HV 10 for machining tools. For some applications it is most efficient to apply surface hardening including carburizing and nitriding or surface coating by, e.g., TiN.

In general, tool steels are quenched and tempered. Quenching a plain carbon tool steel with 1 wt% C from 1000 °C would give retained austenite and a decrease in the hardness according to Fig. 19. In service, this austenite will transform under the service load, and the dimension of the tool would change, which is not tolerable. Therefore, plain carbon tool steels are austenitized at temperatures 30–50 °C above Ac_1, just to get about 0.8 wt% carbon in solid solution in austenite, sufficient to get the maximum hardness of martensite according to Fig. 19. In alloyed steels, the method is, in principle, the same, but the temperature for austenitization varies with the steel grade and may be as high as 1200 °C to get sufficient carbon in solid solution as for high-speed steels. Besides the effect on carbide formation, the alloying elements reduce the transformation rate, allowing oil quenching or even air cooling to still produce martensite at the surface. This slow cooling is important to prevent cracking or dimensional changes during quenching and tempering of thick sections. For the effect of tempering on hardness, see Fig. 24. During this tempering—in alloyed steels it is repeated several times—the volume fraction of retained austenite is also reduced.

Carbon tool steels have carbon contents between 0.6 and 1.4 wt% C. Applications include cutting blades, hammers, and axes. Steels containing up to 5 wt% Cr, 1.5 wt% Mo, 1 wt% W, and 0.5 wt% V are used for cold-work dies. The chemical analysis is adapted to get a transformation characteristic that allows oil quenching or air cooling to get martensite. Applications include reamers, punches, drills, and in some cases plastics molding dies. Heat-resistant die steels are needed—for instance for Al die casting or hot deformation and plastics molding—and have up to 0.5 wt% C, 9 wt% Cr, 3 wt% Mo, 2 wt% V, and 8 wt% W. High-speed steels, used for cutting metals, e.g., by turning, drilling, or punching, have up to 1.4 wt% C, 4 wt% Cr, 10 wt% W, 9 wt% Mo, 4 wt% V, and 10 wt% Co. Quenched and tempered, they have a hardness of about 65 HRc.

Maraging steels contain about 18 wt% Ni, 8 wt% Co, 4 wt% Mo, and 0.5 wt% Ti. After quenching, the microstructure is a lath martensite with a proof stress of about 500 MPa. During tempering about 500 °C there is a precipitation hardening by Ni_3Mo and Ni_3Ti within the martensite, giving an increase of yield stress to about 2000 MPa. Applications include parts with extreme high strength as well as parts for plastics and light metal molding for high accuracy (Rayson, 1992; Wilmes *et al.*, 1993).

9.4 Stainless Steels

In corrosion resistance mainly the concentration of alloying elements in solid solution is important; see Sec. 3.5. The other parameters of the microstructure have much less influence, except some effects in stress corrosion and hydrogen-induced corrosion. The combination of alloying elements needed to get the desired corrosion resistance is in concurrence with that necessary to guarantee other properties such as strength, toughness, ease of forming, and weldability. In general, there are martensitic steels with 0.3–1 wt% C and about 15 wt% Cr, giving a 0.2% proof stress up to 700 N/mm^2 as used for some knife blades or spindles. Ferritic steels with 15–30 wt% Cr and <0.1 wt% C have a proof stress between 300 and 500 N/mm^2 and a tensile strength between 500 and 700 N/mm^2 and are used, for instance, for heat exchangers under very aggressive conditions. Carbon contents of <0.003 wt% in these steels give an improved toughness. Austenitic steels with about 18 wt% Cr and more than 9 wt% Ni have a 0.2% proof stress of about 300 N/mm^2 and a tensile strength of about 700 N/mm^2. This indicates the great work hardenability of these steels. Applications range from kitchen equipment to vessels to resist organic and sulfuric acids in the chemical industry. Lastly, there are ferritic–austenitic steels, which have a 0.2% proof stress of about 400 N/mm^2. All steels containing martensite and ferrite may be sensitive to temper embrittlement at temperatures above 400 °C. Therefore, for high-temperature application in general, austenitic steels are used.

For the corrosion resistance of a steel with more than 12 wt% Cr, see Sec. 3.5 and Fig. 14. In solutions with Cl^- a nonuniform corrosion loss, pitting or a crevice corrosion, occurs. Also crevices between stainless steel and nonconductors, such as plastics or ceramics, may cause this corrosion. The higher the so-called "pitting corrosion equivalent," PRE, the higher the critical pitting and crevice corrosion temperature with PRE = wt% Cr + 3.3 × (wt% Mo) + 30 × (wt% N). Ferritic steels are used with 30 wt% Cr and 5 wt% Mo including some Nb and low C and N contents to prevent precipitation of Cr carbide (Truman, 1992; Chawla and Gupta, 1993; Heinemann *et al.*, 1993; Davis, 1994; Bogaerts and Agema, 1995).

10. STANDARDS

To make trade and application of steels more easy, there are standards that describe the chemical analyses as well as the properties of a steel grade. Further standards define testing methods. International standards are ISO (International Standardization Organisation) and ECISS (European Committee for Iron and Steel Standards). The standards are published as ISO *xxx* and EN *xxx*, respectively, where *xxx* stands for a number. There are national standards published by ASTM (American Society for Testing and Materials) and AISI (American Iron and Steel Institute) in the U.S.A. or JIS (Japanese Institute for Standardization) in Japan. In general, a steel with, for instance, 0.25 wt% C, 1 wt% Cr, and 0.25 wt% Mo standardized according to an EN standard is similar to but not identical with a steel standardized according to an ASTM standard having similar chemical composition. The reason for this divergence is that a new steel in general is developed following the demands in one country and standardized for the application by a national standard. If application is widened, an international standard may be sensible, but now the demands of different countries and a wider field of application must be taken into concern, leading to changes compared to the first national standard. Or, the steel remains of national interest only, and there is no international standard at all. A comparison of steel grades is summarized in various books (International Technical Information Institute, 1990; Verein Deutscher Eisenhüttenleute, 1994; DIN Handbooks, 1993; Wegst, 1995; Unterweiser, 1993; ASTM, 1994).

INTRODUCTION

In the beginning of the 19th century, there was only one heat-driven machine (prime mover), the steam engine. However, the components of such a steam engine were rather primitive with items such as the boiler constructed of inadequate materials like cast iron or bronze. Many accidents occurred with those pressure vessels made of such brittle material, even when the pressure level was only atmospheres. Therefore, several inventors were looking to replace the working medium of water with air in order to avoid storing so much energy.

The invention in 1816 by Robert Stirling, a Scottish clergyman, was the most remarkable. It was one of the first practical regenerative engine cycles. Figure 1 shows the 1816 patent drawing of the first hot-air engine, later called a Stirling engine. The first model built according to the pictured scheme was in use by 1818 pumping water from a quarry.

Hot-air engines were used in considerable numbers during the 19th century. It was

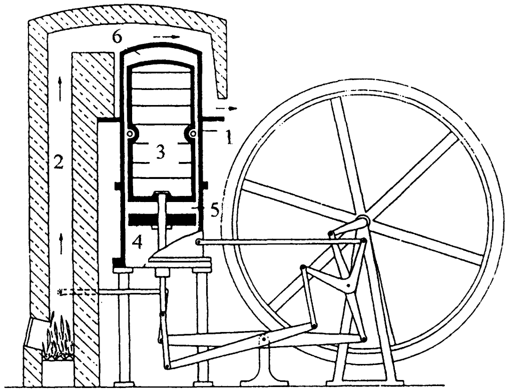

FIG. 1. A long, vertical cylinder 1 is heated on top by the flue gases from the furnace 2. The bottom is cooled either with water or by convection with the atmosphere. The cylinder contains the displacer 3, centered by small rollers, and the power piston 4. As the displacer moves up and down, air in the cylinder 1 passes alternately from the cold space 5 and the hot space 6 via a regenerator and back. The regenerator (not shown here) is in the annular space between the displacer and the cylinder and probably consisted of thin wire wound around the displacer. The air is thus alternately in the cold and the hot spaces and undergoes temperature and pressure variations that cause it to perform work on the piston 4.

even thought, for a time, that this type of prime mover might rival the steam engine as a source of power. However, the comparative weight and volume of the device per unit of delivered power were huge. It is no small wonder that the internal combustion engine that arrived in the late 19th century, with its much greater specific power and higher efficiency, displaced this hot-air engine completely—despite a certain charm that the latter possessed.

A renewed interest came in 1938 when N. V. Philips in the Netherlands started an investigation of very small generator sets and chose the hot-air engine for that purpose. Later Philips was involved in much bigger engines, up to 300 kW per cylinder, during 40 years of research and development. In 1954 the name "hot-air engine" was changed to "Stirling engine" with the introduction of the rhombic-drive engine. This device used hydrogen as the working medium, which rendered the reference to "hot air" irrelevant.

During that time, N. V. Philips acquired several licensees to the technology worldwide including General Motors and Ford in the United States, M.A.N. and M.W.M. in Germany, and United Stirling in Sweden. When the last licensee, Ford, terminated its activity in 1979, N. V. Philips also stopped their research. Stirling Thermal Motors, Inc., a small developing company in the United States, continued the work of Philips on a small scale. In addition, many universities and companies all over the world became interested in the Stirling engine and made worthy contributions to the technology, many times supported in the United States by the Department of Energy (DOE) or National Aeronautics and Space Administration (NASA). Japan also became interested in this cycle and has produced numerous articles describing its research work and prototypes.

1. PHYSICAL AND TECHNICAL PRINCIPLES

The Stirling engine is a prime mover much like the well-known gasoline and diesel engines, where heat of sufficiently high temperature is transformed into mechanical energy. The Stirling engine, however, is based on a closed cycle containing three heat exchangers—heater, regenerator, and cooler—with a variable volume on the cooler side called "cold space" and a variable volume on the heater side called "hot space." These variable volumes are caused by pistons moving with a phase difference to each other. An amount of pressurized working gas, such as helium, is captured between the pistons and manipulated by this arrangement in such a way that heat is supplied to the gas through the wall of the heater; the hot gas is allowed to expand into the hot space, then is pushed through the regenerator where it yields heat in order to be compressed in the cold space at lower temperature. The heat developed by compression is transported through the wall of the cooler into the surrounding space, or ambient. The mechanical energy obtained by expansion at high temperature is always larger than the mechanical energy needed for compression at lower temperature. Therefore, an excess of mechanical energy is obtained.

Because the Stirling engine is based on a closed cycle, its characteristics are different from those of the internal combustion engine. The Stirling engine has a multiple-fuel capability since the heat supplied to the hot heat exchanger can come from any source of sufficiently high temperature. Another advantage occurs when fossil fuel is burned in a well-designed burner. The emissions can be very low since the burner is at atmospheric pressure and exhaust-gas recirculation can be easily applied.

Operational characteristics of a Stirling engine include silent operation because the pressure variation within the engine is sinusoidal (having no sharp peaks) and because combustion is continuous. Another effect of the sinusoidal pressure variation is the constant torque occurring within an engine with four or more cylinders.

Performancewise, an ideal Stirling engine offers the highest efficiency possible, matching that of a Carnot-cycle device operated between the same temperature limits, along with higher specific power. The power is proportional to the pressure of the working gas. With a compact drive design and modern materials, the specific power can be the same as that of the modern gasoline engine. Finally, fast power control is now available with recently developed stroke control of the pistons, making it possible to change the power levels in a fraction of a second.

There have been some issues in the development of Stirling engines, however, that have stopped the technology from reaching the manufacture point. With the closed, pressurized system, the cycles are more difficult to build and operate than an open system. The pressurization of the Stirling engine also makes accessibility to the machine difficult, requiring that the working gas must be vented before there is access to the engine.

An ideal Stirling design requires an oil-free cycle since a lubricating oil and its byproducts will block the gas flow in the heat exchangers. Formerly, the pistons were lubricated with small amounts of oil, but this has shown to be explosive when combined with air as the working medium. Hydrogen has proven to be the best working medium with respect to the performance of the Stirling cycle, and it does not adversely react with any lubrication oil that may be required. However, hydrogen is flammable outside the engine and, if used in the engine, it slowly diffuses through the hot metals of the components. More work has to be done to reduce this leakage.

Piston leakage also has a great influence on the performance of the engine and creates a need for great attention to be given to the seals in this area.

1.1 The Ideal (Isothermal, Reversible) Stirling Cycle

1.1.1 Harmonic Volume Variations, Finite-Volume Regenerator. The ideal Stirling cycle is embodied in the configuration shown schematically in Fig. 2. Two variable-

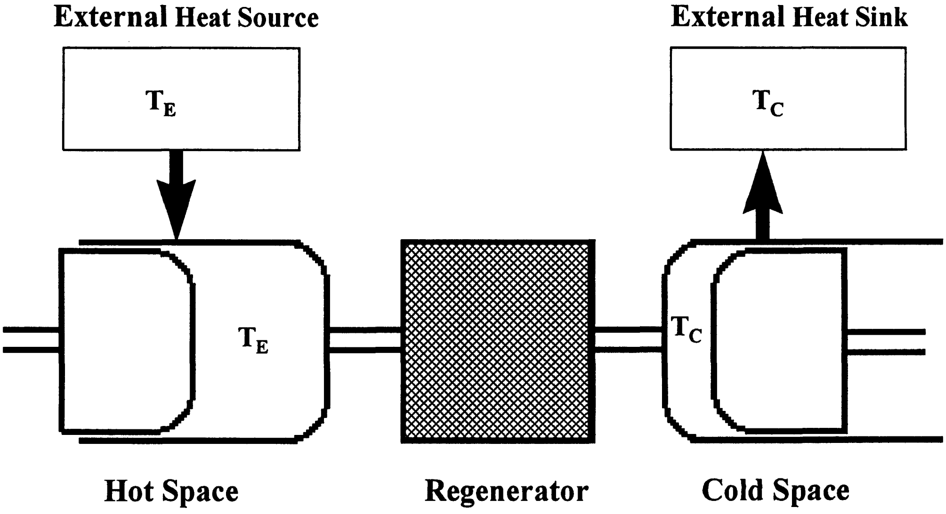

FIG. 2. Stirling engine configuration (schematic).

volume chambers, a cold space and a hot space, are interconnected via a regenerative heat exchanger called a "regenerator." The two pistons undergo harmonic motion in such a way that the volume variation of the cold space lags in phase behind the volume variation of the hot space. The cold and hot spaces are maintained at constant temperatures, T_C and T_E, respectively, by exchanging heat with external hot and cold reservoirs at the same temperatures, T_C and T_E, respectively. The ideal cycle occurs when

1. the gas in the cold and hot spaces undergoes isothermal thermodynamic processes;
2. the regenerator is ideal, i.e., its matrix is in perfect thermal contact with the gas; and
3. the gas is frictionless and flows without dissipating energy so that the instantaneous pressure is uniform throughout the enclosure.

The cold-space volume lags behind the hot-space volume by a phase angle ϕ ($0 < \phi < \pi$) as shown in Fig. 3. This ensures that during expansion (when the total volume increases) most of the gas is in the hot space and during compression (when the total volume decreases) most of the gas is in the cold space, as shown in the figure. Thus, the bulk temperature, and hence the pressure during expansion, is higher than it is during compression, and a surplus of mechanical work is produced by the machine. At the same time, the amount of heat absorbed by the gas from the outside through the enclosure wall during the expansion process is greater than that rejected by the gas to the outside during the compression process. In this way the Stirling engine converts heat supplied from the outside into work done on the pistons by the enclosed gas.

In contrast to other possible representations of the ideal Stirling cycle, the compression and expansion processes here are not separate from the transfer processes: During expansion some of the gas is transferred from the hot space to the cold space, and vice versa during compression. Gas that is

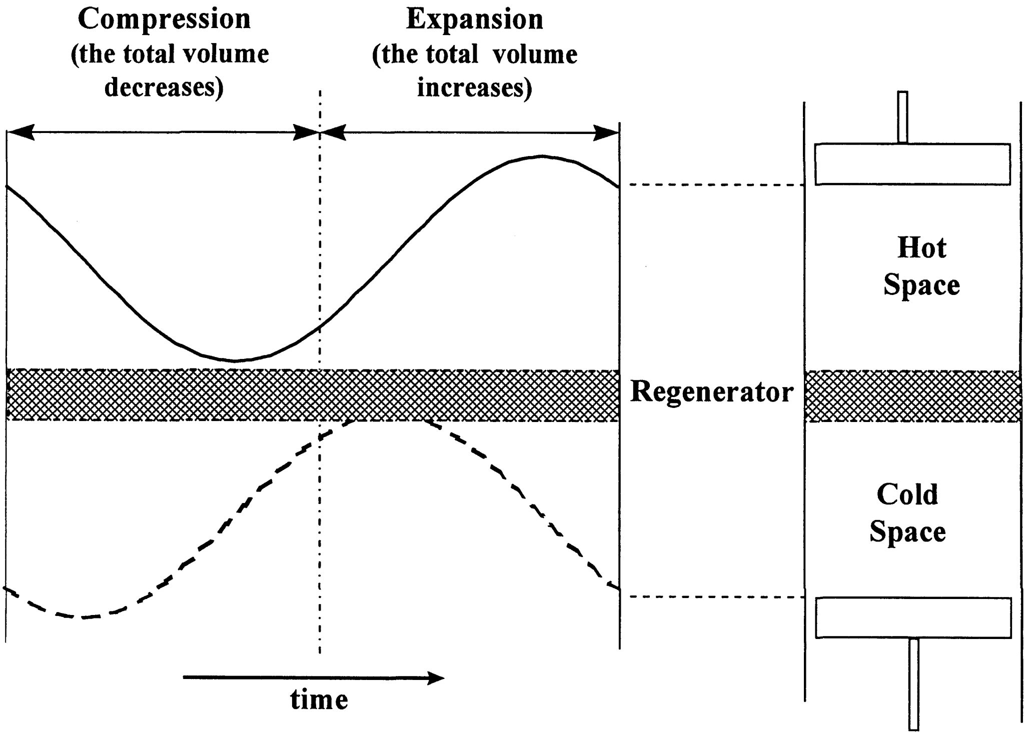

FIG. 3. Piston motion and volume variations in an ideal cycle.

transferred from the hot space to the cold space is cooled en route by storing its heat in the regenerator. This heat is picked up by the gas later in the cycle during the transfer from the cold space to the hot space.

With an ideal regenerator, the processes of storing heat and picking it up are thermodynamically reversible because they occur with no temperature difference between the heat-exchanging elements—the gas and the regenerator matrix. Similarly, the isothermal compression and expansion processes in the variable-volume chambers are reversible because the gas is (ideally) in thermal equilibrium with the enclosure walls with which it exchanges heat. Finally, mechanical equilibrium also prevails throughout the cycle because, with nondissipating gas flow, the instantaneous pressure is uniform throughout the enclosure. In consequence of the thermal and mechanical equilibria, the ideal Stirling cycle is a reversible thermodynamic cycle that converts heat into work at the ideal Carnot efficiency: Efficiency = (net work output)/(heat absorbed from the external hot source) = $1 - T_C/T_E$.

The ideal regenerator prevents the net transfer of enthalpy from the hot space to the cold space: With an ideal regenerator, the enthalpy flow through any imaginary partition in the regenerator, integrated over the part of the cycle during which the flow direction is, say, from the hot space to the cold space, is exactly equal to that integrated over the balance of the cycle when the flow direction is reversed. Therefore, all the heat Q_E absorbed by the gas in the hot space at the source temperature T_E over a cycle is converted into positive work W_E. Similarly, all the work W_C done on the gas in the cold space over a cycle is converted into heat Q_C, which is rejected by the gas in the cold space at the sink temperature T_C, as shown in Fig. 4. Therefore, with $Q_E = W_E$ and $Q_C = W_C$, the net work can be calculated as

$$W_{\text{net}} = W_E - W_C = Q_E - Q_C. \tag{1}$$

Because the compression and expansion processes are isothermal and reversible, the ratio Q_C/Q_E is equal to the absolute temperature ratio T_C/T_E, and the energy conversion efficiency, η, for the ideal Stirling cycle is given by

$$\begin{aligned} \eta &= W_{\text{net}}/Q_E = (Q_E - Q_C)/Q_E \\ &= 1 - Q_C/Q_E = 1 - T_C/T_E. \end{aligned} \tag{2}$$

Different elements of gas in the Stirling cycle undergo, in general, different cyclical processes. Clearly, some of the gas that is in the hot space when the hot space is at its maximum volume will never reach the cold space. Rather, some gas elements will forever shuttle back and forth between the hot space and the regenerator, others will shuttle between the cold space and the regenerator, and some may go completely through the re-

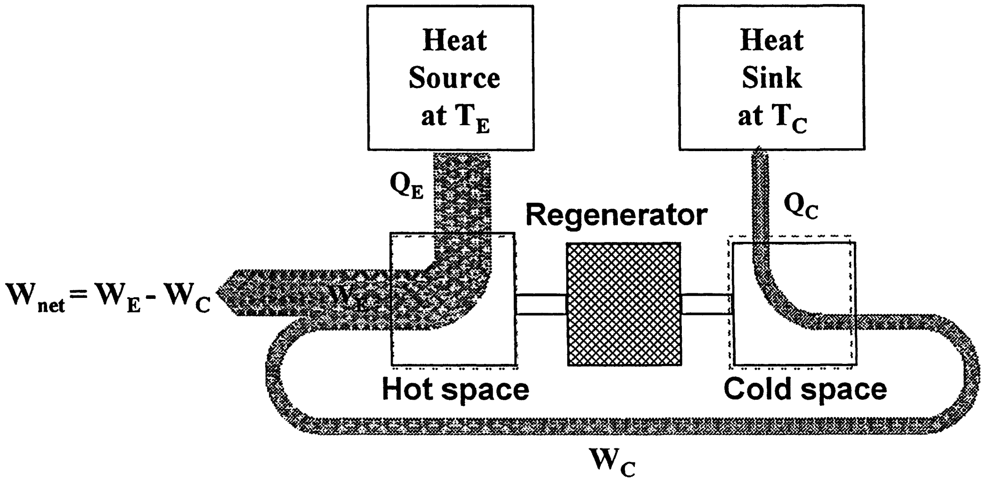

FIG. 4. Energy flow in an ideal Stirling engine.

generator. This is simply a consequence of the heat exchangers containing finite volumes of gas.

1.2 The "Real" Cycle

1.2.1 Adiabatic Variable Volumes with Dedicated Heat Exchangers. In all but the smallest Stirling engines, the wetted areas, the surface areas that allow heat to transfer to the ambient, in the variable-volume chambers are too small to maintain isothermal processes in these chambers. To accommodate the required heat transfer, the hot and cold spaces are each split into variable-volume portions in which little heat exchange takes place and fixed-volume portions where heat exchanges with the outside takes place, as shown in Fig. 5.

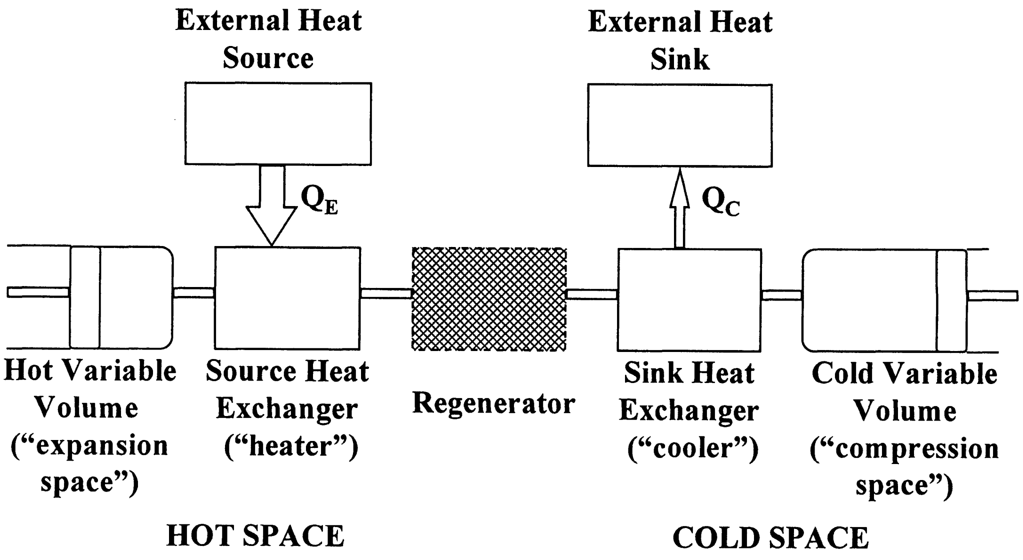
The thermodynamic processes in the heat exchangers are ideally isothermal, while in the variable-volume chambers they are practically adiabatic. This makes the cycle no longer reversible. Because the heat exchangers are fixed-volume spaces, energy transport between a heat exchanger and the adjacent variable-volume space must take the form of a net enthalpy flow. This is shown in Fig. 6, which depicts the temperature of a gas element along its path through the source heat exchanger ("heater"). The gas element in Fig. 6 transports the following amount of enthalpy h_i, per unit of mass, from the heater to the expansion space:

$$h_i = c_p(T_H - T_i), \tag{3}$$

where T_H and T_i are the temperatures shown in the figure and c_p is the heat capacity of the gas.

Thus, thermal equilibrium cannot prevail at the interface between the heat exchanger and the adjacent variable-volume space. Even with an ideal heater the mean bulk temperature in the expansion space must be lower than the source temperature. Similarly, the mean bulk temperature in the compression space must be higher than that of the sink. In consequence, the pressure during expansion is lower and during compression higher than the corresponding values of the ideal Stirling cycle. Less heat will be absorbed from the external source, and more heat will be rejected to the external sink, and so a smaller portion of the heat absorbed is converted into net work. In other words, the efficiency of the engine with adiabatic variable-volume chambers and dedicated heat exchangers is lower than the Carnot efficiency of the reversible ideal cycle.

1.2.2 The Major Loss Mechanisms. The efficiency of a real, practical Stirling engine is further reduced by several effects.



External Heat Source

HOT SPACE
COLD SPACE

FIG. 5. Stirling engine with adiabatic variable chambers and dedicated heat exchangers.

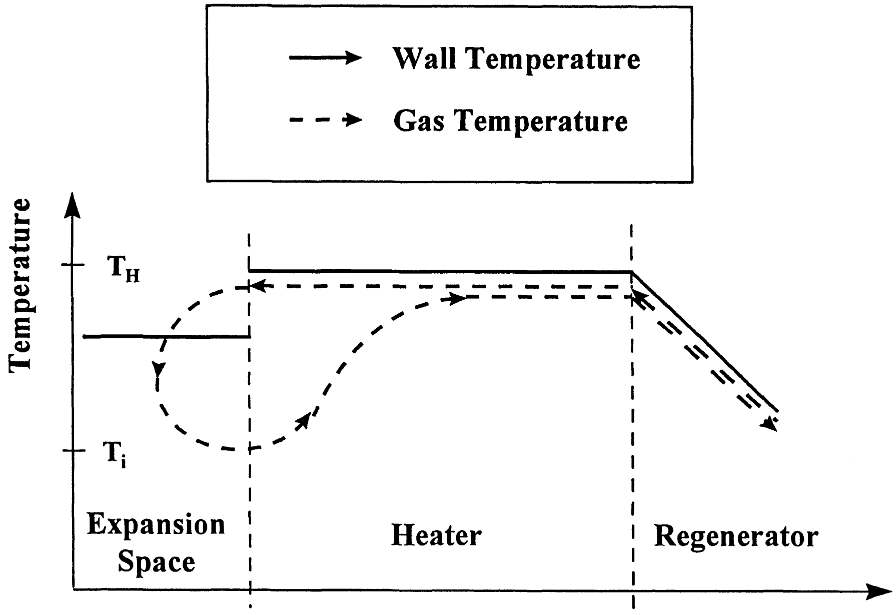

FIG. 6. Temperature of a gas element along its path in a real Stirling engine.

One such item is fluid friction in the heat exchangers, whereby cycle mechanical work is converted back into heat.

A component that can greatly affect the efficiency is a nonideal regenerator. In a typical Stirling engine the amount of heat stored in the regenerator per cycle is about five times larger than the heat absorbed from the external source. Thus every 1% drop in the regenerator effectiveness gives rise to a 5% drop in the engine efficiency. The regenerator is also the major contributor to fluid friction loss. A well-designed regenerator represents the best compromise of effectiveness and flow loss.

Additional losses are associated with a nonideal heater and cooler resulting in a lower bulk expansion temperature, a higher bulk compression temperature, and hence lower efficiency.

Natural and augmented heat conduction from the hot side to the cold side is a direct efficiency loss. Natural conduction takes place primarily in the regenerator, the matrix and housing of which are subjected to a sharp axial thermal gradient. Augmented (and natural) conduction takes place in the annular, blind gap called "appendix gap" between the expansion piston and its cylinder. The expansion cylinder has to be cooled at the end opposite the heater to permit the use of a dry-running piston ring and to protect the lubricated piston drive mechanism. Therefore, it experiences an axial thermal gradient. Natural conduction from the heater to the cooled end of the cylinder is augmented by the hot gas flowing into and out of the appendix gap, as well as by the piston motion.

The exact nature of the piston leakage loss depends on the engine configuration and is difficult to describe in general. Usually, the piston ring separates spaces in which the pressures fluctuate about a common mean pressure but at different phases and/or amplitude. Leakage across the piston ring shifts the phase of the pressure fluctuation closer to that of the total volume variation and reduces the power and the efficiency of the engine.

1.2.3 The Effect of "Dead Volume." Dead volume, or void volume, is that volume enclosed between the two pistons of Fig. 5 that is not swept by either piston. It is made up of the internal volumes of the heater and cooler, the internal void volume of the regenerator, and the volumes of the ducts and passages connecting these components. The larger the ratio of the dead volume to the swept volume (or "displacement") of the engine, the lower the pressure variation amplitude and, hence, the power developed by the engine. Therefore, it may be advantageous to employ compact heat exchangers with small internal volumes.

On the other hand, the dead volume has little or no direct effect on the efficiency. The heat absorbed from the external source is, just as is the power, proportional to the pressure-variation amplitude and is reduced by the same proportion with increasing dead volume. There are various indirect effects of the dead volume on efficiency. Many of these, however, give rise to higher efficiency with increasing dead volume because of smaller pressure variations, making the cycle become more isothermal and sacrificing power.

Dead volume, in itself, is not necessarily a disadvantage. By judiciously sizing and distributing the various dead volumes, the engine designer can trade power for efficiency and obtain an optimal match of the engine to its application and duty cycle.

2. DESIGN, FUNCTION, AND OPERATION

2.1 Mechanical Arrangements

2.1.1 The Displacer Engine. The volume variations necessary for the Stirling cycle can be obtained in several ways. For a single-cylinder engine the most common is the displacer type, the original arrangement designed by Robert Stirling. Figure 7 shows a modern version of the displacer arrangement.

The piston moves up and down by means of a drive mechanism. The displacer is mounted on a rod running through the piston and also moves up and down, by means of this same drive mechanism but with a prescribed phase difference from the piston. The variable volume on the heater side is formed by the stationary wall of the top of the cylinder (labeled "6" in Fig. 7) and the moving top of the displacer (labeled "1" in the figure)—a piston with an insulated dome on top of it—separating the hot space and the cold space. The displacer moves the gas between the hot (or expansion) space and the cold (or compression) space via the heat exchangers, which heat or cool the gas. In the meantime the piston compresses the gas when it is in the cold space or causes the expansion when the gas is in the hot space.

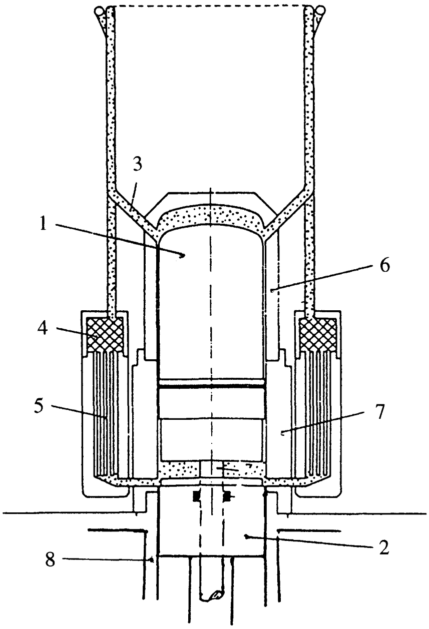

FIG. 7. Displacer and piston arrangement of a single-cylinder displacer engine. 1, Displacer; 2, piston; 3, heater; 4, regenerator; 5, cooler; 6, hot cylinder; 7, cold displacer cylinder; 8, cold piston cylinder.

With a displacer engine the compression work is obtained from the inertia of a moving mass such as a flywheel, and the expansion work is partially stored in this mass with the balance creating useful energy.

2.1.1.1 The Free-Piston Engine. The *free-piston* Stirling engine began its evolution in the early 1960s largely as a result of the work of Professor W. T. Beale of Sunpower, Inc., attempting to avoid the sealing and lubrication difficulties of the crank-type Stirling engines. Since then, efforts by many designers have resulted in a machine that is mechanically simple and designed for long life, as shown in Fig. 8.

The free piston is of the displacer type, but the displacer and the working piston are designated as "free" to indicate that they are not connected to any drive; rather, they are suspended within the "bounce space" by a

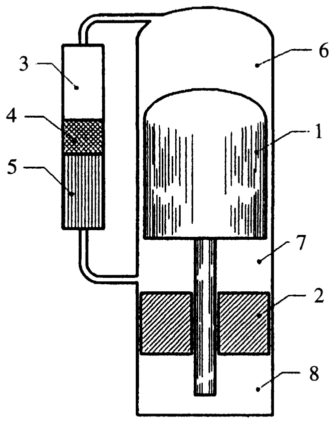

FIG. 8. Typical free-piston Stirling engine arrangement. 1, Free displacer; 2, free piston; 3, heater; 4, regenerator; 5, cooler; 6, hot (expansion) space; 7, cold (compression) space; 8, buffer (bounce) space.

gas buffer. As the displacer oscillates at a rate of 50 to 60 Hz, the working gas shuttles between the cold space and hot space causing pressure variations that move the piston up and down. To accomplish the desired gas cycle, the displacer and piston are tuned as mechanical spring-mass-damper resonators, which ensure the correct phase relation. The power is obtained from the piston by connecting it with a permanent-magnet linear alternator within the sealed cylinder, thus converting piston motion into electricity.

2.1.2 The Double-Acting Engine. A modern multiple-cylinder Stirling engine is a "double-acting" configuration and can be a three-, four-, five-, or six-cylinder engine. A four-cylinder type is shown schematically in Fig. 9. There is only one piston per cylinder. The compression of the gas takes place under the piston (the cold space), and its expansion takes place on top of the piston (the hot space) of the adjacent cylinder. These events are accomplished by the movement of the pistons, each of which differs in phase from its successor by the same angle. After the expansion in the hot space, the gas is shuttled through the heater, regenerator, and cooler into the cold space. There the gas is compressed and forced back to the hot space. Completion of one cycle of the engine results in one revolution and an excess of work.

2.1.3 Other Configurations. In the first days of renewed interest in the hot-air engine (1938), several small models were born. One example of these configurations that survived is shown in Fig. 10. The variable volumes, with a phase difference of 90°, are obtained by a two-cylinder V drive.

2.2 Operational Controls

2.2.1 Variable Charge. The power of a Stirling engine can be controlled by changing the torque of the engine. The torque is

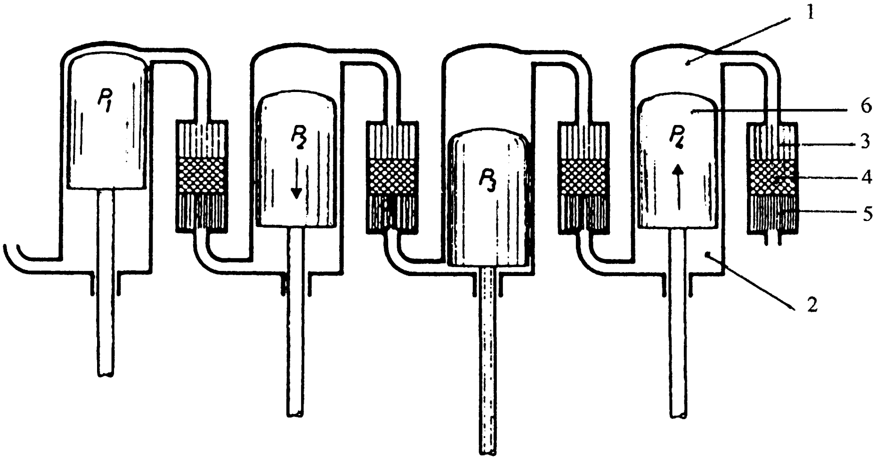

FIG. 9. Schematic arrangement of a four-cylinder double-acting Stirling engine. 1, Hot (expansion) space; 2, cold (compression) space; 3, heater; 4, regenerator; 5, cooler; 6, piston.

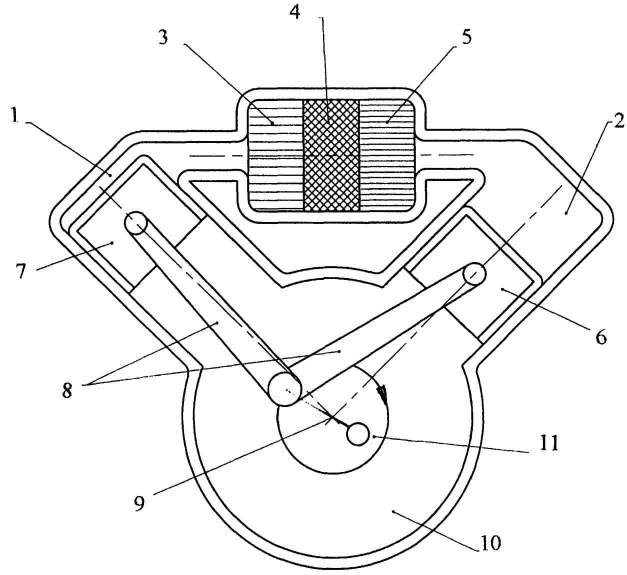

FIG. 10. V engine with cylinders at 90°. 1, Hot (expansion) space; 2, cold (compression) space; 3, heater; 4, regenerator; 5, cooler; 6, compression piston; 7, expansion piston; 8, connecting rods; 9, crankshaft; 10, crankcase; 11, counter weight.

approximately proportional to the pressure of the working gas. Thus, by an increase in the pressure, the torque and, therefore, the power are increased and vice versa. Figure 11 explains how this is done with a single-cylinder engine. This system works quite satisfactorily for single-cylinder engines but becomes rather complex for multiple-cylinder engines.

2.2.2 Variable Displacement. When it became clear that the power control of multiple-cylinder Stirling engines was one of the bottlenecks for commercialization of the en-

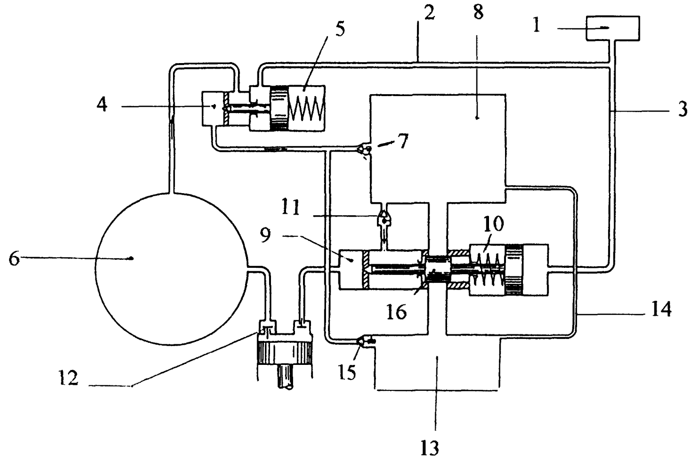

FIG. 11. Variable charge of single-cylinder engine. When the power has to increase, the regulator 1 opens the valve 4, by increasing the hydraulic pressure in the pipes 2 and 3 and in the valve mechanism 5, by which high-pressure gas flows from the high-pressure vessel 6 into the engine 8 and buffer 13 via check valves 7 and 15. This can be done relatively quickly. When the power has to decrease, the regulator opens the valve 9, by decreasing the hydraulic pressure in the valve mechanism 10, and the gas flows via the check valves 11 and 16 and compressor 12 from the engine and buffer back into the vessel 6. However, this would occur slowly with a small compressor, and, therefore, a slide throttle 16 is introduced that connects the cycle with the buffer space 13 to ensure a rapid response when the load is reduced suddenly. The capillary 14 is a connection between the cold space and the buffer to ensure mean pressure in the buffer space in a stationary situation.

gine, a mechanical device was found that could change the stroke of the pistons, thus changing the displacement and power, while keeping all of the working gas inside the engine.

The *swashplate* drive incorporates a disk fixed at a certain angle to the shaft, over which piston rods slide to cause reciprocating movement. By changing the angle of the swashplate with respect to the shaft, the stroke of the pistons is changed causing a change in the power. This mechanism has shown to be very successful in the Stirling engine and is shown schematically in Fig. 12.

2.3 Critical Components

2.3.1 Regenerator. The regenerator is the heart of the high-performance Stirling engine. It ensures that the two processes, compression and expansion, occur over the greatest temperature difference possible. Therefore, this heat exchanger should have a structure allowing very high heat transfer as well as high heat capacity per unit of volume, low heat conduction in an axial direction, and, finally, very low flow resistance for the gas shuttling between the cold space and the hot space. The best performance to date is a regenerator made of layers of wire cloth where the wire diameter, the mesh, and the number of layers are optimized for a given engine.

2.3.2 Seals. The two types of seals in the Stirling engine can be distinguished as either internal (sealing to the pistons) or external (with relation to the ambient). The internal piston rings must be made of dry-running material in order to keep the heat exchangers free of oil. Not only should the leakage along the pistons be small, but in a double-acting engine, the gas mass should not be allowed to migrate to adjacent cylinders. While different designs have been found to obtain such a balance, most come with the cost of increased friction.

External leakage to the ambient has always posed one of the most severe problems with the Stirling engine: preventing gas leakage out of the high-pressure cylinder along a lubricated moving rod while avoiding oil penetration into the cylinder. One of the latest solutions requires a pressure vessel around the drive and uses a rotating shaft seal. In the case of a generator set, the generator can be included within the pressure vessel as is done in the free-piston machine.

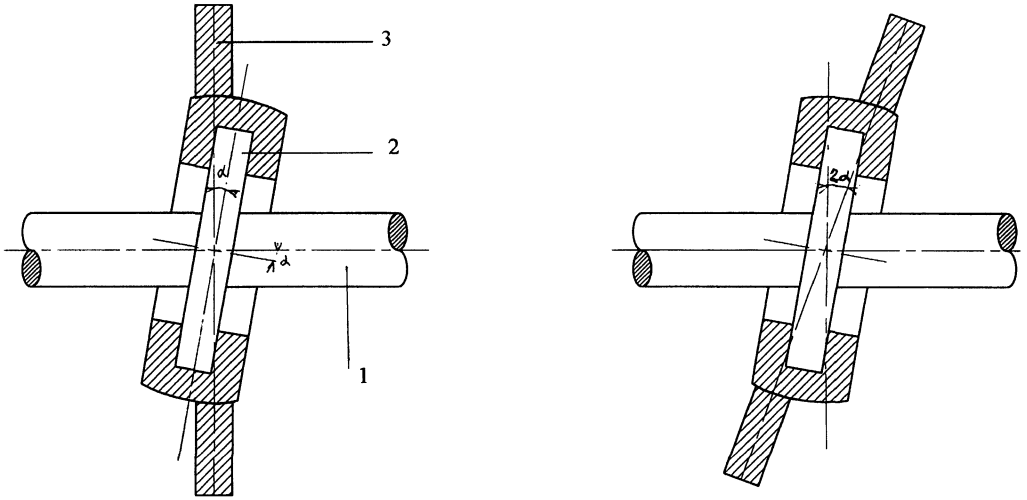

FIG. 12. The variable swashplate mechanism. 1, Crankshaft; 2, fixed disk; 3, variable swashplate. The fixed disk makes an angle α with a plane perpendicular to the shaft. The variable swashplate has a bearing fitting around the fixed disk, which also makes an angle α with the swashplate itself. By turning the swashplate relative to the shaft, the angle that the swashplate makes with the perpendicular plane can be changed from 0° to 2α, thus changing the piston stroke from zero to maximum. See Fig. 15 for mode of application.

2.3.3 High-Temperature Materials. In Robert Stirling's time, cast iron or bronze were the only high-temperature materials available, yet these proved to be brittle and unsuitable for a high-pressure device. Today, there is a wide choice of high-strength, high-temperature materials. The use of heat-resistant materials for a modern Stirling engine can be divided into two categories: castings for the hot cylinder and regenerator cups, and drawn tubes for the hot heat exchanger. However, since the cost of the hot parts of the engine is most critical, there are also attempts to cast the tubes, with or without fins.

In the future, heat- and creep-resistant ceramics are also expected to play a major role as ideal Stirling engine materials. Innovative fabrication techniques are also being investigated in relation to common material properties that could be exploited.

3. MANUFACTURE

3.1 V Engine (SPS V-160)

Stirling Power Systems, Inc., a subsidiary of United Stirling, has developed a generator set that produces 5 to 10 kW, based on a V-type configuration. This machine was also used in recreational vehicles as a cogenerator, heating the water and providing electric power without the use and dangerous storage of propane fuel.

3.2 Displacer Engine with Rhombic Drive (GM's GPU-3)

The rhombic drive has played a very important role in the development of the Stirling engine. It was invented in 1953 at Philips. It led the way to engines with high power because it allowed a completely balanced, single-cylinder engine suitable for high pressure. In addition, this engine was the first optimized for hydrogen as the working gas.

Figure 13 shows a schematic of the rhombic engine. The desired phase difference is obtained from the design of the crank-connecting rod mechanism and, if the reciprocating weight of the piston part is equal to that of the displacer part, only a first harmonic of the inertia forces is left that can be balanced by two counter-rotating weights.

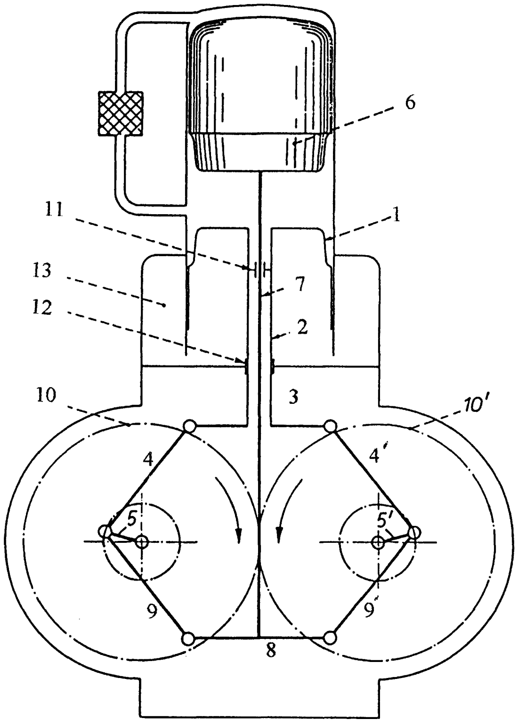

FIG. 13. The rhombic drive mechanism. 1, Piston; 6, displacer; 5 and 5′, cranks on two shafts that rotate in opposite directions and are coupled by the gear wheels 10 and 10′; 4 and 4′, connecting rods pivoting on the ends of a yoke 3, fixed to the hollow piston rod 2; 9 and 9′, connecting rods pivoting on the ends of a yoke 8, fixed to the displacer rod 7, which passes through the hollow piston rod; 11 and 12, stuffing boxes; 13, buffer space filled with gas at the mean pressure of the cycle.

A generator set was manufactured by General Motors according to this principle. This ground power unit (GPU) was produced for the U.S. Army. It was a 3- to 5-kW generator set with a 10-HP (7.5 kW) single-cylinder engine with rhombic drive.

3.3 Double-Acting, Variable-Charge, Crank Drive (MTI MOD II)

Funded by contracts from the U.S. Department of Energy via the NASA Lewis Research Center, Mechanical Technology, Inc. (MTI), has developed a double-acting engine on a V drive for direct propulsion of an automobile, shown in Fig. 14. This is a contin-

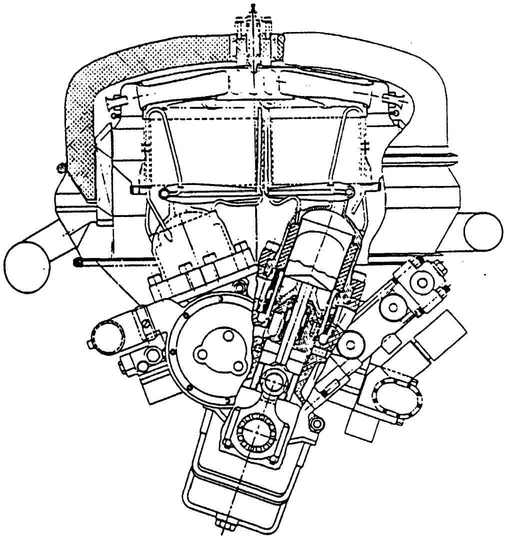

FIG. 14. Double-acting, variable-charge, crank drive engine by United Stirling and MTI (MOD II).

uation of the research originated by United Stirling of Sweden, a licensee of N. V. Philips. United Stirling had successfully developed this same configuration for submarine propulsion, which is in manufacture today.

3.4 Double-Acting, Variable-Charge, Swashplate Drive (Philips' 4-215)

Acting through its licensee, N. V. Philips created a few direct-propulsion engines producing 130 kW for the Ford Torino automobile, which was demonstrated in 1976 in the United States. In order to make the engine as compact as possible, a double-acting swashplate configuration was chosen together with a rotating, regenerative, ceramic preheater, drawing upon Ford's experience with gas-turbine technology. Figure 15 shows a schematic of this configuration with the actual engine appearing in Fig. 16. The power control was obtained by the variable-charge method of Fig. 11, but the Torino system required much more complexity to achieve the response times needed for the automotive application.

Ford's interest in the Stirling engine was its low-emission capability. Table 1 shows the emission levels obtained without the use of a catalytic converter. While these figures were remarkable against the standards of 1970, the emissions levels of today are still impressively low when compared to other technologies. This same characteristic is driving the quest for Stirling engines even more today.

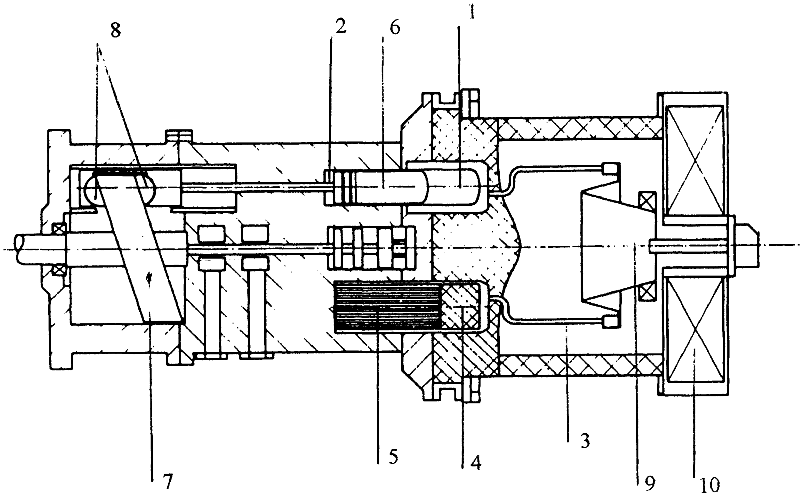

FIG. 15. Double-acting, variable-charge, swashplate drive engine (Philips' 4-215), shown here schematically. As part of the Ford–Philips license agreement, N. V. Philips manufactured four of these 130-kW engines for Ford's Torino automobiles. 1, Hot space; 2, cold space; 3, heater; 4, regenerator; 5, cooler; 6, piston; 7, swashplate; 8, sliders; 9, burner; 10, preheater.

3.5 Double-Acting, Variable-Displacement, Swashplate Drive (STM4-120)

When N. V. Philips terminated its Stirling engine activities in 1979, Stirling Thermal Motors, Inc. (STM), was established in the United States and acquired all rights to the past technology and computer simulation programs used in the design process. Rather than addressing the difficulty of introducing a new, competitive engine to the world, STM sought economical applications where internal-combustion engines could not be used. The focus was to concentrate on one engine size and configuration, solve all the existing problems of the technology, and make the design absolutely reliable.

The chosen engine size was 25 kW at 1800 rpm with an 800 °C heater-wall temperature. This configuration was designated the STM4-120: four cylinders (double-acting) and 120-cm^3 swept volume per piston. The concept was to change only the heater for different applications: direct heating with natural gas or heat from biomass of waste energies, and remote heating via heat pipe for solar or chemical resources.

The two remaining problems were power control and sealing to the ambient. These were solved with the development of the variable swashplate and use of a pressure hull around the relatively small drive, with a rotating shaft seal or including the generator within the pressure hull. The angle position of the swashplate is obtained with a hydraulic vane motor and bevel gears or electrically by means of small planetary gears and bevel gears.

Figure 17 shows a cross section of the STM4-120, and Fig. 18 shows the actual engine with heat pipe heaters.

3.6 Free-Piston Engine (Sunpower, Inc.)

Figure 19 shows the typical features of the current free-piston Stirling engine. This engine delivers about 2.5 kW of electric

power at approximately 25% fuel-electric efficiency. It operates with helium at 4 MPa and 650 °C heater-wall temperature. The piston power is delivered directly to the magnets of a permanent-magnet alternator to produce alternating current. The engine operates at an approximately constant frequency regardless of load or amplitude.

4. APPLICATIONS

It is clear that the Stirling engine as a new prime mover can technically replace internal-combustion engines in many applications when it is proven reliable. At introduction into the market, price will be the biggest handicap. This creates the need for applica-

tion niches to be found where price is a smaller part of the buying decision. Volume production could overcome this handicap, and further markets could be penetrated.

4.1 Special Energy Sources

4.1.1 Solar-Energy Conversion. The use of solar energy is one of the most promising applications. The Stirling engine has already been tested for many hours in large parabolic collectors (80 m^2 or greater) with an energy conversion efficiency of more than 30%. The STM unit, complete with conventional radiators for cooling, is being tested at the proving grounds of Sandia National Laboratories, U.S.A. In this model, the receiver, that part of the engine containing the heater, is heated only by concentrated solar insolation. In order to be accepted by the utilities, the receiver had to be changed to a hybrid receiver that can also be heated by natural gas, making the unit independent of the sunshine.

4.1.2 Submarine Vessels. Since the Stirling engine has an external heating system, it is possible to use any suitable chemical reaction at sufficiently high temperature. A lot of research into this concept was performed by Philips and M.A.N. in the 1970s for the German government with the reaction of the metal Li and the oxidizer SF_6 (sulfur hexafluoride). The heat was transported by heat pipes with sodium as the working medium. This reaction produces no gaseous product, just salts, making this heating system very suitable for underwater applications.

Another successful nongaseous heating system uses stored heat from molten salt, such as LiF, also transported by sodium heat pipes. Finally, United Stirling was very successful in this market using liquid oxygen and diesel fuel.

4.1.3 Power from Biomass. Biomass gas obtained from an incompletely burned organic solid is difficult to use in internal-combustion engines but is quite suitable for Stirling engines with high efficiency because the gases do not needed to be cooled down and the composition of the gas is not too important. Biomass furnaces are already producing clean exhaust gases and have been successfully tested with an STM4-120 engine. Fast-growing wood in the neighborhood of small villages could be the solution for the need for remote electricity. This would not contribute to global warming.

4.2 Remote, Maintenance-Free Operation

4.2.1 Space Power. Photovoltaic cells are the common energy source in space using solar energy. However, sometimes there is need for higher energy density when an exotic heat source, such as that of a nuclear reaction, is available. Therefore, the U.S. Government, under supervision of NASA, has awarded many contracts to companies for the development of a Stirling generator set for space. One result is the 25-kW free-piston engine developed by Mechanical Technology, Incorporated.

4.3 Quiet, Clean, Efficient Power

4.3.1 Generator Sets. Calculations have shown that the cost of a modern Stirling engine, produced in the same numbers as the automotive gasoline engine, is not much different than that of the internal-combustion engine. This fact, together with the same or better reliability of a Stirling engine, makes it is easy to see the potential for a Stirling-engine generator set. In the case of cogeneration, Stirling devices have the advantage because the heat rejection in the cooling water is about twice as high as with the internal combustion engine.

4.3.2 Vehicle Propulsion. There have been a few trials to use the Stirling engine as direct propulsion for vehicles. This was never a success because the existing engines were too sophisticated and not reliable enough to meet the specifications of manufacturability and performance, although the Stirling engine did have a demonstrable superiority in some areas, such as lower emissions.

However, with the successful introduction of the variable swashplate, the situation has changed. Now the modern automotive, multiple-valve gasoline engine looks sophisticated compared to the four-cylinder variable swashplate engine. With the previous handicap eliminated, Stirling machine characteristics can directly compete with those of internal combustion engines as well as being demonstrated in areas unfulfilled by much of today's technology.

5. ECONOMIC ASPECTS

As mentioned, the cost of manufacturing a Stirling engine has prohibited the introduction of the technology into many areas where the advantages are great. Unfortunately, overcoming that obstacle has caused many companies and agencies to give up on the concept. With fewer than a dozen companies in the world maintaining the idea that Stirling devices are a product of tomorrow, many of the materials and subsystems needed to overcome this problem have been developed. In addition, new technologies have introduced new cost savings throughout the engine designs. With the decreased costs, it has allowed reliability, performance, and field tests to be completed in various arenas, letting the data speak for itself.

Finally, with the increased need for environmentally friendly sources of power, heat, and cold, the changing times have created a niche for Stirling engines. With the ability to change quickly from one energy source to another, Stirling has proven to be an old technology ready to face a new world.

INTRODUCTION

What Is a Stochastic Process?

If there are n people in a room and we ask what is the probability that any two have the same birthday, we have a pure probability problem since there is no change with time. Person j has birthday b_j, which can take any of 365 values, presumably with equal probability. There are n random variables, each of which has a discrete state space of 365 points. And with a modest effort, one can show that a coincidence of birthdays will acquire a probability more than 1/2 if $n > 25$.

If a man starts with a capital of \$100 and aims to end up with \$1000 by betting a dollar once a minute on coin tosses, we are dealing with a stochastic process because we have a random variable (the bettor's current capital) that changes (makes transitions) with time. The state space is discrete with the integral values from 0 to 1000, and the time variable is also discrete. This problem can be mapped onto a random-walk problem in which the man's capital is indicated by a position on a line, with absorbing barriers at each end.

The total number of electrons in a cell, in a semiconductor, increases by one in a generation process and decreases by one in a recombination processes. In this case, we have a stochastic process for a single, discrete random variable N as a function of a continuous time.

The current flowing through a resistor is a random process involving a continuous random variable $I(t)$ as a function of a continuous time.

The concept of a stochastic process is, of course, immediately extended to the case of several, or even an infinite number of, random variables. Each cell in a crystal could contain atomic-like states whose occupancy is a random variable, indexed by a discrete triple index. A carrier density, $n(\mathbf{r},t)$, provides a continuous index to an infinite number of continuous-time variables. In this case, carriers can be generated, recombined, or modified by drift and diffusion.

Kinds of Dynamical Systems

The simplest dynamical systems are linear. When the noise is weak, a stable nonlinear system will stray only slightly from a motion, possibly a time-independent state of the nonlinear state. Many important electronic and semiconductor devices are of this nature. We attempt to display some techniques that are universally applicable to fluctuations from a stable nonequilibrium state. We summarize briefly, here and in Sec. 8, problems that violate the requirements just mentioned that permit quasilinear solutions.

We are usually concerned with physical systems in which the noise is intrinsic to the system and related to the dissipative response of the system. There is also a vast literature on the response of nonlinear systems to external noise whose properties are unrelated to the system. See an early summary by Deutsch (1962), and the book by Van Kampen (1992) that provides an overview of stochastic processes with an emphasis on nonlinear processes.

Aside from the distinction between weak and strong noise, there is also a distinction between noise that is white (that is, possesses a flat spectrum) and colored noise whose spectrum is frequency dependent.

If the noise source is white, the problem, even if nonlinear, reduces to a Markoffian one. A Markoff process is a stochastic process whose future depends only on the latest information and is independent of prior information. This absence of memory is guaranteed by the fact that the Fourier transform of a noise constant in frequency is a delta function in time. The zero width of the delta function is the length of the memory time. If $a(t)$ is a random process, and t_j constitute a set of increasing times $t_0 < t_1 < t \cdots < t_n$, then the probability density of $a(t_n)$ conditional on all the values at all the earlier times obeys

$$P(a_n|a_{n-1},a_{n-2},\cdots a_0) = P(a_n|a_{n-1}) \qquad (1)$$

for a Markoffian process, like a person who remembers only the last thing he was told. Markoff processes then have the simplicity that a general multiple-time probability can be written

$$P(t_n,t_{n-1},\cdots t_0) = P(t_n|t_{n-1})P(t_{n-1}|t_{n-2}|) \cdots P(t_1|t_0)P(t_0) \qquad (2)$$

in terms of an initial probability multiplied by a series of two-time transition probabilities. The latter must obey a self-consistency condition known as the Chapman–Kolmogorov relation to insure the Markoffian nature of the process (see Sec. 7.2). See the articles PROBABILITY and RANDOM PROCESSES for more background on these subjects.

If a system is linear (or quasilinear, with a weak noise source), analytic solutions are possible for the probability densities even in the presence of colored noise sources. If the system is nonlinear, but with a white noise source, the probability will obey a generalized Fokker–Planck equation. The problem is thus reduced to (nontrivial) analysis. If the noise sources are also Gaussian, the problem reduces to a standard Fokker–Planck equation (see Sec. 7.2). Then analytic and numerical methods are feasible if the number of variables is small.

A system can be described as stationary if it is stable and none of the parameters describing the system is time dependent. In this case, there will be a steady (time independent) state, and all probability distributions that depend on variables at more than one time will be a function only of the time differences. We added the caveat about stability to exclude such cases as a free particle executing a Brownian motion that permits excursions that will grow indefinitely. Another example is that of an autonomous self-sustained oscillator. The latter has been shown by Lax (1968a, 1968b) always to contain one mode of instability that is usually related simply to an overall phase of the system that can grow at will. (The reason is given in Sec. 8.5.)

Quantum systems also require special handling. By the use of ordered operators, Lax (1968a,b) and Haken and Weidlich (1967) showed that quantum stochastic processes could be exactly expressed in terms of associated c-number ("classical") processes.

An Approach to the Spectrum of Stationary Stochastic Processes

Many experimental articles on semiconductor devices prior to 1960 included a systematic discussion of transport in these devices but an *ad hoc* theory of the associated noise. Lax (1960) recognized that a large class of devices that involved weak fluctuations from a (possibly nonequilibrium) steady state could be treated by a general approach that related noise to transport by an Einstein relation and a regression theorem, outlined as follows:

1. The response of most nonlinear systems to noise sources is sufficiently weak to permit a quasilinear approximation. Generalization of this procedure to self-sustained oscillators including quantum lasers is reviewed elsewhere (Lax, 1991).
2. The time decay of a correlation such as $\langle A(t)B(0)\rangle$ is the same as the time dependence of $\langle A(t)\rangle$, the dissipative relaxation of an initial deviation from the steady state. This is referred to as Onsager's regression hypothesis for deviation from an equilibrium state. Lax (1963, 1968b) proposed it as a theorem for Markoffian systems for fluctuations from a steady, possibly nonequilibrium, steady state. The angular brackets denote an average over an ensemble. In probability, ⟨something⟩ is often written E[something] and is called an expectation.
3. To the equations of time dependence determined from transport theory, we must add an initial condition, namely the value of $\langle A(0)B(0)\rangle$. For fluctuations from the equilibrium state, the second moments are known thermodynamically (Callen, 1985):

$$\langle A(0)B(0)\rangle \equiv \langle AB\rangle = -k\partial\langle A\rangle/\partial F_B. \qquad (3)$$

When regarded as a thermodynamic quantity, it is customary to rewrite $\langle A\rangle$ simply as A. Here, F_B is the force "conjugate" to the variable B in the sense that the negative of the pressure, $-P$, is conjugate to the volume V. (The negative sign is necessary since pressure decreases volume rather than increasing it.)

Sometimes, we must deal with quasiequilibrium states. For example, in a semiconductor, the electrons come to equilibrium with each other rapidly. So do the holes. But the radiative and nonradiative processes that produce recombination and generation of electron–hole pairs are slow. It is then customary to introduce quasi-Fermi levels, one for the electrons and one for the holes. In that case, Eq. (3) is useful, even though complete equilibrium is absent. In more complicated cases, one must make use of more detailed knowledge of the noise processes involved.

In Sec. 1 we discuss the above-mentioned approach to obtaining correlation functions for stochastic processes. In Sec. 2 we develop the relation between the Fourier transform of the correlation functions, the ideal noise measurement, and real noise measurements. In Sec. 3 we discuss the set of noise sources that arise from thermal origins. In Sec. 4 we discuss the "shot noise sources" that arise from the discrete nature of the charges that give rise to this noise. In Sec. 5 we discuss examples of these noise sources. In Sec. 6 we discuss noise in homogeneous semiconductors. In Sec. 7 we review the Langevin noise-source approach and describe its relation to the Fokker–Planck approach. Pitfalls in the use of the Ito definition of a stochastic integral are elucidated. In Sec. 8 we discuss a variety of nonlinear examples including random-walk theory, linear noise with time-dependent decay, reaction-rate theory, stochastic resonance, and self-sustained oscillators.

1. THE TREATMENT OF STATIONARY STOCHASTIC PROCESSES

1.1 Correlation Functions and the Regression Theorem

When equilibrium statistics cannot be utilized, the second moments can be obtained by using a generalization of the Einstein relation.

If $\mathbf{a}(t)$ is a set of random variables, $a_1(t)$, $a_2(t), \cdots$, then Lax (1960) has derived a generalized Einstein relation of the form

$$\frac{d}{dt}\langle\mathbf{aa}\rangle = 2\langle\mathbf{D}(\mathbf{a},t)\rangle + \langle\mathbf{aA}(\mathbf{a},t)\rangle + \langle\mathbf{A}(\mathbf{a},t)\mathbf{a}\rangle. \tag{4}$$

Here, **aa** is a dyadic abbreviation for a set of products a_ia_j, and **aA** is a corresponding abbreviation. The "drift vector," $\mathbf{A}(\mathbf{a},t)$, is defined by

$$\mathbf{A}(\mathbf{a},t) \equiv \lim_{\Delta t\to 0}\frac{\langle\mathbf{a}(t+\Delta t)-\mathbf{a}(t)\rangle}{\Delta t} \text{ so that}$$
$$\frac{d\langle\mathbf{a}(t)\rangle}{dt} = \langle\mathbf{A}(\mathbf{a},t)\rangle, \tag{5}$$

and the "diffusion matrix," $\mathbf{D}(\mathbf{a},t)$, is defined by

$$2!\mathbf{D}(\mathbf{a}) \equiv \lim_{\Delta t\to 0}\frac{\langle\Delta\mathbf{a}(t)\Delta\mathbf{a}(t)\rangle}{\Delta t}. \tag{6}$$

We understand the abbreviation

$$\Delta\mathbf{a}(t) = \mathbf{a}(t+\Delta t) - \mathbf{a}(t). \tag{7}$$

The 11 component

$$D_{11} = \langle[\Delta a_1(t)]^2\rangle/2\Delta t \tag{8}$$

reduces to the conventional diffusion constant when a_1 has the meaning of a position, x. If the diffusion coefficient D_{11}, labeled D_{xx} to remind us of its nature, is a constant, the mean square displacement $\langle[\Delta x]^2\rangle$ grows linearly with the time interval, the conventional Brownian-motion result (see RANDOM PROCESSES).

The evaluation of the averages in Eqs. (5) and (6) will make use of the nature of the noise process. For example, the system may be in interaction with a thermal reservoir. Or the noise may have shot-noise character, that is, it may arise because discrete particles are involved, and all the occupancies of states must be integers. We illustrate these mechanisms in Secs. 3 and 4.

The important point for the purposes of this section is that two major simplifications are possible. In the quasilinear case, there will be a set of associated stationary variables $\mathbf{a}_0$ and a set of small deviations

$$\boldsymbol{\alpha}(t) \equiv \mathbf{a}(\mathrm{t}) - \mathbf{a}_0. \tag{9}$$

The stationary points $\mathbf{a}_0$ are those at which the drift vectors vanish:

$$\mathbf{A}(\mathbf{a}_0) = 0. \tag{10}$$

Expanding around the steady operating point yields

$$\mathbf{A}(\mathbf{a}) \approx -\boldsymbol{\Lambda}\cdot\boldsymbol{\alpha},\ \langle\mathbf{A}(\mathbf{a})\rangle \approx -\boldsymbol{\Lambda}\cdot\langle\boldsymbol{\alpha}\rangle,$$
$$\frac{d\langle\boldsymbol{\alpha}(t)\rangle}{dt} = -\boldsymbol{\Lambda}\cdot\langle\boldsymbol{\alpha}(t)\rangle, \tag{11}$$

$$\mathbf{D}(\mathbf{a}) \approx \mathbf{D}(\mathbf{a}_0) \equiv \mathbf{D}. \tag{12}$$

In that case, the generalized Einstein relation, Eq. (4), simplifies to

$$\frac{d\langle\boldsymbol{\alpha\alpha}\rangle}{dt} = 2\mathbf{D} - \boldsymbol{\Lambda}\cdot\langle\boldsymbol{\alpha\alpha}\rangle - \langle\boldsymbol{\alpha\alpha}\rangle\cdot\boldsymbol{\Lambda}^{\dagger} \tag{13}$$

where $\mathbf{\Lambda}^\dagger$ is the transpose of $\mathbf{\Lambda}$. (In the complex case, the Hermitian adjoint would be needed, which is why we use the dagger symbol even though we are dealing with real variables here.)

The second major simplification is that we are dealing with fluctuations from a stationary state. In that case, a correlation such as $\langle \alpha_i(t)\alpha_j(t)\rangle$ is a function only of the time difference $t - t$. Hence, the time derivative vanishes, and we arrive at the stationary Einstein relation

$$2\mathbf{D} = \mathbf{\Lambda}\cdot\langle\boldsymbol{\alpha\alpha}\rangle + \langle\boldsymbol{\alpha\alpha}\rangle\cdot\mathbf{\Lambda}^\dagger. \tag{14}$$

For the case of a single variable, Eq. (14) reduces to the original Einstein relation between the diffusion constant and mobility; see Eq. (89).

In the presence of time reversal, the two terms on the right-hand side in Eq. (14) have been shown to be equal; see Onsager (1931) and Eq. (6.18) of Lax (1960). Thus the initial value $\langle\boldsymbol{\alpha}(0)\boldsymbol{\alpha}(0)\rangle$ is given by

$$\langle\boldsymbol{\alpha}(0)\boldsymbol{\alpha}(0)\rangle = \mathbf{\Lambda}^{-1}\cdot\mathbf{D}. \tag{15}$$

Equation (11) yields the conditional mean motion (transport)

$$\langle\boldsymbol{\alpha}(t)\rangle_{\boldsymbol{\alpha}(0)} = \exp(-\mathbf{\Lambda}t)\cdot\boldsymbol{\alpha}(0). \tag{16}$$

By calculating the autocorrelation in two steps—first an average conditional on the initial condition, and second an average over the initial condition,

$$\begin{aligned}\langle\boldsymbol{\alpha}(t)\boldsymbol{\alpha}(0)\rangle &= \langle\langle\boldsymbol{\alpha}(t)\rangle_{\boldsymbol{\alpha}(0)}\boldsymbol{\alpha}(0)\rangle\\ &= \exp(-\mathbf{\Lambda}t)\cdot\langle\boldsymbol{\alpha}(0)\boldsymbol{\alpha}(0)\rangle\end{aligned} \tag{17}$$

—we have established the regression theorem, that the fluctuation contains the same time dependence as the transport. The Markoffian assumption was tacitly made, since only in the Markoffian case is the conditional average independent of any earlier history that could affect the second average.

Equation (16) is restricted to positive times, and so necessarily is Eq. (17). However, stationarity permits us to write

$$\begin{aligned}\langle\boldsymbol{\alpha}(-t)\boldsymbol{\alpha}(0)\rangle &= \langle\boldsymbol{\alpha}(0)\boldsymbol{\alpha}(t)\rangle\\ &= \langle\boldsymbol{\alpha}(0)\boldsymbol{\alpha}(0)\rangle\cdot\exp(-\Lambda^\dagger t).\end{aligned} \tag{18}$$

2. SPECTRAL MEASUREMENTS AND CORRELATIONS

2.1 Introduction: An Approach to the Spectrum of Stochastic Processes

In this section we compare three definitions of noise: The standard engineering (SE) definition takes a Fourier transform over a finite time interval, squares it, divides by the time, and then takes the limit as the time approaches infinity. The second definition is the Fourier transform of the autocorrelation function. The equality between these two definitions is known as the Wiener (1930)–Khinchin (1934) theorem. The third procedure, introduced by Lax (1968a), passes the signal through a realizable filter of finite bandwidth, squares it, and averages over some large finite time. This simulates an actual measurement of the noise spectrum. As the bandwidth is allowed to approach zero, the result will (aside from a normalization factor) approach the ideal value of the two preceding definitions.

2.2 Standard Engineering Definition of Noise

The spectrum of noise $G_s(\alpha,\omega)$ in a single random variable $a(t)$ is a measure of the fluctuation energy in the frequency interval $[\omega, \omega + d\omega]$ associated with the fluctuating part $\alpha(t)$, where

$$\alpha(t) = a(t) - \langle a(t)\rangle;\ \langle\alpha(t)\rangle = 0. \tag{19}$$

The SE definition of noise, denoted by G_s, is chosen to obey the normalization

$$\int_0^\infty G_s(\alpha,\omega)df = \langle|\alpha(t)|^2\rangle, \tag{20}$$

because it is customary in engineering to emphasize positive frequencies $f = (\omega/2\pi) > 0$ only. For this reason, we adopt the definition

$$\begin{aligned}\tfrac{1}{2}G_s(\alpha,\omega) &\equiv \tfrac{1}{2}G_s(\omega) \equiv (\alpha^2)_\omega\\ &= \lim_{T\to\infty}\frac{1}{2T}\left\langle\left|\int_{-T}^{T}\alpha(t)e^{-j\omega t}dt\right|^2\right\rangle\end{aligned} \tag{21}$$

and verify the normalization later.

The letter j is used to denote imaginary unit customarily in electrical engineering. The SE convention is that $\exp(j\omega t)$ describes positive frequencies and $R + j\omega L + 1/j\omega C$ is the impedance of a series circuit of a resistance R, an inductance L, and a capacity C. Because propagating waves are described by $\exp(ikx - i\omega t)$ in physical problems, we regard $\exp(-i\omega t)$ as describing positive frequencies so that the physics convention is equivalent to setting $j = -i$ consistently.

In this definition, Eq. (21), the interval on t is truncated to the region $-T \le t \le T$, its Fourier transform is taken, and the result is squared. Since such a measurement would attempt to filter out one component ω and square it, this definition is reasonable. Since the integral is not expected to converge, it must be normalized by T. What is not clear yet is why one divides by T rather than T^2. The angular brackets denote an ensemble average. It is curious that both the limit $T \to \infty$ and an ensemble average are taken. For an ergodic process, a time average—by definition—is equal to an ensemble average. One might guess that the ensemble average could have been eliminated—that its use is primarily for convenience of computation. The above assumption is, however, wrong! Middleton (1960) shows that if the ensemble average is not performed, substantial fluctuations occur in the value of $G_s(\omega)$.

Presumably, this sensitivity occurs because we are asking for the noise at a precise frequency. Because of the Fourier relation between frequency and time, a measurement accurate to $\Delta\omega$ requires a time $t > 1/\Delta\omega$. Realistic noise measurements, to be discussed below, using filters of finite width, are presumably ergodic.

The above definition assumes that the noise is stationary. A more general definition of the noise at a frequency ω and time t is given by the Fourier transform

$$\tfrac{1}{2}G(\alpha,\omega,t) = \int_{-\infty}^{\infty} e^{j\omega\tau}R(\tau,t)d\tau \tag{22}$$

of the Wigner (1932)–Moyal (1949) type of autocorrelation function,

$$R(\tau,t) = \langle \alpha(t + \tau/2)^*\alpha(t - \tau/2)\rangle, \tag{23}$$

guaranteed to yield a real $G(\alpha,\omega,t)$. For future use, we note that the inverse of Eq. (22) is

$$\langle \alpha(v)^*\alpha(u)\rangle = \frac{1}{4\pi}\int_{-\infty}^{\infty} e^{-j\omega(v-u)} \times G(\alpha, \omega, (u + v)/2)d\omega. \tag{24}$$

The nonstationary case is discussed further in Lax (1968a). In the stationary case, to which we now restrict ourself in this section, the autocorrelation, Eq. (23), is invariant under a shift of time origin, hence to a change in t. Thus both $R(t,\tau)$ and $G(\alpha,\omega,t)$ are independent of t. Equation (22) can then be simplified to

$$G(\alpha,\omega) = 2\int_{-\infty}^{\infty} e^{j\omega t}\langle \alpha^*(t)\alpha(0)\rangle dt. \tag{25}$$

According to the SE definition, Eq. (21), the noise is manifestly real. Equation (25) can also be shown to be real by taking its complex conjugate and introducing $-t$ as a new variable of integration. This conclusion remains true even if α is a complex variable, or a non-Hermitian operator. In the classical case when time-reversal invariance holds, the ensemble average is an even function of time and

$$\begin{aligned} G(\alpha,\omega) &= 4\int_0^{\infty} \cos\omega t\langle \alpha^*(t)\alpha(0)\rangle dt \\ &= 4\mathrm{Re}\int_0^{\infty} \exp(j\omega t)\langle \alpha^*(t)\alpha(0)\rangle dt. \end{aligned} \tag{26}$$

It is easy to verify from Eq. (25) that the normalization integral

$$\int_{-\infty}^{\infty} G(\alpha,\omega)d\omega/4\pi = \langle |\alpha(0)|^2\rangle \tag{27}$$

is consistent with our original aim in Eq. (20).

If we have a classical variable V expressed as a linear combination of variables,

$$V(t) = \sum_m C_m\alpha_m(t), \tag{28}$$

then the noise in V is given by

$$G(V,f) = \sum_{mn} C_m^*C_nG_{mn}(\boldsymbol{\alpha},f), \tag{29}$$

where the noise matrix

$$G_{mn}(\boldsymbol{\alpha}) = 4\mathrm{Re}\int_0^\infty \exp(j\omega t)\langle\alpha_m^*(t)\alpha_n(0)\rangle dt. \tag{30}$$

If the variables $\boldsymbol{\alpha}$ have the decay matrix $\boldsymbol{\Lambda}$ of Eq. (11), the noise correlation G_{mn} is given by

$$G_{mn}(\boldsymbol{\alpha}) = 4\mathrm{Re}\sum_s [(-j\omega\mathbf{1} + \boldsymbol{\Lambda}^*)^{-1}]_{ms}\langle\alpha_s\alpha_n\rangle. \tag{31}$$

2.3 The Wiener–Khinchin Theorem

We shall prove the Wiener–Khinchin theorem by evaluating $G_s(\alpha,\omega)$ in terms of $G(\alpha,\omega)$:

$$G_s(\alpha,\omega) = \lim_{T\to\infty}\frac{1}{T} \times \left\langle\int_{-T}^{T}\alpha(v)^*\exp(j\omega v)dv\int_{-T}^{T}\alpha(u)\exp(-j\omega u)du\right\rangle. \tag{32}$$

In the stationary case (for which the theorem is valid), Eq. (24) can be written

$$\langle\alpha(v)^*\alpha(u)\rangle = \frac{1}{4\pi}\int_{-\infty}^{\infty} e^{j\omega(v-u)}G(\alpha,\omega)d\omega. \tag{33}$$

If Eq. (33) is inserted into Eq. (32), with ω replaced by ω', we have

$$\begin{aligned} G_s(\alpha,\omega) &= \lim_{T\to\infty}\frac{1}{T}\int_{-\infty}^{\infty} G(\alpha,\omega')d\omega' \times\frac{1}{4\pi}\left|\int_{-T}^{T}\exp[j(\omega-\omega')u]du\right|^2 \\ &= \lim_{T\to\infty}\int_{-\infty}^{\infty} G(\alpha,\omega')d\omega'\,\frac{\sin^2(\omega'-\omega)T}{\pi(\omega'-\omega)^2T} \\ &= G(\alpha,\omega). \end{aligned} \tag{34}$$

This completes our heuristic proof of the Wiener–Khinchin theorem. The last step moved the limiting procedure under the integral sign and used

$$\lim_{T\to\infty}\frac{\sin^2(\omega'-\omega)T}{\pi(\omega'-\omega)^2T} = \delta(\omega'-\omega). \tag{35}$$

The appropriateness of the limit, Eq. (35), is based on the facts that

1. the integral of the left-hand side, for any T, is 1;
2. the width of the function is of order $1/T$, and the maximum height, at $\omega' = \omega$, is of order T. This function becomes very tall and narrow. An integration against this function by any function $G(\omega')$ of bounded variation will be sensitive only to its value at the peak $\omega' = \omega$.

Note that Eq. (33) with $u = v = t$ leads to the normalization condition

$$\langle\alpha(t)^*\alpha(t)\rangle = \frac{1}{4\pi}\int_{-\infty}^{\infty} G(\alpha,\omega)d\omega. \tag{36}$$

This normalization is equivalent to the customary choice, Eq. (20), when $G(\alpha,\omega)$ is even in ω, but is generally valid even when it is not. It follows easily from time-reversal invariance that for classical variables evenness follows, but this is not true for quantum mechanical variables. (Our definitions apply to the quantum case if α^* is replaced in the quantum case by the Hermitian conjugate, $\alpha^\dagger$.)

2.4 Noise Measurements Using Filters

An actual measurement of noise at a frequency ω_0 passes the signal $\alpha(t)$ through a filter described in the time domain by

$$\alpha_{\text{out}}(t) = \int_{-\infty}^{t} K(t-t')\alpha(t')dt', \tag{37}$$

where $K(t)$ is known as the indicial response of the filter, or its response to a $\delta(t)$ input pulse. In order that the filter be realizable, hence causal, output can only appear after input, so that

$$K(t) = 0 \text{ for } t < 0. \tag{38}$$

The upper limit in Eq. (37) can thus be extended to infinity. In terms of Fourier components,

$$\alpha(\omega) \equiv \int_{-\infty}^{\infty}\exp(-j\omega t)\alpha(t)dt, \tag{39}$$

Eq. (37) yields the convolution-theorem result

$$\alpha_{\text{out}}(\omega) = k(\omega,\omega_0)\alpha(\omega), \tag{40}$$

where

$$k(\omega,\omega_0) \equiv \int_0^\infty \exp(-j\omega t)K(t)dt. \tag{41}$$

The ω_0 is arbitrarily introduced into our notation to be a reminder that we shall be dealing with a filter that emphasizes the frequency region near ω_0. Thus we expect the output spectrum to be $|k(\omega,\omega_0)|^2$ times the input spectrum:

$$(\alpha_{\text{out}}^2)_\omega = |k(\omega,\omega_0)|^2(\alpha^2)_\omega. \tag{42}$$

However, this argument is heuristic, since the integral for α_ω does not converge in the usual sense.

What is actually measured is

$$G_m(\omega_0) = \frac{1}{2T}\int_{t_0-T}^{t_0+T} |\alpha_{\text{out}}(t)|^2 dt, \tag{43}$$

the time average of the squared signal. For long enough T we expect ergodicity and can replace the time average by the ensemble average. Because of stationarity, this result simplifies to

$$\begin{aligned} G_m(\omega_0) &= \langle|\alpha_{\text{out}}(t)|^2\rangle = \int_{-\infty}^{t} K(t-t')^*dt' \\ &\quad \times \int_{-\infty}^{t} K(t-t'')dt''\langle\alpha(t')^*\alpha(t'')\rangle \\ &= \int_0^\infty\int_0^\infty K(u)^*K(v) \\ &\quad \times \langle\alpha(t-u)^*\alpha(t-v)\rangle dudv \\ &= \int_0^\infty K(u)^*du \int_0^\infty K(v)dv\langle\alpha(v)^*\alpha(u)\rangle. \end{aligned} \tag{44}$$

Order has been preserved in the above steps so that they remain valid for noncommuting operators. Using the Wiener–Khinchin theorem in reverse, Eq. (33), to eliminate the autocorrelation, we obtain

$$G_m(\omega_0) = \frac{1}{4\pi}\int_{-\infty}^{\infty} G(\alpha,\omega)d\omega|k(\omega,\omega_0)|^2. \tag{45}$$

The factor 4π arises because of the convention followed in Eq. (36).

2.4.1 A Realizable Filter. The simplest example of a realizable filter is to regard $\alpha(t)$ as a voltage placed across an R-L-C circuit, with the output $\alpha_{\text{out}}(t)$ obtained across the resistance. The differential equations describing this filter are

$$RI(t) = \frac{1}{C}\frac{dQ}{dt} + L\frac{dI}{dt} = \alpha(t), \tag{46}$$

$$\alpha_{\text{out}}(t) = I(t)R. \tag{47}$$

These equations result in the Fourier relation

$$\alpha_{\text{out}}(\omega) = k(\omega,\omega_0)\alpha(\omega) \tag{48}$$

with

$$k(\omega,\omega_0) = \frac{R}{R + j(\omega L - 1/\omega C)}, \tag{49}$$

where $\omega_0 = 1/\sqrt{LC}$ is the resonance frequency.

The measured spectrum $G_m(\omega_0)$ continues to be given by Eq. (45). In the limit when the $Q \equiv \omega_0 L/R$ of the oscillator becomes large, there are two sharp resonances at $\pm\omega_0$, and we can approximate

$$|k(\omega,\omega_0)|^2 = [\delta(\omega-\omega_0) + \delta(\omega+\omega_0)]\pi R/2L, \tag{50}$$

where the coefficient $\pi R/(2L)$ was chosen to yield the correct integral

$$\int_{-\infty}^{\infty} \frac{R^2 d\omega}{R^2 + (\omega L - 1/\omega C)^2} = \frac{\pi R}{L}. \tag{51}$$

This integral was evaluated using formula 031.10 in Gröbner and Hofreiter (1950). Equations (45) and (50) combine to yield

$$G_m(\omega_0) = RG(\alpha,\omega_0)/4L, \tag{52}$$

a result sensitive only to the measurement frequency with a known renormalization factor $R/(4L)$.

3. THERMAL NOISE

3.1 Johnson Noise

Johnson (1928) measured the voltage noise in a variety of materials, as a function of resistance. He found the results shown in Fig. 1, namely, that $\langle V^2\rangle$ is proportional to the resistance R, independent of the mate-

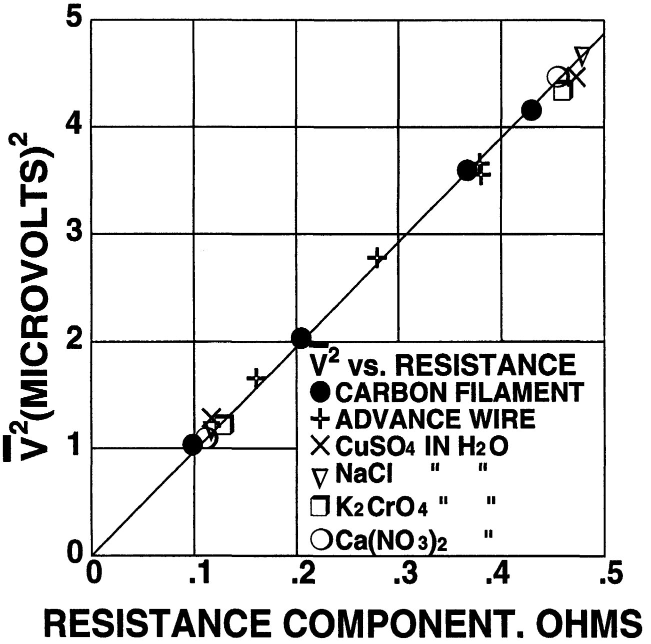

FIG. 1. The noise measured by Johnson (1928) versus resistance in six diverse materials.

rial. See also Kittel (1958). He also found that the measured noise power in the frequency interval df is proportional to the temperature of the resistor from which the noise emanates:

$$\langle v^2 \rangle = 4kdfRT = G(v,f)df. \tag{53}$$

To within his experimental accuracy, k is found to agree with the Boltzmann constant. The theoretical support for this choice is based on the equipartition theorem and Nyquist's theorem discussed in Secs. 3.2 and 3.4.

Moullin (1938) gives a review of the experimental measurements of noise. He considers two resistors in parallel at two different temperatures and concludes that the noise in a frequency interval df is given by

$$\begin{aligned}\langle v^2 \rangle &= 4kdf\frac{R_1R_2}{(R_1+R_2)^2}[T_1R_2 + T_2R_1] \\ &\equiv 4kdfR_eT_a, \end{aligned}\tag{54}$$

where k is Boltzmann's constant and R_e is an effective resistance that is compared with experimental data in Fig. 2 by Williams (1937). Williams chooses T_a to be T_1, except in the limiting case of $R_1 = \infty$, in which there is only one resistance, and he then takes T_a to be room temperature.

Moullin (1938, p. 31) generalizes this result to the case of an arbitrary number of impedances in parallel:

$$Z = \left[\sum_n (1/Z_n)\right]^{-1}, \tag{55}$$

$$\langle v^2 \rangle = 4kdf|Z|^2 \sum_n \frac{R_nT_n}{|Z_n|^2}\,. \tag{56}$$

If we remember that admittance Y_n is related to the impedance $Z_n \equiv R_n + jX_n$ by

$$Y_n = \frac{1}{Z_n} = \frac{R_n - jX_n}{R_n^2 + X_n^2} \equiv g_n - js_n \tag{57}$$

and write $V = ZI$, this result takes a simpler form in terms of current fluctuations,

$$\langle I^2 \rangle = 4kdf\sum_n g_nT_n. \tag{58}$$

These alternative expressions are not surprising in terms of Thevenin's and Norton's theorems. The terms g_n and s_n are referred to as conductance and susceptance. The result, Eq. (54) or (58), used equilibrium theory to

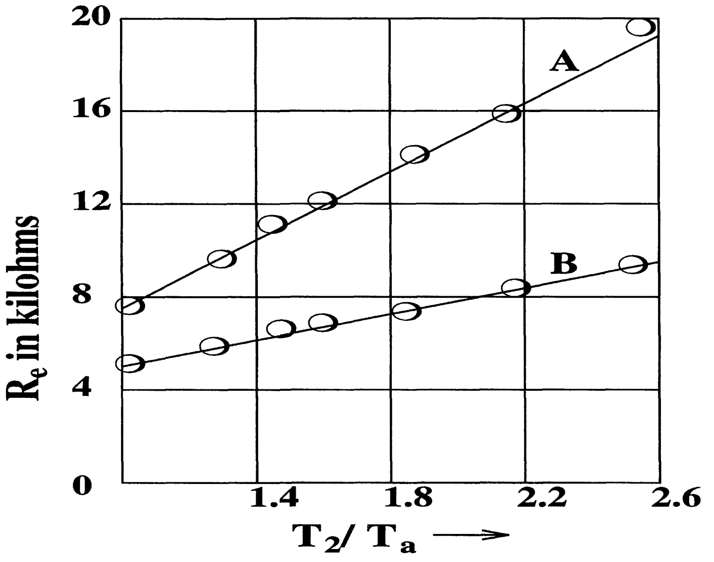

FIG. 2. Thermal noise for two resistors in parallel versus temperature obtained by Williams (1937) is plotted as an effective resistance defined by $R_e = \langle v^2\rangle/[4kdfT_a]$ against T_2/T_a. Williams takes T_a to be T_1, except in the one-resistor case, for which T_1 is infinite, and he then chooses T_a to be room temperature. Both theory, in Eq. (54), and experiment are linear functions of the abscissa. Line B is the two-resistance case, and line A is the one-resistance case.

obtain results when true equilibrium (all temperatures equal) is absent.

3.2 Equipartition

In this section we establish a fundamental compatibility between Johnson noise and thermodynamic equilibrium by demonstrating that this noise source generates an energy $kT/2$ in inductances and capacitances to which it is connected.

Consider a series circuit of resistor R, inductance L, and capacitor C, with a Johnson noise voltage v in the resistor. Then the resulting current and charge fluctuations i and q are

$$i = \frac{v}{R + j(\omega L - 1/\omega C)}; \quad q = i/j\omega. \tag{59}$$

The fluctuation energy in the inductance is, from Eq. (53),

$$\begin{aligned}\tfrac{1}{2}L\langle i^2\rangle &= \tfrac{1}{2}L\int \frac{G(v,f)df}{R^2 + (\omega L - 1/\omega C)^2} \\ &= 2kTRL\int_0^\infty \frac{df}{R^2 + (\omega L - 1/\omega C)^2} = \tfrac{1}{2}kT.\end{aligned} \tag{60}$$

Similarly, the energy stored on the capacitance is

$$\begin{aligned}\tfrac{1}{2}\frac{1}{C}\langle q^2\rangle &= \frac{2RkT}{C}\int_0^\infty \frac{df}{\omega^2[R^2 + (\omega L - 1/\omega C)^2]} \\ &= \tfrac{1}{2}kT.\end{aligned} \tag{61}$$

Thus, for both the inductance and the capacitor, the energy stored because of the noise in the resistor is precisely that expected by the equipartition theorem ($kT/2$ for each degree of freedom quadratic in the coordinate or the velocity.) Note that Eq. (59) is a relation between Fourier components, so that, for example, i and q should be written i_ω and q_ω, whereas in Eqs. (60) and (61), we are really dealing with the time-dependent quantities $\langle i(t)^2\rangle$ and $\langle q(t)^2\rangle$, respectively.

A fundamental truth now emerges. Fluctuations must be associated with dissipation in order that $\langle q^2\rangle$ does not decay to zero, but maintains the appropriate thermal equilibrium energy.

3.3 Thermodynamic Derivation of Johnson Noise

In view of the compatibility with thermal equilibrium shown in the preceding section, it is not surprising that a simple thermodynamic argument can be used to demonstrate that the noise emanating from a resistor must be proportional to its resistance.

Consider two resistors in a series circuit shown in Fig. 3. The current i_1 through resis-

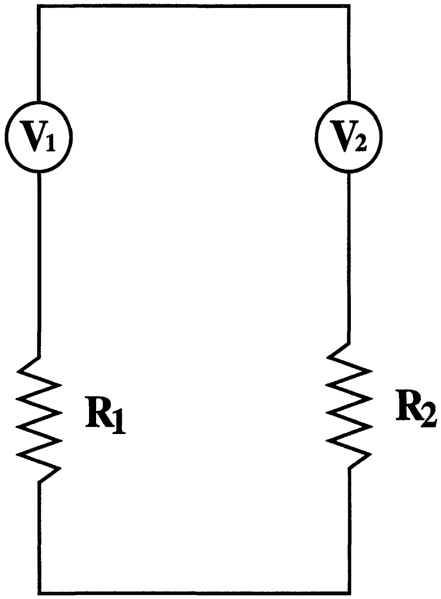

FIG. 3. The power transfer between two resistances in parallel, where v_j is the Johnson noise voltage in resistor j.

tor 2 produced by the noise voltage v_1 in the first resistor is

$$i_1 = v_1/(R_1 + R_2). \tag{62}$$

The power from v_1 into R_2 is given by

$$P_{2\leftarrow 1} = \left(\frac{v_1}{R_1 + R_2}\right)^2 R_2 = i_1^2 R_2. \tag{63}$$

Conversely, the power from 2 into 1 is given by

$$P_{1\leftarrow 2} = i_2^2 R_1 = \frac{v_2^2 R_1}{(R_1 + R_2)^2}\,. \tag{64}$$

If both resistors are at the same temperature, the second law of thermodynamics requires that there can be no steady net flow (in either direction). Equating Eqs. (63) and (64), we obtain

$$\frac{v_1^2}{R_1} = \frac{v_2^2}{R_2} \text{ or } \frac{G(v_1,f)}{R_1} = \frac{G(v_2,f)}{R_2} = W(f), \tag{65}$$

where $W(f)$ is a possibly frequency-dependent factor that is independent of the various resistances. In summary, the noise spectrum associated with an arbitrary resistance R is given by

$$G(v,f) = W(f)R. \tag{66}$$

If we connect a resistor R_1 to an impedance $R(f) + jX(f)$, the same equality requires

$$R(f)\left|\frac{v_1}{R_1 + R(f) + jX(f)}\right|^2 = \left|\frac{v_2}{R_1 + R(f) + jX(f)}\right|^2 R_1. \tag{67}$$

Thus we can conclude that the noise $G(v,f)$ associated with impedance $Z(f)$ is given by

$$G(v,f) = W(f)R(f) = W(f)\mathrm{Re}Z(f). \tag{68}$$

Thus the noise is proportional to $R(f) = \mathrm{Re}Z(f)$ even when the impedance $Z(f)$ is frequency dependent.

3.4 Nyquist's Theorem

A more complete derivation of the fluctuation–dissipation relation including a determination of the universal coefficient $W(f)$ is provided by Nyquist (1927, 1928). Nyquist's procedure is to calculate the power dissipated in a load connected to the end of a transmission line in two different ways and compare the results. Equation (63) for the power from resistor R_1 into R_2 in the frequency interval df reduces with Eq. (66) to

$$P_{2\leftarrow 1} = \frac{W(f)R_1R_2}{(R_1 + R_2)^2}\,df. \tag{69}$$

The maximum power is transferred when the impedance is matched, $R_1 = R_2$:

$$P_{2\leftarrow 1} = \frac{1}{4}W(f)\Delta f. \tag{70}$$

A transmission line can be terminated with its "characteristic impedance"

$$R_0 = \sqrt{L_1/C}, \tag{71}$$

where L_1 is the inductance per unit length of the line and C is its shunt capacitance per unit length. In this case, waves down the line are not reflected. The line acts as if it were infinite. Nyquist therefore chooses as his proof vehicle a transmission line terminated by R_0 at both ends. The line is assumed to have length L. The transmission line can be described in terms of harmonic-oscillator modes. If U is the energy density per mode, then the energy per mode is

$$UL = kT, \tag{72}$$

where we have made use of the equipartition theorem.

If the modes are described as plane waves $\exp(\pm ikx)$, then k takes the discrete values

$$k = 2\pi n/L, \quad \text{whence } \Delta k = 2\pi/L \tag{73}$$

is the mode spacing. With $\omega \equiv 2\pi f$ related to k by the group velocity, $v = \partial\omega/\partial k$, the number of modes propagating to the right in a given frequency interval is

$$\begin{aligned}\text{No. of modes} &= \frac{\text{modes}}{\delta k}\cdot\frac{\delta k}{\delta f}\Delta f\\ &= \frac{L}{2\pi}\frac{2\pi}{v}\Delta f = \frac{L}{v}\Delta f.\end{aligned} \tag{74}$$

Since each mode carries an energy U with the group velocity v, the power transmission down the line is

$$\begin{aligned}\text{flux} &= (\text{flux/mode})(\text{No. of modes})\\ &= (Uv)(L/v)\Delta f = UL\Delta f.\end{aligned} \tag{75}$$

Comparison with Eq. (70) yields

$$W(f) = 4UL. \tag{76}$$

In the limit of classical physics, Eq. (72) applies, and

$$W(f) = 4kT. \tag{77}$$

This result yields Nyquist's theorem

$$G(v,f)\Delta f = 4kTR\Delta f, \tag{78}$$

a result in agreement with Johnson's experimental results.

The beautifully simple Nyquist proof yields a result independent of frequency because all the harmonic-oscillator traveling modes have the same energy kT. The normalization must, of course, agree with that found in order to obtain the agreement with equipartition found in Sec. 3.2.

An apparent problem with Nyquist–Johnson noise is that the total voltage fluctuation

$$\langle v^2\rangle = \int_0^\infty G(v,f)df \tag{79}$$

diverges. Nyquist suggested that this problem could be removed if the classical energy, kT, associated with a harmonic oscillator were replaced by the quantum energy,

$$kT \rightarrow \hbar\omega\bar{n}(\omega) = \hbar\omega[\exp(\hbar\omega/kT) - 1]^{-1}, \tag{80}$$

which approaches kT at low frequencies and vanishes experimentally at high frequencies.

Of course, the actual energy associated with a harmonic oscillator,

$$E = \hbar\omega[\bar{n}(\omega) + \tfrac{1}{2}], \tag{81}$$

includes the zero-point energy. If the latter is retained, the divergence in the integrated energy reappears.

It is appropriate to argue, however, that the zero-point energy, while real, can never be absorbed and hence should be omitted in the Nyquist proof. This point, however, requires further discussion, as it relates to fundamental considerations of the effects of zero-point motion of the electromagnetic field in the area of quantum optics.

Callen and Welton (1951) considered a general class of systems (quantum mechanically) and established that Eq. (78), and its dual form

$$G(I,f)\Delta f = 4kTG\Delta f = 4kT\,\mathrm{Re}\,Y(\omega)\Delta f, \tag{82}$$

apply to all systems near equilibrium with the replacement of kT by Eq. (80) or (81) when necessary. The importance of the Callen–Welton work is the great generality of potential applications. The fact that all dissipative systems have corresponding noises associated with them is necessary in order that the second law of thermodynamics not be violated when such systems are connected.

3.5 Relation between Nyquist and Einstein

Consider a mechanical system with velocity v. Then the noise, Eq. (21), associated with v can be written

$$G(v,f) = \lim_{T\to\infty} \frac{2}{T}\left\langle \left| \int_{-T/2}^{T/2} v(t)e^{-j\omega t}dt \right|^2 \right\rangle. \tag{83}$$

The zero-frequency noise is

$$G(v,0) = \frac{2}{T}\langle[\Delta x]^2\rangle, \text{ where}$$
$$\Delta x = x(T/2) - x(-T/2). \tag{84}$$

But the usual diffusion constant, D, is defined by $\langle[\Delta x]^2\rangle = 2DT$, where T is the total time traveled. Thus the zero-frequency velocity noise is directly determined by the diffusion constant,

$$G(v,0) = 4D. \tag{85}$$

Conversely, the fluctuation–dissipation theorem, Eq. (82), for the velocity (which is analogous to a current rather than a voltage, since the current is proportional to ev) is given by

$$G(v,f) = 4kT \operatorname{Re} Y(\omega), \tag{86}$$

where

$$Y(\omega) = v/F \tag{87}$$

is the admittance, or velocity per unit applied force. At zero frequency, we refer to v/F as the mechanical mobility B and v/E as the (electrical) mobility μ, so that

$$Y(0) = B = \mu/e. \tag{88}$$

The fluctuation–dissipation theorem at zero frequency now reads

$$D = kTB = (kT/e)\mu, \tag{89}$$

which is simply the Einstein (1905) relation between diffusion and mobility. For a verification of this relation for electrons and holes in semiconductors, see Transistor Teachers' Summer School (1953).

By relating the mechanical mobility to the viscosity determined by Stokes's law, Einstein was able to make a macroscopic determination of Avogadro's number in good agreement with current values. Although Einstein indicates that he had not seen the article by Brown (1828) describing microscopic observations on tiny pollen grains in water, in his second article Einstein (1906) refers to the work of Gouy (1888) with the quote that the "so-called Brownian motion is caused by the irregular thermal movements of the molecules of the liquid."

4. SHOT NOISE

4.1 The Poisson Process

There are two physical problems describable by the same random process. The first process is the radioactive decay of a collection of nuclei. The second is the production of photoelectrons by a *steady beam* of light on a photodetector. In both cases, we can let a discrete, positive, integer-valued variable $n(t)$ represent the number of counts emitted in the time interval between 0 and t. In both cases there is a constant probability per unit time ν such that νdt is the expected number of counts in $[t, t + dt]$ for small dt. We use the initial condition

$$n(0) = 0. \tag{90}$$

Then $n(t)$ will be the number of counts in the interval $[0,t]$. When we talk of $P(n,t)$ we can understand this to mean, $P(n, t|n = 0, 0)$, the conditional density distribution. Since the state $n(t) = n$ is supplied by transitions from the state $n - 1$ with production of photoelectrons at a rate νdt and is diminished by transitions from state n to $n + 1$, we have the rate equation

$$\frac{\partial P(n,t)}{\partial t} = \nu[P(n-1,t) - P(n,t)] \quad \text{for } n > 0. \tag{91}$$

In the first term, n increases from $n - 1$ to n, and in the second, from n to $n + 1$. Since $n \geq 0$, we have no supply from the state $P(-1,t)$ so that

$$\frac{\partial P(0,t)}{\partial t} = -\nu P(0,t), \tag{92}$$

whose solution is

$$P(0,t) = P(0,0)\exp(-\nu t) = \exp(-\nu t) \tag{93}$$

since $P(n,0) = \delta_{n,0}$ at time $t = 0$, corresponding to the certainty that there are 0 particles at time $t = 0$.

The form, Eq. (93), of this solution suggests the transformation

$$P(n,t) = \exp(-\nu t)Q(n,t) \tag{94}$$

with the resultant equation

$$\frac{\partial Q(n,t)}{\partial t} = \nu Q(n-1,t) \tag{95}$$

subject to the initial condition

$$P(n,0) = Q(n,0) = \delta_{n,0}. \tag{96}$$

Thus any $Q(n,t)$ may be readily obtained if $Q(n-1)$ is known. But n, as described by Eq. (91), can only increase. The result is the closed-form solution

$$P(n,t) = P(n,t|0,0) = \frac{(\nu t)^n}{n!}e^{-\nu t} \tag{97}$$

for $n \geq 0$ with a vanishing result for $n < 0$.

Distribution functions, such as Eq. (97), are also characterized by their moments μ_j', and their central moments μ_j, defined by

$$\mu_j' = \langle n^j\rangle;\ \mu_j = \langle (n - \langle n\rangle)^j\rangle. \tag{98}$$

A third set of moments, introduced by statisticians because they indicate clearly the deviation of a random process from that of a Gaussian, are called Thiele (1903) semi-invariants or cumulants by Kendall and Stuart (1969). The cumulants or linked moments $\kappa_j \equiv \langle n^j\rangle_L$ are defined in terms of the characteristic function (see PROBABILITY),

$$\begin{aligned}\langle \exp(ikn)\rangle &\equiv \sum_n \exp(ikn)P(n,t)\\ &= \exp\left[\sum_{j=1}^{\infty}\frac{(ik)^j}{j!}\kappa_j\right]\\ &= \exp\langle \exp(ikn) - 1\rangle_L.\end{aligned} \tag{99}$$

By taking the logarithm of this equation, expanding in powers of k, and comparing coefficients, one can read off the cumulants. The first four are particularly simple:

$$\kappa_1 = \langle n\rangle;\ \kappa_2 = \langle n^2\rangle_L = \langle (\Delta n)^2\rangle; \tag{100}$$

$$\kappa_3 = \langle n^3\rangle_L = \langle (\Delta n)^3\rangle; \tag{101}$$

$$\langle n^4\rangle_L = \langle (\Delta n)^4\rangle - 3\langle (\Delta n)^2\rangle^2; \tag{102}$$

where $\Delta n \equiv n - \langle n\rangle$ is the deviation from the mean. Cumulants beyond the second describe deviations from a Gaussian distribution.

The Poisson process is stationary. But no limit exists as $t \to \infty$, so that there is no time-independent $P(n)$. We can, however, evaluate the characteristic function of the conditional probability density:

$$\begin{aligned}\langle \exp(ikn)\rangle &\equiv \phi(k, t|n = 0, t = 0)\\ &= \sum_n e^{ikn}\frac{(\nu t)^n}{n!}e^{-\nu t}\\ &= \exp[\nu t(e^{ik} - 1)].\end{aligned} \tag{103}$$

Comparison of Eq. (103) for the Poisson process with Eq. (99) shows that for this process all cumulants have the same value,

$$\kappa_j = \nu t. \tag{104}$$

4.2 Pure Shot Noise

The Poisson process just described is, in fact, the simplest example of shot noise. We can picture the actual number $n(t)$ as a staircase function that is flat except at a set of times, t_j, at which a jump of unity occurs. Mathematically, this is describable as the solution of the stochastic differential equation

$$\frac{dn}{dt} = \sum_j \delta(t - t_j) \equiv \hat{\nu}(t). \tag{105}$$

We shall first show that the noise source, $\hat{\nu}(t)$, in Eq. (105) is indeed white noise and demonstrate its relation to conventional shot noise.

The average pulse rate over the large time interval $[0,T]$ is

$$\nu(t) = \langle \hat{\nu}(t)\rangle = \frac{1}{T}\sum_j \int_0^T \delta(t - t_j)dt_j = \frac{N}{T} = \nu, \tag{106}$$

where N is the number of pulses in the interval $0 < t_j \leq T$. We call the ratio ν to conform with the Poisson process in Sec. 3.1 and assume that this ratio is independent of t, and of the location of the time interval of length T.

The correlation in the fluctuation $\alpha(t) = \hat{\nu}(t) - \nu$ can be calculated in a similar way:

$$\langle \alpha(t)\alpha(t')\rangle = \langle \hat{\nu}(t)\hat{\nu}(t')\rangle - \langle \hat{\nu}(t)\rangle\langle \hat{\nu}(t')\rangle. \tag{107}$$

The first term involves a double sum

$$\langle \hat{\nu}(t)\hat{\nu}(t')\rangle = \sum_{i,j} \langle \delta(t - t_i)\delta(t' - t_j)\rangle, \tag{108}$$

but the diagonal ($j = i$) term involves the simpler average

$$\frac{1}{T}\sum_i \int_0^T \delta(t - t_i)\delta(t' - t_i)dt_i = \frac{N}{T}\delta(t - t'). \tag{109}$$

The terms with $j \neq i$ involve an uncorrelated average, which cancels against the last term in Eq. (107) in the limit as T goes to infinity, with the result

$$\langle \Delta\hat{\nu}(t)\Delta\hat{\nu}(t')\rangle = \nu\delta(t - t'). \tag{110}$$

The noise, by the Wiener–Khinchin formula, is

$$G(\nu,\omega) = 2\int_{-\infty}^{\infty} \langle \Delta\hat{\nu}(t)\Delta\hat{\nu}(t')\rangle dt = 2\nu, \tag{111}$$

a constant, or white noise.

If the pulses carry a charge e, the current is

$$\hat{I}(t) = e\hat{\nu}(t), \tag{112}$$

and we arrive at the traditional shot-noise formula

$$G(I,\omega) = 2e^2\nu = 2eI, \tag{113}$$

where $I = \langle \hat{I}\rangle$ is the average current.

4.3 Generalized Characteristic Functions

We must establish the equivalence of this pulse description in Eq. (105) with the Poisson distribution characterized by Eq. (91), by calculating the characteristic function by a direct method, and demonstrate its equality with that of the Poisson process given in Eq. (103). The characteristic function is defined by

$$\phi(k,t) = \langle \exp[ikn(t)]\rangle = \left\langle \exp\left[ik\int_0^t \hat{\nu}(s)ds\right]\right\rangle. \tag{114}$$

To save duplication later, we consider an appreciably more general problem. In this problem, the sequence of pulses that arrive can have a localized shape $f(t - t_j)$ that need not be a delta function. In the original problem considered by Campbell (1909), the discontinuity involved the charge on the electron, and so a factor q was added. The model was further generalized by Rice (1944, 1945, 1948) to permit the jumps to contain a random factor η. Thus Rice considered the process

$$\Theta(t) = q\sum \eta_j f(t - t_j), \tag{115}$$

where the η_j's are random jumps with a distribution independent of t_j, of t, and of j.

Our procedure for dealing with the same problem consists in writing

$$\Theta(t) = \int f(t - s)S(s)ds, \tag{116}$$

where the shot-noise function $S(s)$ is now given by

$$S(s) = q\sum_j \eta_j\delta(s - t_j). \tag{117}$$

Equation (116) describes $\Theta(t)$ as filtered shot noise. We can always remove the filtering to obtain results appropriate to pure shot noise.

We can now relate the ordinary characteristic function of Θ to the generalized characterized function of the shot-noise function, $S(s)$,

$$\langle \exp ik\Theta(t)\rangle = \left\langle \exp i\int_{-\infty}^{\infty} y(s)S(s)ds\right\rangle \tag{118}$$

by setting

$$y(s) \equiv kqf(t - s). \tag{119}$$

The average in Eq. (118), for general $y(s)$, was evaluated in two ways in Lax (1966b). The first made explicit use of Langevin techniques. The second, which follows Rice, is presented here. It makes use of the fact that the average can be factored:

$$\left\langle \exp i\int_{-\infty}^{\infty} y(s)S(s)ds\right\rangle = \prod_{j=1}^{N} \langle \exp[i\eta_j y(t_j)]\rangle. \tag{120}$$

Here, we have supposed that N pulses are distributed uniformly over a time interval T at the rate $\nu = N/T$. All N factors are independent of each other and have equal averages, so that after adding and subtracting 1 inside the brackets, the result is

$$\begin{aligned}\prod_{j=1}^{N}\int g(\eta_j)d\eta_j\left[1+\frac{1}{T}\int_{-T/2}^{T/2}\{\exp[i\eta_j y(t_j)]-1\}dt_j\right] \\ =\left[1+\frac{1}{T}\int g(\eta)d\eta\int_{-T/2}^{T/2}\{\exp[i\eta y(s)]-1\}ds\right]^N \\ =\exp\left[\nu\int g(\eta)d\eta\int_{-\infty}^{\infty}\{\exp[i\eta y(s)]-1\}ds\right],\end{aligned} \tag{121}$$

where $g(\eta)$ is the normalized probability density for the random variable η. In the last step, we assumed that the integral over s converges and replaced it by its limit before taking a final limit in which N and T approach infinity simultaneously with the fixed ratio $N/T = \nu$.

4.4 Rice's Generalized Campbell Theorem

Campbell's two theorems are the first and second moments, $\langle\Theta\rangle$ and $\langle(\Delta\Theta)^2\rangle$, evaluated explicitly in Eqs. (126) and (127) below. Rice's generalized Campbell's theorem is obtained by setting $y(s) = kqf(t - s)$ in Eq. (118). The result is not just the first two moments, but the complete characteristic function

$$\begin{aligned}\langle\exp ik\Theta(t)\rangle &= \left\langle\exp\left[ikq\sum_j \eta_j f(t-t_j)\right]\right\rangle \\ &= \exp\left(\nu\int g(\eta)d\eta\int_{-\infty}^{\infty}\{\exp[ikq\eta f(t-s)]-1\}ds\right).\end{aligned} \tag{122}$$

Let us now specialize to the case of the original Campbell process by setting $g(\eta) = \delta(\eta - 1)$:

$$\begin{aligned}&\langle\exp ik\Theta(t)\rangle \\ &= \exp\left[\nu\int_{-\infty}^{\infty}\{\exp[ikqf(t-s)]-1\}ds\right].\end{aligned} \tag{123}$$

The probability density of the variable Θ of Eq. (115) may then be obtained by taking the inverse Fourier transform of the characteristic function in Eq. (122):

$$\begin{aligned}P(\Theta) &= \frac{1}{2\pi}\int_{-\infty}^{\infty}\exp(-ik\Theta)dk \\ &\times \exp\left[\nu\int g(\eta)d\eta\int_{-\infty}^{\infty}\{\exp[ikq\eta f(s)]-1\}ds\right].\end{aligned} \tag{124}$$

This form of generalized Campbell's theorem, like its antecedents, assumes that the t_j are randomly (and on the average uniformly) distributed in time. Moreover, there is assumed to be no correlation between successive pulse times. Lax and Phillips (1958) have found it convenient to exploit Eq. (124) in studying one-dimensional impurity bands.

The cumulants of the Rice process can be obtained from Eq. (122) as the coefficients of $k^r/r!$ in the exponent:

$$\begin{aligned}\kappa_r &= \left\langle\left[q\sum_j \eta_j f(t-t_j)\right]^r\right\rangle \\ &= \nu q^r\int g(\eta)\eta^r d\eta\int_{-\infty}^{\infty} f(s)^r ds \\ &= \nu q^r\langle\eta^r\rangle\int_{-\infty}^{\infty} f(s)^r ds.\end{aligned} \tag{125}$$

4.5 Campbell's Theorems

The choice $g(\eta) = \delta(\eta - 1)$ reduces the Rice process to the original Campbell process. Campbell's theorem itself includes only the cases $r = 1,2$. These take the form

$$\langle\Theta\rangle = \nu q\int_{-\infty}^{\infty} f(s)ds, \tag{126}$$

$$\langle[\Delta\Theta]^2\rangle = \nu q^2\int_{-\infty}^{\infty} f(s)^2 ds. \tag{127}$$

We close this section with an application of Campbell's theorem to the RC circuit shown in Fig. 4. A charge e from a vacuum tube generates a voltage pulse

$$ef(t) = (e/C)\exp(-t/RC) \tag{128}$$

across the resistor R. Campbell's theorems then yield

$$\langle V\rangle = \nu(e/C)\int_0^{\infty} e^{-t/RC}dt = \nu eR = IR \tag{129}$$

and

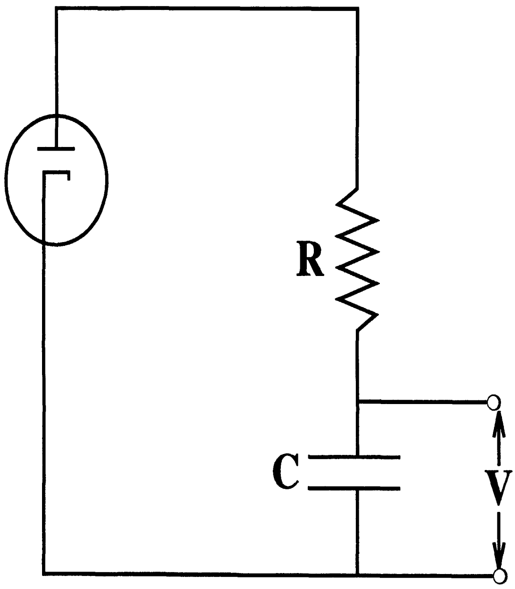

FIG. 4. The voltage fluctuation induced by shot noise into an *RC* circuit.

$$\langle(\Delta V)^2\rangle = \nu\frac{e^2}{C^2}\int_0^\infty e^{-2t/(RC)}dt = \frac{IeR}{2C}. \tag{130}$$

The electronic charge can be determined by comparison of $\langle(\Delta V)^2\rangle$ with $\langle V\rangle$:

$$e = 2C\langle(\Delta V)^2\rangle/\langle V\rangle. \tag{131}$$

4.6 Equivalence of Shot Noise to the Poisson Process

If we further specialize Eq. (123) by setting

$$qf(t - s) = 1 \quad \text{for } 0 \le s \le t \tag{132}$$

and zero elsewhere, then Eq. (116) reduces to

$$\Theta(t) = \int_0^t \hat{\nu}(s)ds = n(t). \tag{133}$$

The characteristic function, Eq. (132), of Θ is then identical to that of n and is given by

$$\langle \exp ikn(t)\rangle = \exp\left[\nu\int_0^t [\exp(ik) - 1]ds\right], \tag{134}$$

which reduces immediately to Eq. (103) as desired. This completes our proof that the shot-noise process of Eq. (105) is equivalent to the Poisson process of Eq. (91).

4.7 Transit-Time Effects

A set of carriers, j, leave a source (e.g., a cathode) at a set of times t_j and move to a destination (e.g., a plate) with a velocity $v(t - t_j)$. All carriers travel the fixed distance L and take the same travel time T, such that

$$\int_0^T v(t)dt = L. \tag{135}$$

The current in the external circuit will be

$$I(t) = \frac{e}{L}\sum_j v(t - t_j). \tag{136}$$

This intuitive result can be justified by a detailed calculation using Maxwell's equations.

The current can then be written as a convolution

$$I(t) = \frac{1}{L}\int_{-\infty}^{\infty} v(t - s)S(s)ds, \tag{137}$$

where the shot-noise function is

$$S(s) = e\hat{\nu}(s) = e\sum_j \delta(s - t_j) \tag{138}$$

as in Eq. (112) or (117) with $\eta = 1$. This convolution translates into a product of Fourier transforms that are squared to get the desired noise result

$$G(I,\omega) = G(S,\omega)W(\omega) = 2eIW(\omega), \tag{139}$$

where we have used the pure shot-noise result, Eq. (113), and the window factor

$$W(\omega) = \left|\frac{1}{L}\int_0^T v(t)e^{(-j\omega t)}dt\right|^2 \tag{140}$$

accounts for the transit-time effects and reduces the noise from the maximum value of $W(0) = 1$ eventually to $W(\infty) = 0$, although not necessarily monotonically. The time dependence of the velocity will be determined by the nature of the forces acting on the electron.

4.8 Generation–Recombination Process

The generation–recombination process in semiconductors is a second example of a shot-noise process in which the diffusion constants can be calculated from first principles on the basis of an understanding of the physics of the process. It is also an example of what statisticians refer to as a birth and death process.

Let us define the random integer variable n as the occupancy of some state. We assume that the particles are generated at the rate $G(n)$ and disappear at the rate $R(n)$ (recombination). Then our mean equation of motion is

$$\frac{\partial\langle n\rangle}{\partial t} = \langle G(n)\rangle - \langle R(n)\rangle \equiv \langle A(n)\rangle, \tag{141}$$

where $\langle A(n)\rangle$ is our drift vector. Since the occupancy of state n is increased by generation from the state $n - 1$ and reduced by generation out of the state n, whereas it is increased by recombination out of state $n + 1$ and reduced by recombination out of state n, the probability distribution function $P(n,t)$ obeys the following equation:

$$\begin{aligned}\frac{\partial P(n,t)}{\partial t} &= G(n-1)P(n-1,t) - G(n)P(n,t)\\ &\quad + R(n+1)P(n+1,t) - R(n)P(n,t).\end{aligned} \tag{142}$$

The Poisson process is a special case of the present one with $R = 0$, $G = \nu$. If the derivative is written as a difference, and the symbol n is replaced by n', Eq. (142) can be written as a master equation

$$\begin{aligned}&\frac{P(n',t+\Delta t) - P(n,t)}{\Delta t} = \\ &\sum_n P(n',t+\Delta t|n,t)/\Delta t P(n,t)\end{aligned} \tag{143}$$

with the transition rate

$$\begin{aligned}&\frac{P(n',t+\Delta t|n,t)}{\Delta t}\\ &\quad = \sum_n \{G(n)\delta_{n,n'-1} + R(n)\delta_{n,n'+1}\\ &\quad - [G(n) + R(n)]\delta_{n,n'}\}.\end{aligned} \tag{144}$$

The rth diffusion coefficient D_r, defined by (see Secs. 7.1 and 7.2)

$$\begin{aligned}r!D_r &= \frac{\langle (n'-n)^r\rangle}{\Delta t}\\ &= \sum_{n'} \frac{(n'-n)^r P(n',t+\Delta t|n,t)}{\Delta t}\end{aligned} \tag{145}$$

takes the value

$$\begin{aligned}r!D_r &= \sum_{n'} (n'-n)^r[G(n)\delta_{n,n'-1} + R(n)\delta_{n,n'+1}]\\ &= G(n) + (-1)^r R(n)\end{aligned} \tag{146}$$

after omission of noncontributing terms from Eq. (144).

A simpler procedure is to use Taylor's theorem in the operator form

$$\exp\left(h\frac{\partial}{\partial n}\right)F(n) = F(n+h), \tag{147}$$

with h set to $+1$ or -1, to rewrite Eq. (142) in the operational form

$$\begin{aligned}\frac{\partial P}{\partial t} &= \left[\exp\left(-\frac{\partial}{\partial n}\right) - 1\right]G(n)P(n)\\ &\quad + \left[\exp\left(\frac{\partial}{\partial n}\right) - 1\right]R(n)P(n).\end{aligned}$$

Expanding the Taylor series leads *immediately* to

$$\frac{\partial P}{\partial t} = \sum_{r=1}^{\infty}\left(-\frac{\partial}{\partial n}\right)^r \frac{[G(n) + (-1)^r R(n)P(n)]}{r!}P(n). \tag{148}$$

The rth-order diffusion constant derivative term read off from the coefficient of the rth derivative, in accord with Eq. (273), agrees with Eq. (146). [See Sec. 7.2 and Lax (1966a) for a detailed discussion of the generalized Fokker–Planck equation.] Thus all the even-numbered diffusion constants are proportional to the sum of the rate in plus the rate out, while all the odd-numbered *diffusion* constants are proportional to the difference, i.e., the rate in minus the rate out. In particular, the first and second moments, D_1 and D_2, obey

$$D_1 = A(a) = G - R, \tag{149}$$

$$2!D_2 = 2D = G + R = \text{rate in} + \text{rate out}. \tag{150}$$

These results are characteristic of shot noise.

Thus, in the quasilinear approximation, the operating point n_0 and decay parameter Λ are determined by Eqs. (10) and (11):

$$A(n_0) = G(n_0) - R(n_0) = 0, \tag{151}$$

$$\Lambda \equiv -\frac{\partial A}{\partial n}\bigg|_{n=n_0} = R'(n_0) - G'(n_0), \tag{152}$$

and the diffusion coefficient is

$$D = \tfrac{1}{2}[G(n_0) + R(n_0)] = G(n_0). \tag{153}$$

Then the Einstein relation, Eq. (15), in the case of a single variable yields the mean square fluctuation from the average value in terms of the diffusion constant D and the decay constant Λ:

$$\langle(\Delta n)^2\rangle = \frac{D}{\Lambda} = \frac{G(n_0)}{R'(n_0) - G'(n_0)}. \tag{154}$$

We now want to calculate the autocorrelation function, $\langle\Delta n(t)\Delta n(0)\rangle$. Since the transport equation and its solution are

$$\begin{aligned}\frac{\partial\langle\Delta n(t)\rangle}{\partial t} &= \langle A\rangle \approx -\Lambda\langle\Delta n\rangle,\\ \langle\Delta n(t)\rangle &= e^{-\Lambda t}\Delta n(0),\end{aligned} \tag{155}$$

the regression theorem and stationarity determine the correlations, via Eq. (18), to be

$$\langle\Delta n(t)\Delta n(0)\rangle = e^{-\Lambda|t|}\langle[\Delta n(0)]^2\rangle. \tag{156}$$

The noise in n is then given by Eq. (26),

$$G(n,\omega) = \frac{4\Lambda}{\Lambda^2 + \omega^2}\langle(\Delta n)^2\rangle. \tag{157}$$

5. RESISTANCE MODULATION FLUCTUATIONS

5.1 Conductivity Fluctuations

Information about carrier-number fluctuations can be obtained by injecting a constant current and measuring the voltage fluctuations induced by the conductivity modulation caused by carrier-concentration fluctuations. The admittance can be written

$$Y = A(pe\mu_p + ne\mu_n) = (Pe\mu_p + Ne\mu_n)/L, \tag{158}$$

where μ_p and μ_n are the hole and electron mobilities, p and n are the hole and electron concentrations, and P and N are the total hole and electron numbers over the volume AL between the electrodes, of area A and separation L. Thus the fractional voltage fluctuations are given by

$$\frac{\Delta V}{V} = -\frac{\Delta Y}{Y} = -\frac{\Delta P\mu_p + \Delta N\mu_n}{P\mu_p + N\mu_n}. \tag{159}$$

If only electrons and holes are present (and not traps), charge neutrality will be enforced up to the (very high) dielectric relaxation frequency, so that to an excellent approximation

$$\Delta N(t) = \Delta P(t). \tag{160}$$

Thus the voltage autocorrelation is given by

$$\begin{aligned}\langle\Delta V(t)\Delta V(0)\rangle &= V^2[(1 + b)/(P + Nb)]^2\\ &\quad\times\langle\Delta P(t)\Delta P(0)\rangle,\end{aligned} \tag{161}$$

where $b = \mu_n/\mu_p$. It follows that the voltage noise is given by

$$G(V,\omega) = V^2\left(\frac{1 + b}{P + Nb}\right)^2\langle(\Delta P)^2\rangle\int_0^\infty 4\cos\omega t dt\,\Phi(t), \tag{162}$$

and the total voltage fluctuation may be obtained by replacing the integral by unity. The "after-effect function" $\Phi(t)$ is defined by

$$\langle\Delta P(t)\Delta P(0)\rangle = \langle(\Delta P)^2\rangle\Phi(t). \tag{163}$$

The total noise, which only involves $\Phi(0) = 1$, is consistent with the normalization condition, Eq. (27), in the noise spectrum. The after-effect function will be calculated in later sections.

5.2 A Thermodynamic Treatment of Total Carrier Fluctuations

We first consider a set of free electrons in the nondegenerate case when Boltzmann (rather than Fermi) statistics are applicable. Then Shockley (1950) has shown that the total number of electrons obeys the statistical mechanical relation

$$N = N_c \exp[(\mu - E_c)/kT], \tag{164}$$

where E_c is the energy at the bottom of the conduction band and N_c is a temperature-dependent effective density of states. The conventional symbol μ is used to represent the electron Fermi level or chemical potential. Since it will not appear later, there will be no confusion with the mobility. The thermodynamic formula, Eq. (3), then yields

$$\langle(\Delta N)^2\rangle = kT\left(\frac{\partial N}{\partial \mu}\right)_T = N. \tag{165}$$

This result is not entirely surprising, since the total number of carriers is an integral

$$N = \int_V \sum_j \delta(\mathbf{r} - \mathbf{r}_j)d^3r; \tag{166}$$

this is the three-dimensional analog of Eqs. (105) and (133). Indeed, Eq. (165) can be derived directly from Eq. (166) using only the assumption that the $\mathbf{r}_j$ are uniformly distributed in space.

A less obvious case is that of a set of N_t traps interacting with a reservoir of chemical potential μ_t. We assume that the trap occupancy is sufficiently high that Fermi statistics are necessary. In that case, the number of filled traps by use of Fermi–Dirac statistics is

$$\hat{N} = \frac{N_t}{1 + \exp[(E_t - \mu_t)/kT]}. \tag{167}$$

In that case, the thermodynamic formula, Eq. (165), becomes

$$\langle(\Delta \hat{N})^2\rangle = kT\left(\frac{\partial \hat{N}}{\partial \mu_t}\right)_T = \hat{N}\left[1 - \frac{\hat{N}}{N_t}\right]. \tag{168}$$

It can be seen that the fluctuations are reduced by a factor equal to the fraction of empty states. The reason for this result is made clear in the next section, in which a kinetic approach is used for the same problem. If both N and $\hat{N}$ are allowed to vary simultaneously, the simplest distribution consistent with these second moments is

$$W \propto \exp\left[-\frac{(\Delta N)^2}{2\langle(\Delta N)^2\rangle} - \frac{(\Delta \hat{N})^2}{2\langle(\Delta \hat{N})^2\rangle}\right]. \tag{169}$$

The term in $\Delta N \Delta \hat{N}$ vanishes because N does not depend on μ_t and $\hat{N}$ does not depend on μ. Within the quasilinear approximation, it is appropriate to ignore higher cumulants than the second and stop at the Gaussian approximation.

Suppose, now, that the electrons in traps do not have an independent reservoir, but are obtained from the free carriers. Then we must impose the conservation condition

$$\Delta \hat{N} = -\Delta N. \tag{170}$$

If this constraint is inserted into Eq. (169), we obtain a Gaussian in a single variable with the second moment

$$\begin{aligned}\langle(\Delta N)^2\rangle = \langle(\Delta \hat{N})^2\rangle &= \frac{\langle(\Delta N)^2\rangle\langle(\Delta \hat{N})^2\rangle}{\langle(\Delta N)^2\rangle + \langle(\Delta \hat{N})^2\rangle} \\ &= \frac{N\hat{N}(N_t - \hat{N})}{NN_t + \hat{N}(N_t - \hat{N})}.\end{aligned} \tag{171}$$

In the next section, we show that this result can be derived by the Einstein relation.

The situation for holes is similar to that for electrons. If the holes have their own reservoir, then the typical Poisson process prevails:

$$\langle(\Delta P)^2\rangle = P. \tag{172}$$

If holes, traps, and electrons are all present and coupled to each other, then charge neutrality imposes the constraint

$$\Delta N + \Delta \hat{N} = \Delta P. \tag{173}$$

In the presence of compensating centers, N_{co}, there is also a neutrality condition for the steady state:

$$N + \hat{N} = P + N_t - N_{\text{co}}. \tag{174}$$

The influence of these constraints on the fluctuations is developed in the next section.

5.3 Einstein Derivation of Carrier Fluctuations with Traps

As in the previous section, we consider traps interacting with free electrons. This problem is a generation–recombination problem with a generation rate proportional to the number of carriers in the traps and a recombination rate proportional to the product of the number of free carriers and the number of empty traps,

$$g(N) = \gamma\hat{N}, \qquad r(N) = \rho N(N_t - \hat{N}). \tag{175}$$

We regard g and r as functions only of N since $\hat{N}$ is a function of N given in Eq. (174). The diffusion coefficient in the steady state is then

$$D(N) = r(N) \tag{176}$$

in view of Eqs. (151) and (153); and the decay coefficient, in accord with Eq. (152), is

$$\Lambda = r'(N) - g'(N) = \rho[(N_t - \hat{N}) + N] - (-\gamma), \tag{177}$$

where the derivatives were taken using $\Delta\hat{N} = -\Delta N$. The electron carrier fluctuation $\langle(\Delta N)^2\rangle = D/\Lambda$ is in agreement with Eq. (171).

We next consider carrier fluctuations in a p-type material in the presence of electrons and traps. We will regard N and $\hat{N}$ as the determining variables, with P obtained from the neutrality constraint, Eq. (174). Our discussion will follow Lax and Mengert (1960) with the replacement of C/Ω in that article by ρ, and of g in that article by γ, to conform with our notation in Eq. (175). Our nonlinear transport equation is taken to be

$$\begin{aligned}\frac{d\langle N\rangle}{dt} &= \langle G - R + \gamma\hat{N} - \rho(N_t - \hat{N})N\rangle,\\ \frac{d\langle\hat{N}\rangle}{dt} &= \langle\rho(N_t - \hat{N})N - \gamma\hat{N}\rangle.\end{aligned} \tag{178}$$

The terms in G and R refer to generation and recombination of electron–hole pairs, and the other terms refer to generation and recombination from the traps, as in Eq. (175).

The underlying transition rate per unit time for this model is

$$\begin{aligned}&w(N',\hat{N}';N,\hat{N})\\ &\quad= [G\delta(N',N+1) + R\delta(N',N-1)]\delta(\hat{N}',\hat{N})\\ &\qquad+ \rho\delta(N',N+1)\delta(\hat{N}',\hat{N}-1)\\ &\qquad+ \gamma(N_t - N)N\delta(N',N-1)\delta(\hat{N}',\hat{N}+1).\end{aligned} \tag{179}$$

The first moments of the transition rate are obtained by summing over the primed variables:

$$\begin{aligned}&\sum(N' - N)w(N',\hat{N}';N,\hat{N}) = G - R + \rho\hat{N} - \nu N,\\ &\sum(\hat{N}',-\hat{N})w(N',\hat{N}';N,\hat{N}) = \nu N - \rho\hat{N},\end{aligned} \tag{180}$$

where we use the abbreviation

$$\nu = \gamma(N_t - \hat{N}). \tag{181}$$

The results agree with our phenomenological transport equations, Eq. (178). If we linearize these equations, we obtain the two-by-two system

$$\frac{d}{dt}\begin{bmatrix}\langle\Delta N\rangle\\ \langle\Delta N\rangle\end{bmatrix} = -\mathbf{\Lambda}\begin{bmatrix}\langle\Delta N\rangle\\ \langle\Delta N\rangle\end{bmatrix} \tag{182}$$

with

$$\mathbf{\Lambda} = \begin{bmatrix}\nu + r & -g'\\ -\nu & g'\end{bmatrix}, \tag{183}$$

where the parameters are now evaluated under the steady-state conditions

$$\gamma\hat{N} = \rho(N_t - \hat{N})N = \nu N, \quad R = G. \tag{184}$$

The symbol r now stands for the experimental electron–hole recombination rate

$$r = \frac{\partial(R - G)}{\partial N}, \tag{185}$$

and

$$g' = \gamma + \rho N. \tag{186}$$

The diffusion constants may be obtained from the second moments of the transition rate:

$$\begin{aligned}D_{11} &= \sum(N' - N)^2 w(N',\hat{N}';N,\hat{N})/2\\ D_{22} &= \sum(\hat{N}' - \hat{N})^2 w(N',\hat{N}';N,\hat{N})/2\\ D_{12} &= \sum(N' - N)(\hat{N}' - \hat{N})w(N',\hat{N}';N,\hat{N})/2,\end{aligned} \tag{187}$$

so that

$$D_{11} = [(G + R) + (\gamma\hat{N} + \nu N)]/2, \tag{188}$$

where the evaluation of D_{11} was done at the steady state using the conditions

$$G = R, \quad \nu N = \gamma \hat{N}. \tag{189}$$

The complete matrix at the steady state is thus found to be

$$\mathbf{D} = \left| \begin{matrix} R + \gamma\hat{N} & -\gamma\hat{N} \\ -\gamma\hat{N} & \gamma\hat{N} \end{matrix} \right]. \tag{190}$$

The population fluctuations that result from Eq. (15) are then

$$\mathbf{\Lambda}^{-1}\mathbf{D} = \begin{bmatrix} R/r & 0 \\ (\nu R/r - \gamma\hat{N})/g' & \hat{N}\gamma/g' \end{bmatrix}. \tag{191}$$

There is a coupling between the free and bound electron populations. However, if the hole (majority) population P is much larger than N or $\hat{N}$, it would provide uncoupled reservoirs for these two populations, and we would expect the 21 element of the matrix to disappear. If we write the recombination as proportional to the product of the number of holes and electrons,

$$R = \alpha(N + \Delta N)(P + \Delta P), \quad G = NP, \tag{192}$$

then

$$R - G = \alpha[(P + N)\Delta N + N\Delta\hat{N}] \tag{193}$$

after use of charge neutrality, Eq. (173). Thus Eq. (185) yields

$$r = \alpha(P + N) \approx \alpha P = R/N. \tag{194}$$

In view of Eq. (189), the 21 elements vanish. With the help of Eq. (181), we find

$$\gamma/g' = 1 - (\hat{N}/N_t), \tag{195}$$

so that

$$\mathbf{\Lambda}^{-1}\mathbf{D} = \begin{bmatrix} N & 0 \\ 0 & \hat{N}' \end{bmatrix}, \tag{196}$$

where in this connection we have introduced the shorthand notation

$$\hat{N}' = \hat{N}[1 - (\hat{N}/N_t)]. \tag{197}$$

5.4 The Spectrum of Resistance Modulation Fluctuations

We return to the problem of the last section with a large number of majority carriers, P, a smaller number of trapped carriers, $\hat{N}$, and a still smaller number of free electrons, N. Because of the neutrality condition, Eq. (173), the voltage fluctuation of Eq. (159) can be written

$$\Delta V = C_1\Delta N + C_2\Delta\hat{N}, \tag{198}$$

where

$$C_2 = V/(P + bN), \quad C_1 = (1 + b)C_2 \tag{199}$$

and $b = \mu_n/\mu_p$.

In view of the total population fluctuations given in Eqs. (196) and (197), the total voltage noise is given by

$$\begin{aligned} \int_0^\infty G(V,f)df &= \langle(\Delta V)^2\rangle, \\ &= |C_2|^2[\hat{N}' + (1 + b)^2 N]. \end{aligned} \tag{200}$$

The spectrum of voltage fluctuations is given by Eqs. (29) and (31):

$$\begin{aligned} G(V,f) = 4C_2^2\,\mathrm{Re}\{&(i\omega\mathbf{1} + \mathbf{\Lambda})_{22}^{-1}\hat{N}' + (1 + b) \\ &\times [(i\omega\mathbf{1} + \mathbf{\Lambda})_{12}^{-1}\hat{N}' + (i\omega\mathbf{1} + \mathbf{\Lambda})_{21}^{-1}N] \\ &+ (1 + b)^2(i\omega\mathbf{1} + \mathbf{\Lambda})_{11}^{-1}N\}. \end{aligned} \tag{201}$$

Here we have omitted the star, since $\mathbf{\Lambda}$ is real, and replaced $-j$ by i to avoid minus signs. The elements of $\mathbf{\Lambda}$ were given in Eq. (183). An exact evaluation by Lax and Mengert (1960) yields a ratio of a quadratic to a quartic in ω. Lax and Mengert re-expressed their results by a partial-fraction analysis into the more understandable form

$$G(V,f) = \frac{4V^2}{(P + Nb)^2}\left[\frac{A_S\lambda_S}{\omega^2 + \lambda_S^2} + \frac{A_F\lambda_F}{\omega^2 + \lambda_F^2}\right] \tag{202}$$

of a sum of two Lorentzians whose integrated contributions are A_S and A_F associated with the slow and fast modes with eigenvalues λ_S and λ_F. The trace and determinant of $\mathbf{\Lambda}$, Eq. (183), yield the sum and product relations

$$\lambda_F = \nu + r + g' - \lambda_S, \quad \lambda_S = rg'/\lambda_F. \tag{203}$$

Typical parameters from the experiments of Hornbeck and Haynes (1955) and Haynes and Hornbeck (1955), as revised by Lax and Mengert (1960), indicate that the trapping rate $\nu = 3 \times 10^7$/s for free electrons greatly exceeds the effective release rate $g' = 3/\mathrm{s}$ from traps. These would be the basic decay rates for N and $\hat{N}$ respectively. It is then appropriate to assume that the slow rate $\lambda_S \ll \lambda_F$. If we iterate starting with $\lambda_S = 0$, we obtain a first approximation

$$\lambda_F \approx \nu + r + g', \quad \lambda_S \approx g'r/(\nu + r + g') \tag{204}$$

Since $\lambda_F \approx \nu = 3 \times 10^7$, and $\lambda_S \approx g'r/\nu \approx 3 \times 10^{-3}$, Eq. (204) has a relative accuracy of $\lambda_S/\lambda_F \approx 10^{-10}$. Lax and Mengert (1960) use this large decay ratio to simplify the formulas for A_S and A_F to

$$A_S \approx \hat{N}' + (1 + b)N, \quad A_F \approx (b^2 + b)N. \tag{205}$$

Perhaps the surprise in these numbers is that the slow eigenvalue λ_S of the combined system is 1000 times smaller than the emission rate from traps, which represents the decay of $\hat{N}$. The reason this is so is that the electrons rapidly ("adiabatically") respond to the bound trap density and generate captures that almost cancel the release rate. To verify this, we note that the adiabatic procedure in lowest order, as described in Lax (1967), is to set the time derivative of the rapidly changing quantity, $d\langle \Delta N \rangle/dt = 0$. This yields

$$\Delta N = [g'/(\nu + r)]\Delta\hat{N}. \tag{206}$$

When this is inserted into the second equation (for $\Delta\hat{N}$), the effective slow equation takes the form

$$d\langle\Delta\hat{N}\rangle = \lambda_S\langle\Delta\hat{N}\rangle \tag{207}$$

with the reduced value

$$\lambda_S \approx g'r/(\nu + r) \tag{208}$$

obtained after a near cancellation between the two terms.

6. CONCENTRATION FLUCTUATIONS IN SEMICONDUCTORS

6.1 General Theory of Concentration Fluctuations

The thermodynamic discussion of occupancy fluctuations in Sec. 5.2 can be generalized by noting that the average occupancy of a state of energy E is given by

$$\langle n \rangle = 1/\{\exp[\beta(E - \mu) + \epsilon]\}, \tag{209}$$

where for Fermi, Boltzmann, and Bose particles

$$\epsilon = \begin{cases} 1 \text{ for Fermi particles,} \\ 0 \text{ for Boltzmann particles,} \\ -1 \text{ for Bose particles.} \end{cases} \tag{210}$$

For application to a particular state a, replace n by $n(a)$ and E by $E(a)$. The fluctuation in occupancy of that state is given by the thermodynamic formula, Eq. (3), or the first part of Eq. (165), to be

$$\begin{aligned}\langle\Delta n(a)\Delta n(c)\rangle &= n(a)'\delta(a,c) \\ &\equiv n(a)[1 + \epsilon n(a)]\delta(a,c),\end{aligned} \tag{211}$$

which includes all three statistical cases, Fermi, Boltzmann and Bose, with the three choices of ϵ above. This result is true in equilibrium.

We have also established the truth of Eq. (211) for the nonequilibrium steady state in Lax (1960) by explicitly constructing a model in which there are transition probabilities for the transfer of particles between states, by determining the diffusion coefficients for this model, and then by solving the Einstein relation, Eq. (14), for the second moments. Since the details of the analysis are not particularly illuminating, they will not be repeated here except to note that if there is a constraint, such as the total number of particles in all the states being fixed, the simple formula, Eq. (211) above, is replaced by

$$\langle\Delta n(a)\Delta n(c)\rangle = n(a)\delta(a,c) - n(a)'n(c)' \Big/ \sum_b n(b)'. \tag{212}$$

This result clearly obeys the constraint

$$\left\langle\left[\sum_a \Delta n(a)\right]\Delta n(c)\right\rangle = 0. \tag{213}$$

Another point of interest is that the diffusion matrix in Lax (1960), Sec. 12, was found to have the diagonal elements

$$\begin{aligned}2D_{bb} = &\text{ total jump rate out of } b \\ &+ \text{total jump rate into } b,\end{aligned} \tag{214}$$

and the nondiagonal elements are

$$2D_{ab} = -[\text{transition rate from } a \text{ to } b + \text{rate from } b \text{ to } a]. \tag{215}$$

We therefore regard such diffusion constants as characteristic of shot noise because of particle-number quantization.

6.1.1 Application to Semiconductors with Electrons, Holes, and Traps. Equation (212) can be readily applied to the case in which $n(1) = N =$ the number of conduction electrons, $n(2) = \hat{N} =$ the number of trapped electrons, and $n(3) =$ number of electrons in the valence band $= N_v - P$, where N_v is the number of valence-band states and $P =$ the number of holes. Thus

$$n(1)' = N[1 - N/N_c] \approx N, \tag{216}$$

$$n(2)' = \hat{N}[1 - \hat{N}/N_t] = \hat{N}', \tag{217}$$

$$n(3)' = (N_v - P)(P/N_v) \approx P. \tag{218}$$

We have assumed nondegeneracy for the holes and the free electrons, but not for the trapped electrons. Since $\Delta n(3) = -P$, we can write the second moments in the form

$$\langle(\Delta N)^2\rangle = N - N^2/(P + N + \hat{N}'), \tag{219}$$

$$\langle(\Delta\hat{N})^2\rangle = \hat{N}' - (\hat{N}')^2/(P + N + \hat{N}), \tag{220}$$

$$\langle(\Delta P)^2\rangle = P - P^2/(P + N + \hat{N}), \tag{221}$$

$$\langle\Delta N\Delta\hat{N}\rangle = -N\hat{N}/(P + N + \hat{N}), \tag{222}$$

$$\langle\Delta P\Delta N\rangle = PN/(P + N + \hat{N}), \tag{223}$$

$$\langle\Delta P\Delta\hat{N}\rangle = P\hat{N}/(P + N + \hat{N}). \tag{224}$$

These results are consistent with the constraint $\Delta P = \Delta N + \Delta\hat{N}$ of charge neutrality. If the number of traps is zero, they reduce to $\Delta N = \Delta P$ and

$$\langle(\Delta N)^2\rangle = \langle(\Delta P)^2\rangle = NP/(N + P). \tag{225}$$

When $P \gg N$ and $P \gg \hat{N}$, these second moments reduce to those in Eq. (196), for the case of electrons and traps in the presence of majority holes.

6.2 The Influence of Drift and Diffusion on Resistance Modulation Noise

To concentrate on the influence of drift and diffusion on density fluctuations and modulation noise, let us return to the trap-free case discussed in Sec. 5.1. The spectrum of voltage noise, already given in Eq. (162), can be rewritten as a product

$$G(V,\omega) = \langle(\Delta V)^2\rangle g(\omega) \tag{226}$$

of the total noise

$$\langle(\Delta V)^2\rangle = V^2\left(\frac{1 + b}{P + Nb}\right)^2 \langle(\Delta P)^2\rangle \tag{227}$$

and the normalized spectrum

$$g(\omega) = \int_0^\infty 4 \cos\omega t dt \Phi(t), \tag{228}$$

where

$$1 = \int_0^\infty g(\omega) df = \int_{-\infty}^\infty g(\omega) \frac{d\omega}{4\pi}. \tag{229}$$

Note that this normalization is four times that used for $g(\omega)$ in Lax and Mengert (1960). For simplicity, we confine ourselves to a one-dimensional geometry, as was done by Hill and van Vliet (1958), and calculate the total hole fluctuation as

$$\Delta P(t) = \int_0^L \Delta p(x,t) dx. \tag{230}$$

We can now apply our techniques to continuous-parameter systems by replacing the sum

$$\alpha_i(t) = \sum_i [\exp(-\Lambda t)]_{ij}\alpha_j(0) \tag{231}$$

by the integral

$$\alpha_x(t) = \int [\exp(-\Lambda t)]_{xx'} dx' \alpha_{x'}(0). \tag{232}$$

Introducing a more convenient notation for the Green's function

$$[\exp(-\Lambda t)]_{xx'} = K(x,x',t), \tag{233}$$

we can write

$$\Delta p(x,t) = \int K(x,x'',t)dx''\Delta p(x'',0), \tag{234}$$

so that the correlation at two times is, as usual, related to the pair correlation at the initial time:

$$\langle \Delta p(x,t)\Delta p(x',0)\rangle = \int K(x,x'',t)dx'' \times \langle \Delta p(x'',0)\Delta p(x',0)\rangle. \tag{235}$$

It is customary to treat fluctuations at the same time at two places as uncorrelated. This is clearly the case, for independent carriers. It is less obvious when Coulomb attractions (say between electrons and holes) are included. It was shown, however, in Appendix C of Lax and Mengert (1960) that a delta-function correlation is valid, as long as we are dealing with distances greater than the screening radius. Thus we can take

$$\langle \Delta p(x'',0)\Delta p(x',0)\rangle = \langle (\Delta P)^2\rangle L^{-1}\delta(x'' - x'), \tag{236}$$

where the coefficient of the delta function is chosen so that the fluctuation in the total number of carriers $\langle (\Delta P)^2\rangle$ is given correctly by Eq. (225). Here L is the distance between the electrodes.

The definition, Eq. (163), of $\Phi(t)$ yields the expression

$$\Phi(t) = \frac{1}{L}\int_0^L dx \int_0^L dx' K(x,x',t). \tag{237}$$

If the Green's function is defined, appropriately as in Lax (1960), to vanish for $t < 0$, it will obey an equation of the form

$$\left(\frac{\partial}{\partial t} + \Lambda\right)K(x,x',t) = \delta(x - x')\delta(t), \tag{238}$$

where, in the continuous-variable case,

$$\Lambda = r + v\frac{\partial}{\partial x} - D\frac{\partial^2}{\partial x^2} \tag{239}$$

is an operator. Here, v and D are the ambipolar drift velocity and diffusion constants found by Van Roosebroeck (1953) to describe the coupled motion of electrons and holes while maintaining charge neutrality:

$$v = e\mu_a E, \quad \mu_a = (N - P)\mu_n\mu_p/(N\mu_n + P\mu_p); \tag{240}$$

$$D_a = (N + P)D_pD_n/(ND_n + PD_p), \tag{241}$$

where the individual diffusion constants and mobilities are related by the Einstein relation.

Equation (238) for the Green's function can be solved by a Fourier-transform method:

$$K(x,x',t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \exp[ik(x - x') - \lambda(k)t]dk, \tag{242}$$

where

$$\lambda(k) = r + ivk + Dk^2. \tag{243}$$

Here $\lambda(k)$ are the eigenvalues of the Λ operator,

$$\Lambda \exp(ikx) = \lambda(k)\exp(ikx). \tag{244}$$

With Eq. (242) for K, the after-effect function can be calculated from Eq. (237):

$$\Phi(t) = \frac{L}{2\pi}\int_{-\infty}^{\infty} dk\,\frac{\sin^2(z)}{z^2}\exp[-\lambda(k)t], \tag{245}$$

where $z = kL/2$. Thus the spectrum, Eq. (228), is

$$g(\omega) = \frac{4}{\pi}\int_{-\infty}^{\infty} dz\,\frac{\sin^2 z}{z^2}\frac{1}{i\omega + \lambda(z)}, \tag{246}$$

where λ has been re-expressed as a function of z,

$$\lambda(z) = r + 2i(v/L)z + 4(D/L^2)z^2. \tag{247}$$

Lax and Mengert (1960) provide an exact evaluation of this integral. However, the resulting expressions are complicated. It is therefore worth while to treat some limiting cases. For example, if there is no diffusion, then

$$K(x,x',t) = \exp(-rt)\delta(x - x' - vt), \tag{248}$$

and the after-effect function is given by

$$\Phi(t) = \exp(-rt)[1 - (t/T_a)], \tag{249}$$

where $T_a = L/v$ is the transit time and the spectrum is governed by a windowing factor W:

$$g(\omega) = 4T_aW \tag{250}$$

with the window factor given by

$$W = \int_0^{T_a} \cos\omega t e^{-rt}\left[1 - \frac{t}{T_a}\right]d\left(\frac{t}{T_a}\right). \tag{251}$$

Indeed, the current noise, in this special case, can be written in the form given by Hill and van Vliet (1958),

$$G(I,\omega) \equiv (I^2/V^2)G(I,\omega) = 2eI_{\text{eq}}, \tag{252}$$

which emphasizes the similarity to shot noise. The equivalent current is defined by

$$I_{\text{eq}} = 2I\frac{b + 2 + b^{-1}}{|P/N - N/P|}W. \tag{253}$$

The window factor still takes a complicated form,

$$W = \frac{(\tau/T_a)^2}{1 + (\omega\tau)^2}\left\{\frac{T_a}{\tau} - \frac{1 - (\omega\tau)^2}{1 + (\omega\tau)^2} + \frac{\exp(-T_a/\tau)}{1 + (\omega\tau)^2}\right.$$
$$\left.\times \{[1 - (\omega\tau)^2]\cos(\omega T_a) - 2\omega\tau\sin(\omega T_a)\}\right\}. \tag{254}$$

Here $\tau = 1/r$. Even this result is complicated to understand. If we take the limiting case when recombination is unimportant over the transit time, the result simplifies to

$$W = \frac{1}{2}\frac{\sin^2(\omega T_a/2)}{(\omega T_a/2)^2}, \tag{255}$$

a windowing factor similar to that found associated with the effect of transit time on shot noise. See Sec. 4.2.

In the opposite limit, in which diffusion is retained but drift is neglected, the exact result for the spectrum is given by

$$g(\omega) = 4\text{Re}J, \tag{256}$$

where

$$J = (r + i\omega)^{-1} - [D/(r + i\omega)^3]^{1/2}[1 - \exp(-\Gamma L)]/L \tag{257}$$

and

$$\Gamma = [(r + i\omega)/D]^{1/2} \tag{258}$$

is the reciprocal of the diffusion length. The exponential term represents an interference term between the two boundaries that is usually negligible since they are separated by substantially more than a diffusion length. A simple approximate form over intermediate frequencies is

$$g(\omega)/4 \approx r/(\omega^2 + r^2) + (1/L)(D/2\omega^3)^{1/2}. \tag{259}$$

In summary, in addition to the first term, which represents the volume noise easily computed just by using the total carrier, $P(t)$, effects, we get an inverse frequency to the three-halves power that arises from diffusion across the boundary at the electrodes.

7. LANGEVIN PROCESSES

7.1 Simplicity of Langevin Processes

Langevin treated noise by adding a random noise source to the linear equations describing the transport. Langevin methods, at least for a linear or quasilinear system, have the simplicity of the circuit equation of electrical engineering. The noise source may arise from thermal reservoirs as in Johnson noise, or shot noise from the discreteness of particles. But once the noise is represented as a voltage source with known moments, the physical nature of the source is no longer important. We have the analog for noise sources of current sources and Norton's theorem. The sources can be thought of as a black box, with an impedance in series with a voltage source, or an admittance in parallel with a current source. And the original nature of the sources will not enter into the solution of problem.

For the quasilinear case, we can write our set of Langevin equations in the form

$$\frac{d\boldsymbol{\alpha}}{dt} + \boldsymbol{\Lambda}\cdot\boldsymbol{\alpha} = \mathbf{F}(t), \tag{260}$$

where $\boldsymbol{\alpha} = \mathbf{a} - \langle \mathbf{a} \rangle$ is a multicomponent object, as is the force $\mathbf{F}(t)$. Equation (260) can be regarded as the definition of $\mathbf{F}(t)$. What condition must be imposed on $\mathbf{F}(t)$ in order that the resulting process $\boldsymbol{\alpha}(t)$ be a Markoffian process? (A Markoffian process is analogous to a student who only remembers the last thing he was told.) It was shown in Sec. 1 of Lax (1960) that a necessary and sufficient condition for $\boldsymbol{\alpha}(t)$ to be a Markoffian set of variables is for the Langevin forces $\mathbf{F}(t)$ to be delta correlated,

$$\langle \mathbf{F}(t)\mathbf{F}(u)\rangle = 2\mathbf{D}\delta(t-u). \tag{261}$$

The second moments in Eq. (261) are sufficient to calculate all second-order correlation functions of the α's for linear processes. Since these second-order correlations are insensitive to the higher moments of the noise sources, it is then permissible to regard the forces as Gaussian random variables. Then all linked moments beyond the second have been set equal to zero.

Shot-noise sources, however, do have higher linked moments than the second, and, at the linear level, we can consider a complete set of linked moments for any linear Markoffian process:

$$\langle F(t_1)F(t_2)\cdots F(t_n)\rangle^L = n!\mathbf{D}_n\delta(t_1-t_2)\cdots\delta(t_{n-1}-t_n). \tag{262}$$

The delta-function nature of these correlations guarantees the absence of memory required by a Markoffian process.

Indeed, if we choose

$$n!D_n = \langle(\Delta\alpha)^n\rangle/\Delta t = \nu\int \eta^n g(\eta)d\eta, \tag{263}$$

then the Langevin process, Eq. (260), reduces to the generalized one-dimensional shot-noise process of Sec. 4.2, associated with

$$\frac{da}{dt} = \sum_k \eta_k\delta(t-t_k), \tag{264}$$

where $g(\eta)$ is the probability of jumps in a of size η.

7.2 Relation to the Fokker–Planck Equation

To provide a bridge between the Langevin and Fokker–Planck points of view, we must show how the nth-order diffusion constants just introduced, by Eq. (262), into a Langevin description determine the motion of a general function $M(a)$ of the random process $a(t)$.

A general random process (not necessarily a Markoff one) necessarily obeys the relation on conditional probabilities

$$P(a', t+\Delta t|a_0, t_0) = \int P(a', t+\Delta t|a, t; a_0, t_0) \times da P(a,t|a_0,t_0). \tag{265}$$

The transition probability $P(a', t+\Delta t|a, t; a_0, t_0)$ describes the probability of arriving at a' at $t+\Delta t$ if one starts at a at time t, remembering that one started the entire process at a_0 at time t_0. This last bit of information may be omitted if the process is Markoffian. In that case Eq. (265) reduces to the Chapman–Kolmogoroff condition.

The nth-order conditional diffusion constant is defined by the relation

$$\begin{aligned} D_n(a,t|a_0t_0) &= \frac{1}{n!}\lim_{\Delta t\to 0}\int (a'-a)^n \\ &\quad\times P(a', t+\Delta t|a, t; a_0, t_0)\frac{da'}{\Delta t} \\ &= \frac{1}{n!}\lim_{\Delta t\to 0}\frac{1}{\Delta t} \\ &\quad\times \langle[a(t+\Delta t)-a(t)]^n\rangle|_{\substack{a(t)=a\\ a(t_0)=a_0}}. \end{aligned} \tag{266}$$

For a Markoffian process the dependence on a_0 can be omitted everywhere. Equation (265) can then be replaced by

$$P(a', t+\Delta t) = \int P(a', t+\Delta t|a, t)da P(a,t). \tag{267}$$

The average motion of an arbitrary function $M(a)$ of the random process $a(t)$ may be obtained by integrating $M(a')$ against $P(a', t+\Delta t)$. On the right-hand side of the equation, we shall replace $M(a')$ by its Taylor expansion

$$M(a') = M(a) + \sum_{n=1}^{\infty} (a' - a)^n \frac{M^{(n)}(a)}{n!} \tag{268}$$

The integrals over $(a' - a)^n$ give rise to the diffusion coefficients, so that we obtain

$$\langle M(a)\rangle_{t+\Delta t} = \langle M(a)\rangle_t + \Delta t \sum_{n=1}^{\infty} \int D_n(a,t) \times M^{(n)}(a)P(a,t)da. \tag{269}$$

Thus

$$\frac{d}{dt}\langle M(a)\rangle = \sum_{n=1}^{\infty} \left\langle D_n(a,t) \frac{\partial^n (M(a))}{\partial a^n}\right\rangle, \tag{270}$$

where for any function $g(a)$ the average means

$$\langle g(a)\rangle \equiv \int g(a)P(a,t)da. \tag{271}$$

To obtain the equation of motion for $P(a,t)$, we write Eq. (270) in the explicit from

$$\int \left[\sum_{n=1}^{\infty} D_n(a,t)P(a,t) \frac{\partial^n M(a)}{\partial a^n} - M(a) \frac{\partial P}{\partial t}(a,t)\right] \times da = 0. \tag{272}$$

After an integration by parts, we obtain

$$\int \left\{\sum_{n=1}^{\infty} (-1)^n \left(\frac{\partial}{\partial a}\right)^n [D_n(a,t)P(a,t)] - \frac{\partial P(a,t)}{\partial t}\right\} \times M(a)da = 0. \tag{273}$$

Since this equation is to be valid for any choice of $M(a)$, the coefficient of $M(a)$ in the above equations must vanish, yielding the generalized Fokker–Planck equation:

$$\frac{\partial P(a,t)}{\partial t} = \sum_{n=1}^{\infty} (-1)^n \left(\frac{\partial}{\partial a}\right)^n [D_n(a,t)P(a,t)]. \tag{274}$$

The ordinary Fokker–Planck equation is the special case in which the series terminates at $n = 2$.

Since Eq. (267) was true for all processes, including non-Markoffian, the existence of a generalized Fokker–Planck equation does not guarantee that the associated process is Markoffian. If we had done all our averages retaining the initial condition at t_0, we would have obtained the equation of motion

$$\frac{d}{dt}\langle f(a)\rangle_{a(t_0)=a_0} = \sum_{n=1}^{\infty} \left\langle D_n(at|a_0t_0) \frac{\partial^n f(a)}{\partial a^n}\right\rangle_{a(t_0)=a_0}, \tag{275}$$

and the Fokker–Planck equation is

$$\frac{\partial P(at|a_0t_0)}{\partial t} = \sum_{n=1}^{\infty} (-1)^n \left(\frac{\partial}{\partial a}\right)^n \times [D_n(a,t|a_0t_0)P(a,t|a_0t_0)]. \tag{276}$$

In the Markoffian case, Eq. (276) agrees with Eq. (274). Thus if (and only if) the process is Markoffian, $P(at|a_0t_0)$ obeys the same equation of motion as $P(a,t)$. Then, we can calculate $P(at|a_0t_0)$ by solving Eq. (274) subject to the initial condition

$$P(a,t) = \delta(a - a_0) \text{ at } t = t_0. \tag{277}$$

7.3 An Exactly Solvable Gaussian Example

We start with the simple example

$$\frac{dx}{dt} = \mu + \sigma f(t), \tag{278}$$

where μ and σ are constants and $f(t)$ is a Gaussian random process with mean zero and known autocorrelation

$$\langle f(t)f(u)\rangle = 2R(t - u). \tag{279}$$

Then the simpler variable $y = x - \mu t$, which obeys

$$\frac{dy}{dt} = \sigma f(t), \tag{280}$$

represents an integral over Gaussian variables of mean zero; hence it too is Gaussian with mean zero and variance

$$H(t) = \langle [y(t)]^2\rangle = 2\sigma^2 \int_0^t \int_0^t drdsR(r - s). \tag{281}$$

We have used $x(0) = y(0) = 0$ as an initial condition. Thus the Gaussian probability distribution for y is given by

$$P(y,t) = \frac{1}{[2\pi H(t)]^{1/2}} \exp\left[-\frac{1}{2}\frac{y^2}{H(t)}\right]. \tag{282}$$

The special case in which

$$H(t) = Ct^{2H} \tag{283}$$

in which C is an arbitrary constant and H is a constant between zero and one, describes "fractional Brownian motion." Ordinary Brownian motion is the special case $H = 1/2$.

A more interesting generalization occurs when one sets

$$S/S(0) = \exp(x) = \exp(y + \mu t). \tag{284}$$

Using $dx = dS/S$, Eq. (278) becomes

$$\frac{dS}{dt} = \mu S(t) + \sigma S(t) f(t). \tag{285}$$

The relations

$$y = \ln[S/S(0)\exp(-\mu t)], \quad dy = dS/S, \tag{286}$$

can be substituted into Eq. (282) to obtain the distribution for S:

$$\begin{aligned}\hat{P}(S,t|S(0),0)dS &= P(y,t|0,0)dy \\ &= \frac{1}{[2\pi H(t)]^{1/2}} \exp\left[-\frac{\ln^2[Se^{-\mu t}/S(0)]}{2H(t)}\right]\frac{dS}{S}.\end{aligned} \tag{287}$$

In the Brownian-motion limit, the noise is white, as represented by a delta correlation, $R(t - u) = \delta(t - u)$. Equation (281) specializes to $H(t) = 2Dt$ with $D = \sigma^2$. Equation (287) then reduces to

$$\begin{aligned}\hat{P}(S,t|S_0,0) &= \frac{S(0)}{S}\frac{1}{(4\pi Dt)^{1/2}} \\ &\quad \times \exp\left[-\frac{\ln^2[Se^{-\mu t}/S(0)]}{4Dt}\right].\end{aligned} \tag{288}$$

The Fokker–Planck equation obeyed by $P(x,t)$ follows from Eqs. (278) and (276) in the Brownian-motion limit in which $D_n = 0$ for $n > 2$,

$$\frac{\partial P(x,t)}{\partial t} = -\frac{\partial}{\partial x}[\mu P] + \frac{\partial^2}{\partial x^2}[\sigma^2 P]; \tag{289}$$

it contains the constant diffusion term $D = \sigma^2$, and the constant drift term $A = \mu$. One can obtain the equation for

$$\hat{P}(S,t) = P(x,t)S(0)/S \tag{290}$$

by starting from the previous equation for $P(x,t)$, introducing the relation, Eq. (284), of x to S. The result after some labor is

$$\frac{\partial \hat{P}}{\partial t} = -\frac{\partial}{\partial S}[(\mu + \sigma^2)S\hat{P}] + \frac{\partial^2}{\partial S^2}[\sigma^2 S^2 \hat{P}]. \tag{291}$$

The diffusion term [in the notation of Eq. (8)] $D_{SS} = \sigma^2 S^2$ is easy to understand. We can write

$$D_{SS} \equiv \frac{(\Delta S)^2}{2\Delta t} = \left(\frac{\partial S}{\partial x}\right)^2 \frac{(\Delta x)^2}{2\Delta t}. \tag{292}$$

Thus the diffusion constants are related by

$$D_{SS} = S^2 D_{xx} = S^2\sigma^2. \tag{293}$$

One might think that

$$\frac{\Delta S}{\Delta t} = \frac{\partial S}{\partial x}\frac{\Delta x}{\Delta t}. \tag{294}$$

However, this choice omits the second term in the drift vector. There is a correction because the diffusion coefficient D depends on S:

$$\frac{\Delta S}{\Delta t} = \frac{\partial S}{\partial x}\frac{\Delta x}{\Delta t} + \frac{1}{2}\frac{\partial^2 S}{\partial x^2}\frac{(\Delta x)^2}{\Delta t} \tag{295}$$

or

$$A_S = SA_x + \tfrac{1}{2}S(2D) = S(\mu + \sigma^2) \tag{296}$$

in agreement with Eq. (291).

7.4 Stochastic Integrals: The Ito–Stratonovich Controversy

Because mathematicians concentrate on Brownian motion, which is rather singular in behavior, it is not clear how to define the integral of a product of a random variable and a random force. In particular, how should we convert the differential equation

$$\frac{da}{dt} = B(a(t)) + \sigma(a)f(t), \tag{297}$$

where $f(t)$ is a standard white-noise source with

$$\langle f(t)f(u)\rangle = 2\delta(t-u), \tag{298}$$

to an integral? The Riemann sum of integral calculus would be

$$a(t) = a(0) + \sum_j [B(a(\bar{t}_j)) + \sigma(a(\bar{t}_j))f(\bar{t}_j)] \times (t_{j+1} - t_j), \tag{299}$$

where

$$t_j \leq \bar{t}_j \leq t_{j+1}. \tag{300}$$

The Riemann integral exists if the sum approaches a limit independent of the placement of $\bar{t}_j$ in the interval in Eq. (300). But the conditions of boundedness required for the existence of the Riemann integral (see Jeffries and Jeffreys, 1950) are violated. Thus the value of the sum approaches different limits, according to how the point $\bar{t}_j$ is chosen. [This is not true for the B term, but only the one involving the white-noise source $f(t)$.] Ito (1951), Ito and McKean (1965), and Doob (1953) avoid the difficulty by evaluating σ at the beginning of the interval. They also convert the integral to Stieltjes form by introducing

$$w(t) \equiv \int_0^t f(s)ds; \qquad \langle[w(t)]^2\rangle = 2t. \tag{301}$$

Some authors omit the factor of 2 in Eqs. (298) and (301). The result is

$$\int^t \sigma(a(s))f(s)ds = \sum \sigma(a(t_j))[w(t_{j+1}) - w(t_j)]. \tag{302}$$

However, even the latter does not converge to a unique integral, and the evaluation at the beginning is an arbitrary choice. The effect of this choice, since $f(s)$ is independent of $a(t)$ for $t < s$, is that the average of the second term in Eq. (297) vanishes, so that the Ito drift vector that follows from Eq. (297) and the integration rule, Eq. (302), is

$$\text{Ito: } A(a) = B(a) + \langle\sigma(t)f(t)\rangle = B(a). \tag{303}$$

Stratonovich (1963) makes the fortuitous choice of using

$$\overline{a(t_j)} = \tfrac{1}{2}[a(t_j) + a(t_{j+1})], \tag{304}$$

the average of the values at the two end points of each interval. In our notation, Stratonovich's choice is equivalent to equating

$$A(a) = B(a) + \langle\sigma(a)f(t)\rangle = B(a) + \sigma(a)\frac{\partial\sigma(a)}{\partial a}, \tag{305}$$

a result in agreement with the outcome, Eq. (311), below, of the iterative procedure we advocate. It is intuitively clear that an average of the end points is better than using either one. But is the average value always the best choice?

Our viewpoint, expressed in Lax (1966b), Sec. 3, is that mathematicians have concentrated too exclusively on the Brownian-motion white-noise process, which has delta correlation functions. Real processes can have a sharp correlation time of finite width. Thus their spectrum is flat, but not up to infinite frequency. Thus, for real processes, the Riemann sums do converge, and no ambiguity exists. After the integration is performed, the correlation time can be allowed to go to zero, that is, one can then approach the white-noise limit. Thus the ambiguity is removed by approaching the integration limit and the white-noise limit in the correct order.

To obtain the drift vector $A(a)$, the differential equation, Eq. (297), is rewritten as an integral equation:

$$a(t+\Delta t) - a(t) = \int_t^{t+\Delta t} B(a(s))ds + \int_t^{t+\Delta t} \sigma(a(s))f(s)ds. \tag{306}$$

This equation can be solved by iteration. The lowest approximation is obtained by replacing $a(s)$ by $a(t)$ under the integral. This first approximation,

$$(\Delta a)_1 = B(a(t))\Delta t + \sigma(a(t))\int_t^{t+\Delta t} f(s)ds, \tag{307}$$

is equivalent to the Ito choice. The first term is already of order Δt and need not be improved. In the second term, let us insert the first approximation,

$$a(s) = a(t) + B(a(t))(s - t) + \sigma(a(t)) \int_t^s f(u)du, \tag{308}$$

into Eq. (306) to get

$$\begin{aligned}(\Delta a)_2 &= B(a(t))\Delta t + \sigma(a(t)) \int_t^{t+\Delta t} f(s)ds \\ &\quad + \sigma(a(t)) \frac{\partial \sigma}{\partial a(t)} \int_t^{t+\Delta t} ds \int_t^s du f(s)f(u).\end{aligned} \tag{309}$$

We have retained only terms of order Δt, or f^2, but not $\Delta t f$ or higher. If we restrict ourselves to Gaussian processes, their linked moments of order higher than two vanish. Thus the process terminates. Indeed,

$$\langle (\Delta a)^n \rangle_L = 0 \text{ for } n > 2. \tag{310}$$

For $n = 2$ it is sufficient to use the first approximation,

$$\begin{aligned}\langle (\Delta a)^2 \rangle_L &= \sigma^2 \int_t^{t+\Delta t} ds \int_t^{t+\Delta t} du \langle f(s)f(u) \rangle \\ &= 2\sigma^2 \Delta t = 2!D_2 \Delta t.\end{aligned} \tag{311}$$

In the last step, we have specialized to the Brownian, white-noise limit. For $n = 1$ it is necessary and sufficient to use the second approximation of Eq. (309) to get

$$\begin{aligned}\langle \Delta a \rangle &= B(a(t))\Delta t \\ &\quad + \sigma(a(t)) \frac{\partial \sigma}{\partial a(t)} \int_t^{t+\Delta t} ds \int_t^s du 2\delta(s - u),\end{aligned}$$

so that

$$A(a)\Delta t = B(a)\Delta t + \sigma \frac{\partial \sigma}{\partial a} \Delta t. \tag{312}$$

The factor of 2 disappears because only half the area of the delta function contributes at the boundary point s. This result is clear if the correlation function $R(s - u)$ is any sharp symmetric function. In summary, our Langevin process is equivalent to an ordinary (no derivatives higher than second) Fokker–Planck process with coefficients

$$D(a) = [\sigma(a)]^2, \tag{313}$$

$$A(a) = B(a) + \sigma \frac{\partial \sigma}{\partial a} = B(a) + \frac{1}{2} \frac{\partial D}{\partial a}. \tag{314}$$

These results agree completely with those found in the previous section for our exactly solvable example.

We note that the Fokker–Planck can be written in two completely equivalent forms:

$$\begin{aligned}\partial P(a)/\partial t &= -\frac{\partial}{\partial a}[A(a)P(a)] + \frac{1}{2}\frac{\partial^2}{\partial a^2}[D(a)P(a)] \\ &= -\frac{\partial}{\partial a}[B(a)P(a)] \\ &\quad + \frac{\partial}{\partial a}\left[\sigma(a)\frac{\partial}{\partial a}(\sigma(a)P(a))\right].\end{aligned} \tag{315}$$

The Ito choice can be compensated for by choosing the correct Fokker–Planck equation, but his procedure is sufficiently counterintuitive that the wrong choice is often made. In applying Ito's procedure to the financial world Hull (1992) almost always makes the correct choice. Hull uses the equation

$$dx = dS/S = \mu dt + \sigma dw, \tag{316}$$

where w is the Wiener process defined in Eq. (299), which is simply Eq. (278) written in the notation preferred by mathematicians. Since σ is a constant in Hull's application, the second term on the right-hand side of Eq. (314) vanishes, and there is no distinction between the Ito and Stratonovich viewpoints. Hull (1992) then states correctly that $\Delta S/S$ is normally distributed with mean "$\mu \Delta t$ and standard deviation $\sigma\sqrt{\Delta t}$. In other words,

$$\frac{\Delta S}{S} \approx \phi(\mu \Delta t, \sigma\sqrt{\Delta t}), \tag{317}$$

where $\phi(m,s)$ denotes a normal distribution with mean m and standard deviation s." Equation (316) cannot be simply rewritten (Hull, 1992) as an Ito equation in the form

$$dS = \mu S dt + \sigma S dw \tag{318}$$

because Ito's variables do not obey the usual rules of calculus. Equation (318) is correct, as a Stratonovich equation, but the second term does not average to zero but modifies the drift term as in Eqs. (305) and (309). To be an Ito equation, the first term should contain A, the modified *drift term, and not B*, the unmodified drift term. Equation (291) shows that the correct Ito equation is

$$dS = (\mu + \sigma^2)Sdt + \sigma Sdw. \tag{319}$$

This result could also have been obtained using Ito's lemma, which describes how the drift vector changes under a transformation of variables. If, however, one makes the natural error of regarding Eq. (318) as a valid Ito equation and then makes the inverse transformation $x = \ln S/S(0)$ using Ito's lemma (now carefully), one obtains (Hull, 1992)

$$dx = [\mu - \sigma^2]dt + \sigma dw, \tag{320}$$

which disagrees with the natural starting point, Eq. (316), as does the associated distribution after a finite time interval $\Delta t = T - t$, which takes the form

$$\ln S_T - \ln S \approx \phi(\mu - \sigma^2\Delta t, \sigma\sqrt{\Delta t}) \tag{321}$$

that disagrees with Hull's earlier intuitively correct result, Eq. (317). The Ito procedure can be done correctly by using Eq. (319) instead of (318), but its counterintuitive nature can be misleading even to experts.

For the record, we note that the behavior of diffusion constants and drift vectors under a transformation from one set of variables a_j to a new set of variables a'_i was derived in Lax (1966b) from Langevin considerations that are a generalization of the above arguments to the multivariable case. The diffusion constants transform simply as

$$D'_{ij} = \frac{\partial a'_i}{\partial a_k}\frac{\partial a'_j}{\partial a_l}D_{kl}. \tag{322}$$

The B drift vectors also transform simply:

$$B'_i = \frac{\partial a'_i}{\partial t} + \frac{\partial a'_i}{\partial a_k}B_k, \tag{323}$$

where the second term is the natural transformation of a vector, and the first term enters only if the transformation is time dependent. Under a nonlinear transformation, however, there is a change in the contribution from the nonconstancy of the diffusion coefficient as shown by the last term in Eqs. (309)–(314). The A drift vectors, which enter the Fokker–Planck equation, possess therefore the more complicated transformation

$$A'_i = \frac{\partial a'_i}{\partial t} + \frac{\partial a'_i}{\partial a_k}A_k + \frac{\partial^2 a'_i}{\partial a_m \partial a_n}D_{mn}, \tag{324}$$

which can be understood simply from the relation

$$\Delta a'_i = \frac{\partial a'_i}{\partial t}\Delta t + \frac{\partial a'_i}{\partial a_k}\Delta a_k + \frac{\partial^2 a'_i}{\partial a_m \partial a_n}\frac{\Delta a_m \Delta a_n}{2}. \tag{325}$$

In summary, there are two kinds of Langevin equations, those whose random term need not average to zero [as used in Eq. (297)] and those used by Ito in which the average of the random term vanishes by Ito's definition of the stochastic integral. Both can be used correctly, but Ito's choice requires more care because the usually permissible way in which we handle equations is no longer valid. An able analysis of this situation, with references to earlier discussion, is presented by Van Kampen (1992).

Hull's (1992) book is an extremely well-written text on *Options, Futures and Other Derivative Securatives*. The Ito–Stratonovich controversy applies to physics, chemistry, and other fields. We have analyzed Hull's treatment in detail because his use of the Black–Scholes (1973) work involving an application of the Langevin Eq. (316) to the pricing of options coincides with the one example, in Sec. (7.3), for which we have an exact solution.

Although the Ito choice can be dangerous, as shown above, we trust that by now the Ito choice is used consistently in practice. However, there may be more serious problems, since real options may have statistics based on more wildly fluctuating processes than Brownian motion, such as Lévy and fractal processes. This has recently been emphasized by Peters (1994) and Bouchard and Sornette (1994). For an excellent review of Brownian and fractal walks, see RANDOM PROCESSES. Gashghaie *et al.* (1996) have also found a parallelism between prices in foreign exchange markets and turbulent fluid flow. Thus the conventional Brownian-motion approach will be invalid in such markets.

8. FURTHER CONTRIBUTIONS TO STOCHASTIC PROCESSES

8.1 Overview

In the following sections we review current contributions. We start with random walks, since the approach remains linear, and the applications are usually stationary. Then we discuss contributions in which one or more of our assumptions of (1) stationarity, (2) linearity, and (3) white noise are eliminated.

8.2 Random-Walk Problems

Many problems can be mapped into a random-walk problem on a lattice, or actually is a problem on a lattice. These problems are discussed first since the master equation for the probability density is linear, and simple techniques based on discrete periodicity can be used. Our description of the random-walk case is especially brief because the article RANDOM PROCESSES has covered the random-walk problem in detail.

Recent contributions have been made to diffusion and reaction kinetics by considering one or more walkers on a lattice. Discrete-time random walks have been generalized to continuous-time walks. For such walks the distribution $\Psi(t)$ of time intervals to a hop from a given site are not exponential. If the first or second moment of $\Psi(t)$ is not finite, one generates a "Lévy" process. Other choices lead to stretched-exponential processes. Analytic solutions are often possible by taking advantage of the regularity of the lattice, as has been shown by Montroll, Weiss, Scher, Shlesinger, and others as summarized in RANDOM PROCESSES. An extension was also made to walks on fractals and to disordered lattices. Scher and Lax (1973) showed that a disordered lattice could be replaced by a continuous-time random walk that yields a conductivity varying approximately as $\omega^{0.9}$, in agreement with the experimental conductivity found in semiconductor impurity bands.

8.3 Linear with Time-Dependent Decay

The case of homogeneous noise with linear (time-dependent) damping [namely, $\mathbf{\Lambda}(t)$, but $\mathbf{D}(t) = \mathbf{D}$] is only mentioned here since an analytic evaluation was found for the generalized characterized functional

$$M[q] = \left\langle \exp\left[i \int_0^t q(u)a(u)du \right] \right\rangle, \tag{326}$$

where $q(u)$ is an arbitrary function of u, in Eq. (2.16) of Lax (1966b). Many desired multiple-time averages can be deduced from this generalized characterized function. For example, the multiple-time moments are given by a functional derivative

$$m(t_1,t_2,\ldots t_n) = i^{-n} \left. \frac{\delta^n M[q]}{\delta q(t_1) \cdots \delta q(t_n)} \right|_{q=0}, \tag{327}$$

as discussed by Hänggi (1989).

Lax (1966a) introduced a more general functional involving an arbitrary nonlinear function of $q(u)$, and Lax and Zwanziger (1973) evaluated it for quadratic functions to obtain the photocount distribution in lasers near threshold.

8.4 The Nonlinear (Fokker–Planck) Case: Reaction-Rate Theory

If we eliminate the linearity assumption, including the case of weak noise and a quasilinearity approximation, many possibilities arise. If the variables are continuous and the noise is white and Gaussian, the problem is properly described by a Fokker–Planck equation.

Many applications have been made of Fokker–Planck theory, often with approximations that are special to a particular application. One example is to the theory of self-sustained oscillators discussed in Sec. 8.5. Applications have been made to systems subject to bifurcation, and to quantum mechanical systems. An application of long standing is to reaction-rate theory, which is described briefly here, and to stochastic resonance, which is described briefly in Sec. 8.5. Many of these applications are reviewed in the three-volume series by Moss and McClintock (1989). An excellent review of reaction-rate theory, which we cannot summarize adequately here, is the 90-page review by Hänggi *et al.* (1990).

The modern surge of effort in reaction-rate theory stems from the widely read article by Kramers (1940), since the author made a simple Fokker–Plank model for the escape of a particle from a metastable state. However, Landauer (1989), in a review, points out many examples of the rediscovery of previously published ideas. In particular, he remarks on an earlier article by Pontryagin *et al.* (1933) (PAV) that contained the essential ideas in Kramers's article.

Kramers's model, in the notation of Jung (1993), is

$$\frac{dx}{dt} = \frac{p}{m} \qquad (328)$$

$$\frac{dp}{dt} = -\gamma p - V'(x) + \sqrt{m\gamma k_B T}\,\xi(t) + E\sin\theta;$$
$$\theta \equiv \Omega t + \text{const.}, \qquad (329)$$

where $E \sin\theta$ is the periodic term needed in the next section on stochastic resonance, and the Brownian motion is induced by the noise with second moment

$$\langle \xi(t)\xi(u)\rangle = 2\delta(t-u). \qquad (330)$$

(The periodic term is not included in the articles by Kramers or PAV.)

Kramers considered both weak and strong damping cases. We review only the strong-damping case here because Kramers's extensive mathematical treatment was reviewed by Hänggi *et al.* (1990) and the main ideas, contained in the strong-damping case, are easier to explain because they lead to a closed-form solution.

In the strong-damping case, we assume that γ is faster than any other decay mechanisms, or reciprocal times. Then d/dt can be neglected compared to γ. Thus the term in dp/dt can be omitted. It is thus possible to solve Eq. (329) for p and substitute the result into Eq. (328). Discussions of the adiabatic approximation are given by Lax (1967) and Van Kampen (1985). The resulting equation for x is

$$\frac{dx}{dt} = A(x) + \sqrt{D}\xi(t), \qquad (331)$$

where

$$A(x) = -V'(x)/m\gamma + (E/m\omega)\sin\theta, \qquad (332)$$

$$D = k_B T/m\gamma. \qquad (333)$$

The Fokker–Planck equation associated with Eqs. (332) and (333) is

$$\frac{\partial P(x,t)}{\partial t} = -\frac{\partial}{\partial x}[A(x,t)P(x,t)] + \frac{\partial^2}{\partial x^2}[D(x)P(x,t)]. \qquad (334)$$

In the PAV article, there is no time-dependent force, and $A(x)$ and $D(x)$ are regarded as known arbitrary functions of x [with $D(x)$ written as $b(x)/2$].

The Fokker–Planck equation can be regarded as an equation of continuity:

$$\frac{\partial P(x,t)}{\partial t} + \frac{\partial J(x,t)}{\partial x} = 0, \qquad (335)$$

where

$$J(x,t) = A(x,t)P(x,t) - \frac{\partial D(x)P(x,t)}{\partial x}. \qquad (336)$$

If the periodic force is absent, there will be a stationary solution if $A(x)$ is a restoring force, namely, negative for large positive x and positive for large negative x. Such a stationary solution obeys

$$\frac{dJ(x)}{dx} = 0; \qquad J(x) = AP(x) - \frac{d[D(x)P(x)]}{dx}, \qquad (337)$$

and the current must be a constant,

$$J(x) = C_1. \qquad (338)$$

Although Lax (1966b), Sec. 4, has encountered a case in which a current flow is present, we are normally concerned with stationary states that carry no current. If we set $C_1 = 0$, $P(x)$ obeys a simple first-order equation whose solution will be denoted $P_0(x)$:

$$P_0(x) = \frac{C}{D(x)}\exp[-U(x)]U(x) \equiv -\int_{x_{st}}^{x}\frac{A(y)}{D(y)}dy. \qquad (339)$$

Here it is customary to choose x_{st} to be the stationary point, which obeys

$$A'(x_{st}) = 0. \qquad (340)$$

This is the point, Eq. (10), about which a quasilinear expansion would be made. PAV then introduce a probability $\phi(x,t)$ that a particle starting at $t = 0$ in the interval $a < x < b$ will reach a boundary in the time interval $[0,t]$. Instead of a direct attack on this problem, they introduce the modern approach of invariant embedding made popular by Bellman (1968) and Casti and Kalaba

(1973) by writing a recursion relation relating $\phi(x, t + \tau)$ to $\phi(x,t)$ for small τ:

$$\phi(x, t + \tau) = \int_a^b \phi(y,t)dyP(y, t + \tau|x, t), \tag{341}$$

which assumes that a limit in which $\tau \to 0$ will be taken and that "the probability of the random point leaving the interval *ab* during the short time τ is very small." PAV then expand $\phi(y,t)$ about $\phi(x,t)$. The results involve the incomplete moments

$$\mu_n = \int_a^b (y - x)^n dy. \tag{342}$$

Because the conditional probability is so narrow in y (of order $\sqrt{D\tau}$), the limits of integration can be extended to full interval $[-\infty,\infty]$ for almost all x. Then

$$\mu_0 \to 1; \qquad \mu_1 \to A(x)\tau; \qquad \mu_2 \to D(x)\tau; \tag{343}$$

with higher moments vanishing faster than linearly in τ. The result is that ϕ obeys the equation adjoint to Eq. (334) for $P(x,t)$:

$$\frac{\partial\phi(x,t)}{\partial t} = \frac{\partial\phi}{\partial x}A(x) + \frac{\partial^2\phi}{\partial x^2}D(x). \tag{344}$$

Equation (344) is no easier to solve analytically than the original Fokker–Planck equation (334). However, $dt\ \partial\phi/\partial t$ is the probability of a crossing in the interval $[t, t + dt]$, so that

$$M(x) = \int_0^\infty t\frac{\partial\phi}{\partial t}dt \tag{345}$$

is the mean time to a crossing, starting at x. By taking the time derivative of Eq. (344), multiplying by t, and integrating over t, PAV obtain

$$\int_0^\infty t\frac{\partial^2\phi}{\partial t^2}dt = A(x)\frac{dM(x)}{dx} + D(x)\frac{d^2M(x)}{dx^2}. \tag{346}$$

Since $\phi(x,0) = 0$ and $\phi(x,\infty) = 1$, integration by parts shows that the left-hand side of Eq. (346) is -1. Thus $dM(x)/dx$ obeys a first-order ordinary differential equation. The integral of this equation subject to the boundary conditions

$$M'(a) = 0, \qquad M(b) = 0, \tag{347}$$

appropriate to the case of a being a reflecting boundary and b being an absorbing boundary, is

$$M'(x) = -\exp[U(x)]\int_a^x \exp[-U(z)]\frac{dz}{D(z)}. \tag{348}$$

As pointed out by Stratonovich (1989), the final integral can be written in terms of the steady-state distribution itself:

$$M(x) = \int_x^b \frac{dy}{D(y)P_0(y)}\int_a^y dzP_0(z). \tag{349}$$

More explicit formulas are available only after making some approximations. Stratonovich (1989) simplifies the mean lifetime to

$$\begin{aligned}\bar{T} &= 2M(x_{st})\\ &= 2\pi[D(b)/D(x_{st})]^{1/2}[|A'(x_{st})|A'(b)]^{-1/2}\\ &\quad\times \exp[U(b) - U(x_{st})] = 2T_{\mathrm{K}},\end{aligned} \tag{350}$$

where T_K is referred to as the Kramers time. The factor of 2 was inserted on the assumption that after reaching the point b there is a 50% chance of escaping and a 50% chance of returning to the point x_{st} of stable equilibrium. If we revert to the original definitions of A and D in Eqs. (332) and (333), the Kramers time is given by

$$T_{\mathrm{K}} = \pi\frac{\gamma}{\omega_{st}\omega_b}\exp\left\{\frac{V(b) - V(x_{st})}{k_{\mathrm{B}}T}\right\}, \tag{351}$$

where $(\omega_j)^2 = |V''(x_j)|/m$ are the frequencies associated with quadratic approximations to the local potential at the points in question.

The results display the expected Arrhenius law associated with the activation energy. The mean rate of transition vanishes with γ demonstrating explicitly that the noise associated with the damping induces the transitions.

Although we have demonstrated the result for the one-dimensional case, the original authors all considered x to be a one-dimensional coordinate along the direction of the reaction embedded in a multidimensional space. The qualitative ideas remain the same, but the results are, of course, sensitive to details such as symmetry that are not present in the one-dimensional case. Contributions by Brinkman (1956), Landauer and Swanson (1961), and Langer (1968) are summarized in detail by Hänggi *et al.* (1990). A recent review of the current status of Kramers's reaction-rate theory is given by Talkner and Hänggi (1995).

8.5 Stochastic Resonance

The subject of stochastic resonance is concerned with systems such as those discussed by Kramers, Pontryagin *et al.*, Stratonovich, and others, to which has been added an applied periodic force. Such a term was already included in Eq. (329). Since this field is more complex than the original reaction-rate theory, there are more limits and approximations to consider. The aim of this section is to indicate the different regions for which approximate solutions have been found and to explain the nature of stochastic resonance, namely, the way in which noise-induced transitions are enhanced by a periodic force, and conversely the way in which noise can enhance the response to a periodic force. For a detailed examination of stochastic resonance, the reader is referred to the review of this subject by Jung (1993) and to the NATO Conference Proceedings (Bulsara *et al.*, 1993).

The simplest case is the application of a periodic force to an Uhlenbeck–Ornstein (1930) system. Since this system is linear, an analytical solution is possible, both of the Fokker–Planck equations and of the Langevin equations themselves. Since the linear response to Gaussian forces is Gaussian, the full time-dependent distribution function is a Gaussian in all its variables. The form is the same as if there were no force applied, except that each variable has a mean shifted by the force. The shift is, in fact, simply calculable by ignoring the noise. The Gaussian distribution function is readily expressible in terms of the second moments (taken relative to the mean). And these are unchanged from those in the original Uhlenbeck–Ornstein article. For details see Jung (1993).

The next simplest case is that in which the frequency of the driving force is low compared to all the other rates in the problem. Then the adiabatic procedure can be applied just as when no periodic forces were present. We discuss one such example later.

The case of a high-frequency force can only be handled (by perturbation theory) if the force is weak. Since the force is periodic, the solution for the Fokker–Planck probability distribution takes the Floquet form. Perturbation theory has been applied to obtain correlation functions and/or the Green's function for the Fokker–Planck equation in terms of the corresponding solutions in the absence of a force by Presilla *et al.* (1989), Fox (1989), and Gang *et al.* (1990). For the escape problem, an extensive set of numerical results are plotted in Jung (1993). For large driving frequencies, the enhancement of escape rates, according to Jung, Eq. (8.43), decrease inversely with the square of the driving frequency. Resonance activation appears to occur. But the results are largely numerical, except for one result quoted by Jung from an unpublished thesis by Linkowitz (1989).

A simple qualitative explanation for the fairly broad stochastic resonance is that it occurs when the potential is modulated at a period T that is synchronized with the Kramers reaction time T_K. In a double-well system, the potential modulation must complete one period in a time T just large enough for a Kramers transition from one well to the other and back. See Fig. 5.

Thus we require

$$T = 2T_K,$$

where T_K is the Kramers time given in Eq. (350). This resonance not only appears in the escape rate but also appears as an enhancement in the output spectrum at the driving frequency. The signal-to-noise ratio in a bistable ring laser displays this smooth resonance in Fig. 6

8.6 Self-Sustained Oscillators

The quasilinear approximation to a nonlinear system can break down because of an instability in some coordinate. Lax (1968a) and Hempstead and Lax (1967) have argued that all autonomous self-sustained oscillators possess one degree of freedom that is neutrally unstable. These are oscillators described by a set of ordinary differential equa-

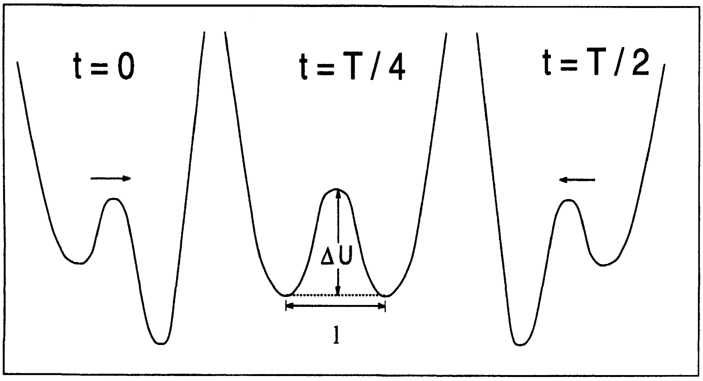

FIG. 5. Bistable potential with external modulation, shown at three times [after Jung (1993), but recomputed].

tions containing no coefficients that depend explicitly on the time. For this reason, if $a_j(t)$ is a solution (in the absence of noise), then so is $a_j(t + \tau)$ for arbitrary τ. This instability against a shift of the time origin is equivalent to an instability in a phaselike variable.

The onset of oscillation is like a phase transition characterized by a long time constant. Thus most internal degrees are relatively fast and can be adiabatically eliminated, leaving one complex (field) amplitude to describe the behavior near threshold.

A self-sustained oscillator operates by connecting an absorptive system, such as a laser cavity containing absorbing materials and windows for energy to escape, to a gain system such as a set of pumped atoms. In equivalent-circuit terms, the absorptive system has a positive resistance, and the pumped system has a negative resistance. The oscillator will stabilize at a level of operation at which these two (nonlinear) resistances cancel. The frequency of operation will be that at which the reactances cancel. Lax and Louisell (1967) found an equation for a laser of the form

$$\frac{d\beta}{dt} = -(1 - i\alpha)R(|\beta|^2)\beta + f(t) \qquad (352)$$

for the complex electromagnetic field ampli-

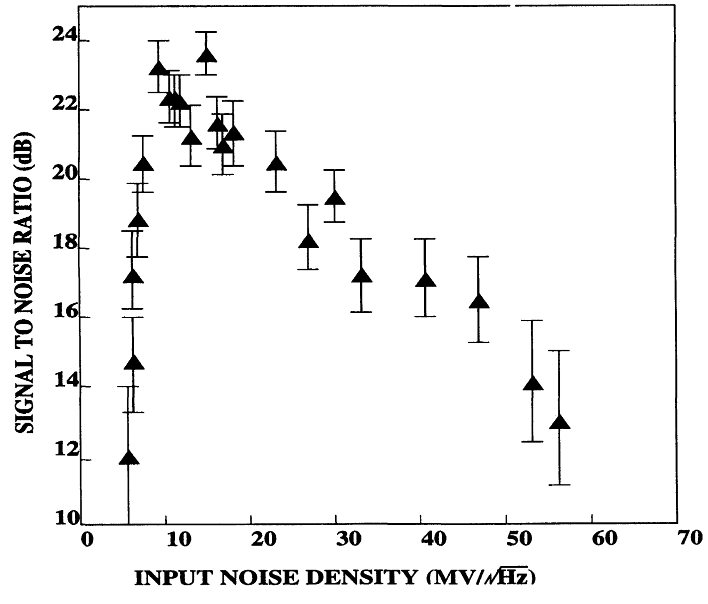

FIG. 6. Signal-to-noise ratio of one mode in a bistable laser. Taken from Jung (1993), based on experimental results of Roy and Mandel (1980) and Lett and Mandel (1985).

tude β after the rotating-wave approximation has been made.

The parameter α, which first appeared as the detuning parameter in Lax (1965) also appears in Lax (1967) as a coupling parameter between amplitude and phase fluctuations. [The parameter α of Lax (1965) is identical to $\tan\beta$ of Lax (1967). Thus in both cases, the linewidth is enhanced by a factor $1 + \alpha^2$.] It is this coupling between intensity and phase fluctuations that produces the strong enhancement of linewidth in semiconductor lasers found by Fleming and Mooradian (1981) and explained by Henry (1986). The function R describes the dependence of the net resistance on the intensity $|\beta|^2$. At the operating point, $|\beta|^2 = p$, this resistance must vanish. For any well-designed self-sustained oscillator, it was shown in Appendix B of Hempstead and Lax (1967) that it is adequate to expand the resistance to the linear term $|\beta|^2 - p$. The relative importance of the first neglected term is shown to be of the order of the ratio of the noise in the oscillator to the signal. For a well-designed oscillator, this ratio is small. In Appendix A of Hempstead and Lax, the ratio is shown to be one over the number of photons in the cavity. Once this expansion is made, it is possible to rescale both amplitude and time to obtain a universal equation that we have called the rotating-wave van der Pol with noise:

$$\frac{d\beta}{dt} = (1 - i\alpha)(p - |\beta|^2)\beta + h(t). \tag{353}$$

The rescaling in amplitude was chosen to make the coefficient of $|\beta|^2$ unity. The scaling in time was chosen to yield the simple correlation function for the c-number noise source:

$$\langle h(t)h(u)\rangle = 4\delta(t - u), \tag{354}$$

ignoring, here, the coupling between reactive and resistive effects, by setting the parameter α equal to zero.

Away from threshold, Lax (1967) carried out a quasilinear treatment of self-sustained oscillators. Near threshold, fluctuations of the order of 100% are possible, and a numerical solution of the associated Fokker–Planck equation becomes necessary. Risken and Vollmer (1967) and Hempstead and Lax (1967) carried out such calculations to obtain the linewidth associated with field-amplitude fluctuations and the linewidth associated with intensity fluctuations. Comparisons of these theoretical predictions with subsequent experimental results are shown in Fig. 7 and Fig. 8, respectively.

GLOSSARY

Brownian Motion: The limit of a random-walk process in which the individual steps become negligible. The position is continuous but not differentiable. The mean square displacement grows linearly with time. The particle density obeys the diffusion equation.

Characteristic Function: The Fourier transform of the probability density.

Chapman–Kolmogoroff Condition: A statement that conditional probabilities must obey if the process is to be Markoffian.

Fokker–Planck Process: A stochastic process that generalizes the Brownian process by having drift and diffusion coefficients that can be position dependent.

Fokker–Planck Equation: The partial differential equation, involving a single time derivative and up to two space derivatives, obeyed by a Fokker–Planck process. The independent (position) variables can be replaced by other variables—for example, spin angles in the description of spin diffusion.

Generalized Fokker–Planck Equation: A Fokker–Planck equation that may contain derivatives to all orders in the independent (position) variables.

Langevin Equation: An equation for a random variable in which the randomness is generated by a random ("force") term added usually on the right-hand side. The noise source is typically delta correlated in time (white noise) but nondelta correlation (colored noise) is permitted.

Markoff Process: A random process in which the probability of future events depends on present information and no prior information.

Noise Spectrum: The power as a function of frequency obtained by passing the signal through a narrow filter, squaring the output, and averaging it.

Shot Noise: The input noise assumed to be associated with a series of Dirac delta-function pulses arriving at random at a uni-

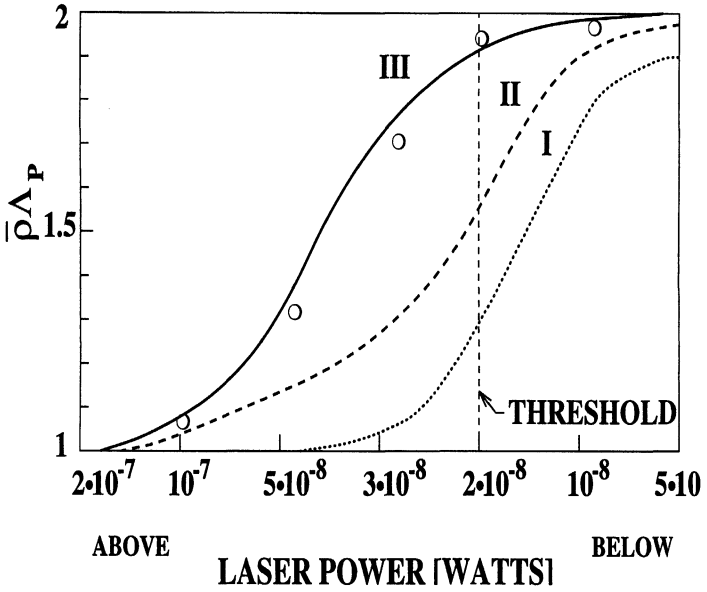

FIG. 7. Spectrum for phase and amplitude fluctuations of a laser is Lorentzian to a good approximation. The dimensionless half-width Λ_p times the dimensionless mean power $\bar{\rho} \equiv \langle|\beta|^2\rangle$ is plotted against laser power. The experimental results are those of Gerhardt *et al.* (1972). The theoretical curves I and II are due to Grossman and Richter (1971), and curve III is due to Risken and Vollmer (1967) and Hempstead and Lax (1967).

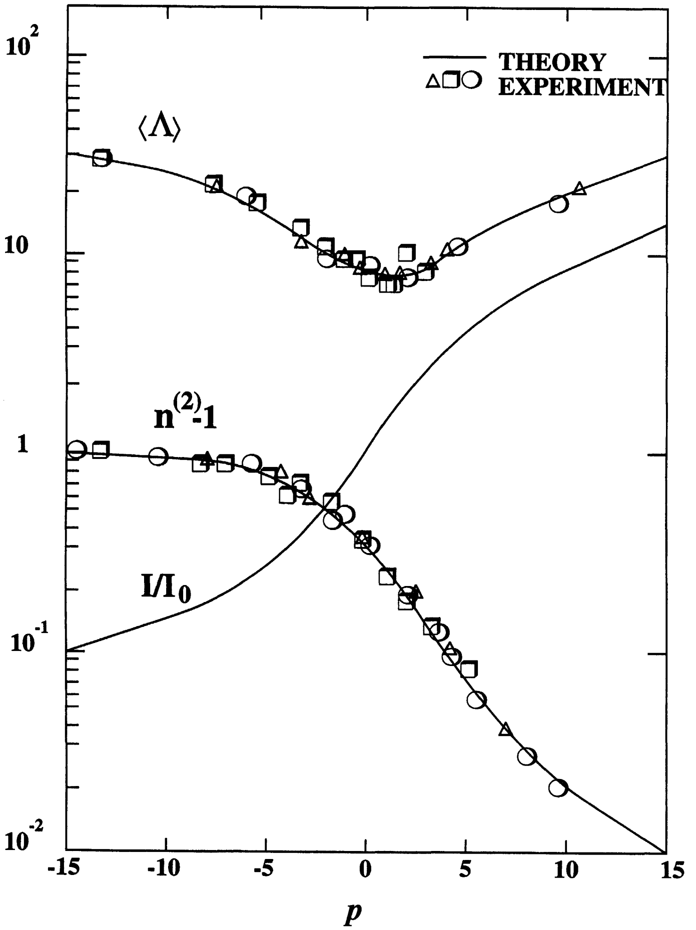

FIG. 8. Experimental verification of the Van der Pol model for lasers operating near threshold. The theoretical curves are from Hempstead and Lax (1967). The experimental points △, □, and ○ are from Gamo *et al.* (1968), Davidson and Mandel (1967), and Arecchi *et al.* (1967a, 1967b), respectively. Lower-case p is the pump parameter of the model, $\langle\Lambda\rangle$ is the effective linewidth of intensity fluctuations, and $n^{(2)}$ is the normalized second factorial moment $\langle n(n-1)\rangle/\langle n\rangle^2$ of the photocount distribution $p(n,T)$ as $T \to 0$. In this limit, $n^{(2)} - 1 = \langle(\Delta\rho)^2\rangle/\langle\rho\rangle^2$, and I/I_0 is the light intensity normalized to threshold value ($p = 0$); i.e., $I/I_0 = \langle\rho\rangle/\langle\rho\rangle_{th} = \langle\rho\rangle/1.128$. Here ρ is an abbreviation for $|\beta|^2$.

form average rate. The term is also used to describe the response a physical system to such input white noise.

Wiener–Khinchin Theorem: Equality between the noise spectrum and the Fourier transform of the autocorrelation function.

INTRODUCTION

The industrial nations of the world have become conscious of their energy requirements. The spiraling escalation of the cost of fuel and of capital investment in new power plants has instigated an intensive effort to identify more efficient methods of processing energy. A study sponsored by the U.S. National Academy of Sciences (NAS, 1976) has indicated that if economically efficient storage devices can be developed, as much as 10% of the installed generating capacity required by the electric utilities can be displaced by less costly storage systems. The size of these storage units would range from 15 MW to several thousand megawatts with a storage duration from 2 h to 2 d.

The subject matter of this article is concerned with a review of the salient features of storage systems of the scale and size mentioned in the National Academy report. As will be seen later in the discussion, large-scale storage devices display unique characteristics that give rise to complex technical issues. Another family of storage systems that are covered in the present article comprises systems used with sources capable of delivering energy pulses of great intensity and short durations. The increasing number of practical applications that require such sources has warranted the inclusion of such devices in the list of storage systems reviewed here.

1. CLASSIFICATION OF ENERGY-STORAGE SYSTEMS

Energy can be stored in many ways: in electrostatic form as in a charged capacitor, as magnetic energy in an inductor, as kinetic energy in a flywheel, or as chemical energy in a battery. It is possible to store energy in

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

a compressed gas, in hydrogen, or in an explodable liner of a vessel. The extraction of energy in a controlled fashion from the latter systems is no longer a simple matter. Special machinery or devices are needed to execute the appropriate energy transfer from the store to the load.

As a result of advances in materials science, new compounds with unusual physical and chemical properties have been produced. These innovations have led to the invention of several novel energy stores with impressive figures of cost, energy stored per unit weight, and efficiency of energy transfer.

A question of paramount importance to the design of an energy system is the selection of the energy storage best suited to the specific application. Now there is no single general law capable of categorizing all energy-storage devices. This is because of the vast conceptual difference in the governing principles for the mode of operation of these devices.

The task of selecting suitable storage may be facilitated by examining its intended function. It is noticed, for instance, that most storage devices that have been used fall in one of three major groups of classes that are defined by the temporal behavior of the transfer of energy from the storage to the load.

An example of the first group is the energy storage systems used in electric power grids. In such systems, the storage devices are distributed over several substations and are installed for the purpose of accepting energy from base-load generators when the load demand falls below the base-load generating capacity. This stored energy is then released to the power grid when peak load conditions demand it. This transfer of energy takes place *slowly.* In this manner the electric network can deliver power to a peak load that exceeds the installed capacity. The addition of storage thus effectively improves the capability and reliability of the service of the electric grid. Analogs to the storage systems used in the power grid are the flywheel storage systems installed in electric cars and trains.

A subclass of this group of applications comprises the so-called uninterrupted power systems (UPS). In these systems, it is required to maintain a continuous supply of power whenever the primary source of power is interrupted. Typical illustrations for this class are solar-energy power plants (land based or in space) and power supplies for computers. It is obvious that unlike the case of the electric power grid, the capacity of the primary source of power must be greater than that of the power consumption in the load.

In the second group the storage devices are used in *oscillatory* systems. The frequency of oscillations could be in the microwave range or very low. An example of the latter case is the use of a superconducting inductive energy-storage system to damp out the power oscillations in an ac intertie transmission line.

The third and final group belongs to a growing number of applications that require *bursts* of nonoscillatory power of short duration but of great intensity. For pulses between 1 and 100 ms long, as needed in nuclear fusion research, there is an advantage in using electromechanical storage devices such as pulsed homopolar machines or explodable liners. For shorter durations as required for the operation of lasers, radar, plasma guns, etc., the pulse generator consists of a stationary capacitive or inductive energy-storage device, sometimes combined with a pulse-shaping network.

Other factors that influence the selection procedure of a specific device are the cost, the level of energy to be stored, and the weight and the size of the storage. For the case of pulsed sources, additional consideration is given to the duty cycle and rise time of the energy delivered to the load.

Energy storage is too vast a subject to do it justice in one article. Accordingly, the discussion has been narrowed down to a few selected systems of great practical importance. This article has been divided into seven sections that deal with the features, characteristics, and performance of mechanical, thermal, electrical, magnetic, and chemical devices used in energy storage.

The transfer of energy from a storage system to the load is not the central topic covered here. A discussion of a general nature on the features of storage systems with slow and impulsive energy transfer will be given first. These comments will be helpful to the understanding of the operation of some of the storage schemes considered here.

1.1 Energy Storage with Slow Energy Transfer

Fernandes (1976) suggested a convenient method of classification of energy-storage systems used in the electric utility industry. These typify the storage systems with slow transfer time. He identified two categories of storage systems.

The first is the single-input shaving storage system that is charged with off-peak energy. Examples of the single-input systems are batteries, flywheels, pumped hydro storage, and superconducting magnetic storage. Analysis of the off-peak energy requirement in the electric system indicates that a storage system with a capacity between 6% and 14% of that of the grid can handle most of the off-peak demand. Interestingly enough, this also applies to a storage system for electric cars or trains.

The second category is a dual system that generates electric power from a charge cycle obtained with off-peak electricity as well as from a primary or secondary fuel supply. Examples of such systems are hydrogen storage systems and compressed-air/natural gas storage. Dual systems are specially useful when large (18% to 20%) reserve capacity margin is needed.

1.2 Pulsed Energy-Storage Systems

Carruthers (1962) recognized the economic advantage of using inductors over capacitors when the energy stored exceeds 100 kJ. Unfortunately, in pulsed applications the load is inductive. Now a generalized equation governing the impulsive transfer of energy from charged inductors to another inductor can be obtained from a theorem due to Carnot (Sturm, 1861). It can be shown (Mawardi, 1982) that

$$E_1 - E_2 = \sum \tfrac{1}{2} L_1 (I_{i,1} - I_{i,2})^2, \tag{1}$$

where E_1 is the energy stored in the system before the transfer, E_2 the energy in the system after the transfer, L_i the inductance of the ith element, $I_{i,1}$ the current in L_i before the transfer, and $I_{i,2}$ the current after the transfer. An important consequence of this theorem, which was further investigated by Lord Kelvin (1863), is that no matter how clever the scheme, the transfer of energy from a purely inductive system to another inductance always will be accompanied by a loss of energy.

To remove the limitations imposed by Carnot's theorem, a number of methods have been developed, which introduce a capacitor in the circuit and trigger the transfer of energy by opening or closing a switch. Another option has been to initiate the transfer of energy from charged inductors to an inductive load by altering the shape of the storage inductors (Fowler *et al.*, 1962) or their relative position (Smith and Lewin, 1970) without interrupting the current. Either one of these two options will permit a lossless transfer of energy.

It is interesting to note that in a pulsed electric rotating machine the inertia of the rotor does act as the dynamical analog of a capacitor. Hence in such a system the energy transfer is in accordance with the first procedure mentioned in the previous paragraph. On the other hand, for the case of an imploding metallic liner embracing a magnetic field, the resulting flux compression that leads to the transfer of energy operates along the lines of the second option described above.

2. MECHANICAL ENERGY-STORAGE SYSTEMS

Energy in mechanical form can be stored as kinetic or as potential energy. The most common mechanical potential-energy storage devices are the springs. The state of the art of springs has been fairly stable for decades, and for this reason this will not be discussed here. The interested reader is referred to several classic texts on this subject (Timoshenko, 1951). On the other hand, there have been several impressive innovations in mechanical kinetic-energy–storage devices, specially in the rotational devices, viz., flywheels.

Flywheels have been used in a variety of applications that fall in the classification schemes discussed in Sec. 1. For example, a flywheel when installed on the shaft of an internal-combustion engine helps to maintain an even average angular torque delivered by the engine. Another example is the drive of steel rolling mills: the Ward–Leonard system (Thaler and Wilcox, 1966), which consists of a combination of a flywheel and an electric motor. The flywheel acts as an energy accumulator during the no-load cycle of the drive. In its discharge mode, the flywheel conspires with the electric motor to overcome the initial surge of starting the process of forcing the white-hot steel ingot through the rollers.

2.1 Flywheel Design

Modern flywheel "accumulators" are incorporated nowadays in systems considerably more complex than the two examples given above. Flywheels of advanced design use rotors of composite materials, and they spin much faster. Furthermore, since the flywheels often are enclosed in burst-containment casings (Coppa and Zweben, 1980), they can operate in a low-pressure environment, which reduces the windage losses (Barlow, 1980). An additional feature of very high-speed rotors is the introduction of magnetic bearings (Pourbeau, 1980), which further reduce the friction losses.

A figure of merit for the performance of a flywheel is its specific stored energy, which is defined as the energy stored per unit mass. This figure of merit can be related to the maximum energy that can be stored in the flywheel or, more specifically, to the bursting elastic stress in the rotor. It can be shown (Genta, 1985) that

$$E/M = K(\sigma_c)_{\max}/\rho, \tag{2}$$

where E is the energy stored in the rotor of mass M, K is a constant related to the rotor shape, $(\sigma_c)_{\max}$ is the maximum allowable stress, and ρ is the density of the rotor material.

It is helpful to the analysis of flywheel dynamics to render ω, the angular speed of the rotor, dimensionless by referring it to ω_0, the angular speed of a thin rim that has the same outer diameter and density and is equally stressed. The dimensionless speed is thus

$$\xi = \omega/\omega_0. \tag{3}$$

The evaluation of K and ξ require laborious calculations because solutions in closed forms are not available for rotors of practical shapes. The stress analysis must consequently be performed by means of numerical computations.

2.1.1 Disk Flywheels.

Disk flywheels have a most advantageous disposition of mass and consequently display a high specific energy. Values of 50 W·h/kg are common. For this reason they are of special interest to energy-storage systems. But disk flywheels must operate at high speeds to be used to their full advantage.

When the thickness of the disk is small compared to its diameter and its thickness profile is a monotonically decreasing function of the radius, then it is reasonable to approximate the stress field by a plane stress. An intriguing concept due to de Laval (Stodola, 1934) is to consider constant stress profiles. De Laval's hypothesis implies that the radial stress is equal to the circumferential stress everywhere in the rotor. Under these conditions it is found that (Genta, 1985)

$$\xi = \sqrt{2F}, \tag{4}$$

where $F = \rho(\omega r_0)^2/(2\sigma)$ in which σ is the constant stress in the disk. The de Laval profile is too thin at the rim. To be practical an outer rim has to be added that will exert a radial stress equal to σ. An example of such a configuration is shown in Fig. 1, where the rim has been selected to have a constant width.

The K and ξ factors for a constant-stress flywheel are illustrated in graphical form in Fig. 2. The dependence of K on the width of the rim is indicated on the same figure by α, defined by

$$\alpha = (r_0 - r_D)/h_0; \tag{5}$$

the meaning of the radii r_0 and r_D and the thickness h_0 are given in Fig. 1.

Constant-stress disks should not have a central hole, as it would cause a departure from the plane stress distribution, and the local strength of the stress can increase beyond the design value for the maximum stress in the disk. A row of equally spaced holes makes matters worse. It was estimated by Johnson (1956) that the stress intensification can exceed a factor of 2. The disk should not be attached to a flange with

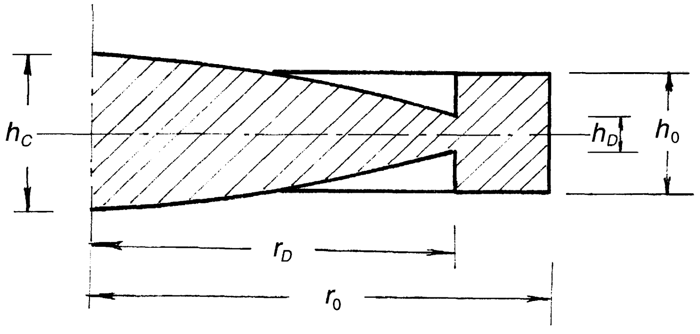

FIG. 1. Profile of disk flywheel with constant radial stress. The rim has a uniform thickness h_0 and width $r_0 - r_D$. The maximum thickness of the flywheel at its axis of rotation is h_C. (After Genta, 1985.)

equally spaced bolts. Instead, it is better to use a short stub shaft or flange made as an integral part of the disk.

2.1.2 Rim Flywheels. There is a range of applications that require rotating power delivered from an energy storage at relatively low angular speeds. Rim flywheels are ideal devices for this type of load. In these flywheels the major fraction of the mass is in the rim. Spokes attached to the hub of the wheel are used to support the rim. To optimize the energy stored in the flywheel, its radius is made as large as possible. The limits on the size and the peripheral velocity of the rotor are set by the stresses in the wheel. Because of the difference in the radial displacements of the rim and of the spokes under the influence of the centrifugal forces, the rim will sense bending moments. These bending moments are highest in the regions where the spokes are attached to the rim. The corresponding stresses from the bending moments can be quite severe and will be the factors determining the limiting speed of rotation of the flywheel.

Various configurations of commonly used rim flywheels are shown in Fig. 3. These have been compiled by Oberg and Jones (1976). The maximum safe speed that can be reached for the rim with such construction and with stacked steel plates has been 160 m/s. Higher speeds have been reported by investigators using rims made of Kevlar (Rabenhorst, 1979).

A considerable amount of work has been done in adapting composite materials (*q.v.*) to rim flywheels. The search for improved specific energy densities has been instigated by the adaption of these flywheels to electric cars and more recently to the uninterrupted-power-supply market for computers. Some of the materials investigated have been fiberglass–epoxy (Boutman and Krock, 1974), graphite–epoxy (Loud, 1977), and quasi-iso-

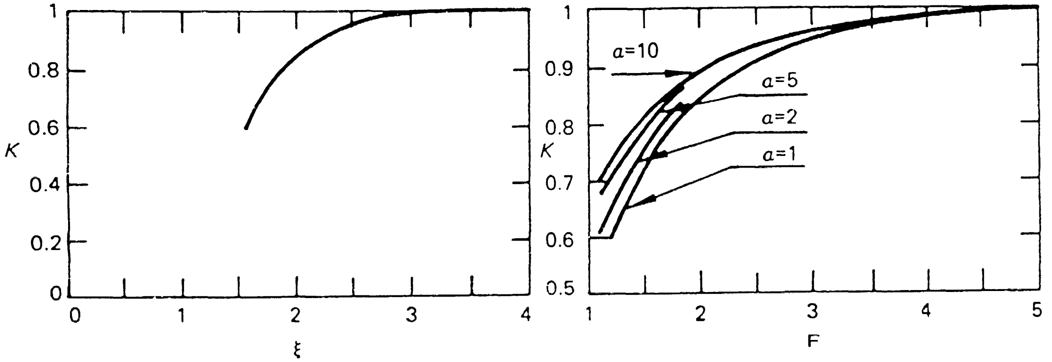

FIG. 2. The graph on the left shows K, the rotor shape factor, vs. ξ, a normalized angular rotational speed; that on the right, K vs. F, the normalized peripheral force at the rim, for different values of the aspect ratio α (after Genta, 1985).

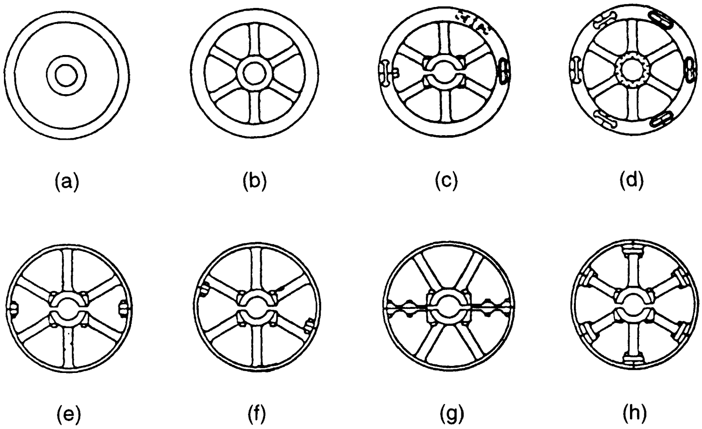

FIG. 3. Schematic representation of some rim flywheels. (a), (b) Solid cast wheels; (c), (d) rim in halves or in sections; (e), (f) rims with bolted flanges; (g) a wheel in two halves; (h) a wheel with joints. (After Oberg and Jones, 1976.)

tropic laminate disks (Sapowith and Hardy, 1981).

Several flywheel designs with composite materials have exploited the high tensile strength of these synthetic fibers and assumed that the stresses are mainly circumferential. In rim flywheels with relatively thin rims, the stresses indeed are chiefly hoop stresses. But the radial stresses in the rim, small as they are by comparison to the hoop stresses, still can induce failure of the rim by forcing the layer of fibers to split apart.

A quantitative estimate of the maximum allowable stress of an isotropic composite material when used in a rim flywheel has been evaluated (Lupton *et al.*, 1976). As expected, the radius of the flywheel and its angular speed of rotation affect the onset of failure. The net effect of the isotropy of the medium is to lower the shape factor K (which defines the figure of merit) to well below unity. For a fiberglass–epoxy combination, K rarely exceeds 0.6.

2.2 Inertial Storage and Electric Machines

The extraction of stored energy in electrical form from flywheels is not an easy task. This is because the flywheel in its discharge mode is in a decelerating mode and continuously losing speed. Consequently, if an electric dc generator is attached to the shaft of the flywheel and energy is extracted *slowly,* means must be provided to continuously adjust the field excitation of the generator to maintain a constant output voltage from the generator. From practical considerations no more than 10% of the energy stored in the flywheel can be extracted, as otherwise it would be difficult for the control circuit to track the drooping voltage output of the generator. Should a *steady* ac electric output be required, then an intermediate dc/ac converter has to be added to the dc generator. This approach has been proposed for uninterrupted power-supply systems with the flywheel storage system taking the place of a bank of electrical batteries.

A different situation is encountered when the flywheel storage system is used in a pulsed mode and the transfer of energy is to take place through an electric generator as before. Since the time of discharge is rapid, the electrical conductors in the generator are subjected to such large mechanical forces that they could be pulled out of the slots of the machine unless special reinforcement is provided. Furthermore, these same conductors must be braced also for the centrifugal forces due to rotation. The combination of these two factors will lead to an increase of the mass and cost of the system. On the other hand, if the flywheel is replaced with the rotor of a homopolar generator, one obtains a rugged machine of simple construction and specially suited to the delivery of pulsed power of great magnitude.

2.2.1 Pulsed Homopolar Generators. The rotor of a homopolar machine consists of a solid axially symmetric conductor rotating about its axis in a unidirectional magnetic field. The conductor can be a disk rotating in an axial magnetic field with radially

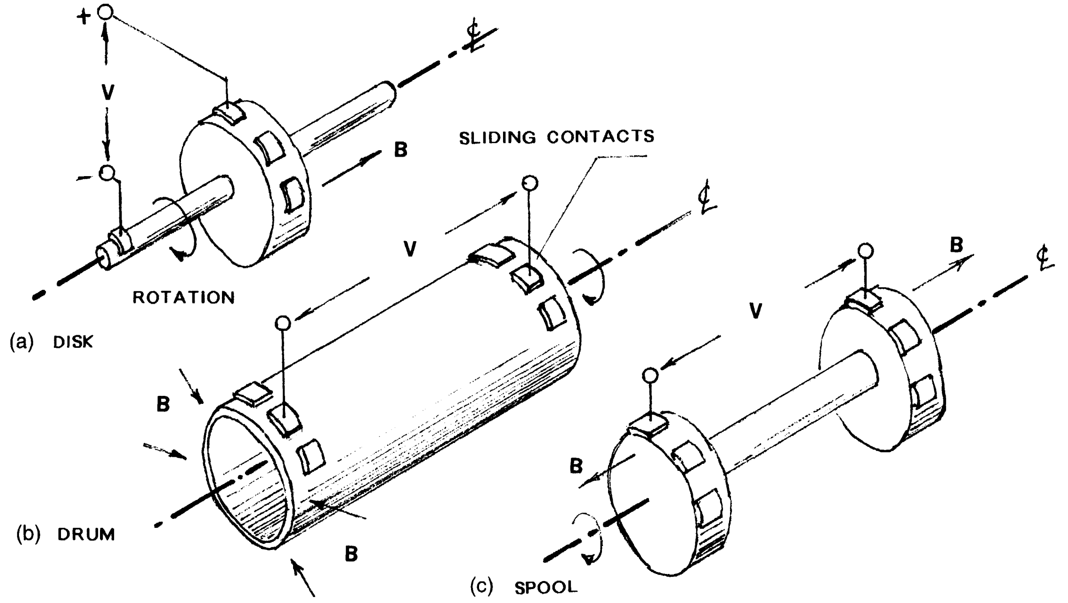

FIG. 4. Possible configurations for the rotor of three classes of homopolar machines. In all of the cases illustrated, the sliding contacts are stationary brushes attached to the frame of the machine. The rotor in (b) is an electrically conducting cylindrical shell mounted on and electrically insulated from a hollow shaft (not shown).

separated contacts [Fig. 4(a)] or a drum rotating in a radial field with axially separated contacts [Fig. 4(b)]. Other configurations are also possible [Fig. 4(c)].

The governing equations for the pulsed generator can be easily derived from basic considerations of electromagnetics. Indeed, it can be shown (Slemon and Straughen, 1980) that this equation is

$$V_t = L\frac{di}{dt} + Ri + \left(\frac{\phi}{4\pi^2 J}\right)\int i\,dt, \tag{6}$$

where i is the current circulating in the homopolar generator whose effective inductance and Ohmic resistance are L and R, respectively, and J is the moment of inertia about the axis of rotation. The quantity Φ is the magnetic flux that links with the rotor. The magnetic field contributing this flux is produced externally and is assumed to be constant with time. The above equation has made use of Kirchhoff's law for an electric circuit whose terminal voltage V_t is the potential difference appearing across the brushes of the homopolar generator. The generator can thus be modeled by the electric circuit of Fig. 5.

It is important to note that the quantity $4\pi^2(J/\Phi)$ associated with the inertia of the rotor is the magnitude of the capacitance of an effective condenser C in Kirchhoff's circuit equation. Now, it is well known from elementary circuit theory that the energy stored in the capacitor C of the circuit shown in Fig. 5 can be totally transferred to a load inductor (except for a small fraction that re-

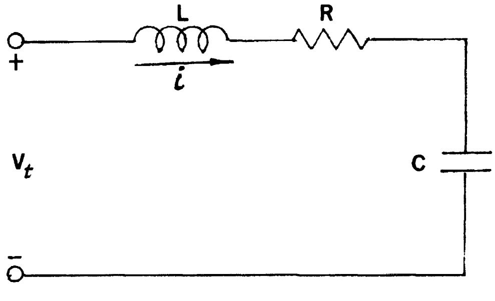

FIG. 5. Equivalent circuit for the pulsed homopolar generator. The inductance L represents the self-inductance of the rotor, R is the equivalent Ohmic resistance of the generator, while the mechanical inertia of the rotor, J, is reflected as an effective capacitance $C = 4\pi^2 J/\Phi$. The quantity Φ stands for the magnetic flux linking the rotor.

mains stored in the self-inductor L and another dissipated in the internal resistor R). These derivations corroborate the statement made earlier that the rotor inertia of a pulsed electric generator will prevent the loss of energy transfer discussed by Carnot.

2.2.2 Design of Pulsed Homopolar Generators. The interest in pulsed homopolar generators is due in great part to their applications to fusion research, rail and plasma guns, and, more recently, welding and metal processing. This warrants a brief review of design innovations that are scattered throughout the technical literature.

The criteria for an efficient pulsed machine are minimal resistance and self-inductance of the generator, magnetic fields of high value concentrated at the rim of the rotor (i.e., at that region that contributes the most to the moment of inertia), low losses in the field excitation, and, finally, selection of the output voltage that will enable the generator to deliver the required peak current.

The introduction of an iron yoke reduces the energy loss by an order of magnitude over that required by an air-core excitation coil. With this arrangement the field coils can be driven with a reasonably small dc supply. The reluctance of the path followed by the magnetic field excitation is further reduced by making the rotor an electrically conducting solid rotor of ferromagnetic material. A band of the rotor where the peripheral velocity is the highest is also the active portion of the generator. This shortened path for the current effectively reduces the inductance of the rotor. The current leads out of the machine are coaxial to minimize their self-inductance. The greatest contributor to the electric resistance of the generator are the brushes. Several materials have been investigated (MacNab *et al.*, 1980). Copper-plated graphite fiber brushes are found to be able to follow surface irregularities of the rotor rim and to maintain good contact.

Homopolar machines are essentially low-voltage generators. The magnitude of the peak current resulting from a given voltage V_t can be estimated by means of the circuit of Fig. 5 that models the pulse generator. Suppose that the energy stored in the rotor is to be discharged in a time τ. Then, from circuit theory (Guillemin, 1953) we find that $i_{\max}$, the maximum value of the current, is approximately

$$i_{\max} = V_t C(2\pi/\tau). \tag{7}$$

But we have also

$$V_t = \tfrac{1}{2} F v_{\text{tip}} R_0, \tag{8}$$

where v_{tip} stands for the peripheral velocity of the flywheel, B for the excitation flux density, and R_0 for the radius of the rotor. By inspection of the above relations, one infers that the peak current will increase with the open-circuit voltage, which, in turn, depends on the magnetic field, the tip velocity, and the size of the rotor. The issue is to find the design that yields the largest value of the open-circuit voltage within constraints of cost and size of the machine.

There is a practical limit to the increase that can be gained with conventional coils. Excessive Ohmic losses and restrictions of space impose a ceiling on the number of ampere-turns that can be fitted in a finite volume. The alternative would be to opt for superconducting or cryogenic coils. Either one of these solutions is expensive. Increasing the size of the radius entails major alterations in the dimensions of the yoke and the excitation coils. If the energy rating of the machine is to remain constant, the axial length of the machine must be reduced. When the length of the machine is too short, the profile of the rotor must be altered to make it stiffer. This is to prevent parasitic flutter vibrations. Clearly, these alterations too are costly.

Finally, the rotor can be spun faster. Here again the velocity of the rim must be kept below the critical speed to avoid failure of the rotor. An alternative would be to construct a new rotor from nonferromagnetic materials that are stronger. Unfortunately, the magnetic excitation system becomes complex and hence costly. The preferred solution must balance the various alternatives and arrive at an optimum trade-off.

2.2.3 Operational Experience. Several research groups have developed and constructed pulsed homopolar machines with a wide spectrum of rotational speeds, of energy ratings, and of time constants. Detailed descriptions of collections of such experimental investigations on these machines have been reported in the technical literature (Intersociety Energy Conversion Conference, 1988). A machine (Gully *et al.,* 1984) conceived by the Center for Electro-mechanics of the University of Texas at Austin is shown in the cut-away Fig. 6. Unlike almost all of the existing generators, which are one-of-a-kind, experimental machines, the Texas device has been refined to the point that it has been commercialized by OIME, Inc.

This machine was designed for a discharge time of 15 ms. To achieve this time constant, two stubby counter-rotating rotors were used. This method of construction not only reduces the response time but improves also the stability against vibrations.

The copper finger brushes used were actuated hydraulically, and when in contact with the rotor they were subjected to a 225-m/s slip speed. The designers felt that the brushes could sustain a current density of 570 A/cm^2. This high density had been verified by Marshall (1980) in an experimental test rig. The actual performance parameters are as indicated in Table 1.

Table 1. Performance parameters for the OIME machine developed by the Center of Electromechanics of the University of Texas (Austin).

Stored energy	6.2 MJ
Rotational speed	6245 rpm
Weight	1545 kg
Terminal voltage	50 V
Effective capacitance	4960 F
Internal inductance	30 mH
Internal resistance	7.5 Ω
Peak current	750 kA

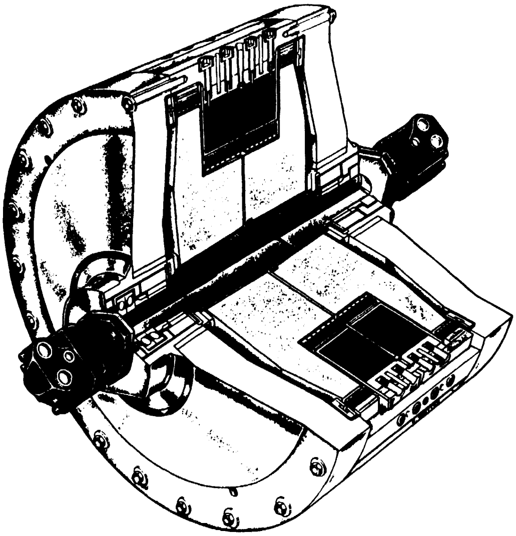

FIG. 6. Sectional view through the pulsed homopolar generator built by OIME, Inc. The cut-away shows the location of the brushes and of the two counter-rotating rotors. (After Gully *et al.*, 1984.)

3. THERMAL ENERGY STORAGE

Approximately 85% of the demand for commercial and residential energy requirements is for heating and/or cooling purposes. In countries that use electrical energy to supply hot water or space heating, thermal storage units installed in individual residences or business establishments can contribute appreciably to easing the demand on the electric utility power plant during the peak hours. These units consists of electrically heated ceramic storage materials (Polland, 1970). Consumers are encouraged to turn on these storage units during the off-peak hours by being offered a much cheaper charging rate. Thermal storage units have been incorporated also in heat-pump installations. In this case the ability of the pump to meet the heat load is improved considerably when the incoming cold air is preheated by a few degrees by passing it through a thermal storage unit. Another application for thermal storage is in air-conditioning plants for large office or apartment buildings where absorption rather than compression-cycle refrigerators are used. These systems are very practical since there are absorption chillers on the market that can be energized with sources as low as 85 °C.

The economic importance of energy savings in the industrial arena through thermal storage has been recognized for a long time. Some of the early work in this connection was initiated in Germany many decades ago. Several innovations related to thermal storage were developed at the Institute of Fuel Economy in Düsseldorf, in particular the two basic concepts of counterflow regenerators and waste heat recovery (Schmidt and Wilmott, 1981). Almost all of the metal-processing industries today make intense use of thermal storage to conserve waste heat. Similarly, the cement, glass, and ceramic industries also store exhaust heat for later use.

3.1 Thermal-Storage Processes

Thermal energy storage can be achieved by the storing of energy through heating, melting, or vaporizing a substance, the energy becoming available as heat when the process is reversed. Storage by causing a material to rise in temperature is referred to as sensible heat storage. Another method of thermal storage, which exploits the heat absorbed by phase transition at constant temperature, is known as latent-heat storage. Both sensible and latent-heat storage may occur in the same material, as when a solid is heated, melted, and then raised in temperature.

There are three basic types of storage systems using the sensible heat concept (Brumleve, 1974). In the first one, the working fluid already at high temperature and at low or high pressure is stored in a thermally insulated container until the energy stored is extracted. Hot water storage as used in homes for domestic water systems falls in this category. The second method relies on the transfer of heat from a stored material at high temperature to the working fluid. One of the most promising materials now available for storage is ferric oxide, Fe_2O_3. This material has a very high volume enthalpy and a close atomic packing and is inexpensive. At ideal single-crystal density, it would have the same thermal energy storage per unit volume as cast iron up to 700 °C. The ferric oxide usually is installed in a packed solid bed and heated. Finally, the third process consists in transferring heat from one fluid to another fluid via a stored material.

The latent-heat storage devices are mostly based on solid–liquid phase change concept because a substantial quantity of heat can be stored over a narrow change of temperature and without a large change of volume of the working substance (Schulten *et al.*, 1974).

Thermal energy-storage systems of the types discussed above can be designed to provide output temperatures between 100 and 1250 °C. The most favored technology, however, is the one based on sensible heat. It has been used with great success (Christensen *et al.*, 1985) in pressurized water storage tanks, in organic-liquid reservoirs for feed-water heating, in packed solid beds, and in fluidized solids. On the other hand, the latent-heat storage method has been applied successfully to the process associated with inorganic phase-change materials like the fluoride eutectics. The latter have been used often in solar-energy systems.

3.2 Heat Exchangers and Thermal-Storage Design

Storage systems that rely on sensible heat are used often enough that they merit some special discussion in this review. There are two classes of such systems that represent two complementary functional operation points of view. The first kind can be viewed as a thermal regenerator used to transfer heat between two fluids. This transfer is accomplished in two discrete steps, which are repeated periodically. Heat is first stored in a permeable packing by flowing a hot fluid through it. During this portion of the cycle, sensible heat is deposited in the packing. Subsequently, the stored heat is regained or "regenerated" by passing a cold fluid through the packing. This mode of operation is often referred to as the "single-blow" procedure because the surface of the packing is submitted to a succession of *intermittent* hot and cold blows.

The second type of thermal storage operates in such a fashion as to allow a continuous exchange of heat between a hot and cold fluid. Several schemes have been developed to achieve this mode of operation. The simplest of these schemes makes use of two packing beds. By means of a combination of valves the cold fluid is diverted alternately to one then the other of the two packings. While one of the beds is being discharged and heating the fluid, the other is heated and made ready for the next phase of the cycle. The result is an almost continuous heating of the cold fluid. In a more complex arrangement, the heated packing is placed on a rotating tray. One-half of the tray is exposed to the hot fluid and the other to the incoming cold fluid. As the tray rotates, heat temporarily stored into the packing is physically moved into the cold stream. Considerable attention must be given to provide seals to minimize the leakage between the counterflowing cold and hot fluids.

The prediction of the performance dynamics of any one of these storage systems is a difficult task. To render the analysis tractable, the packing bed is idealized by a model consisting of a number of conduits or passages imbedded in a matrix of high heat capacity. Now it can be shown (Szego and Schmidt, 1978) that the optimum performance of a thermal-storage system conforming to the idealized model is obtained when the temperature gradient along the direction of flow of the fluid in the conduits is considerably greater than the gradient normal to the flow. A considerable amount of work has been done (Gröber and Erk, 1961; Petukhov, 1970) to evaluate the film thermal resistance at the interface between the flowing fluid and the walls of the conduits in order to satisfy the above-mentioned criterion. Thermal regenerators have been in use for several years for a number of applications. A substantial amount of documentation on their design is readily available in the technical literature (Kays and London, 1964).

4. COMPRESSED-AIR STORAGE

Air storage system energy transfer (ASSET) uses a process of great interest to the electric utilities. ASSET systems are simple to install and operate. They are less costly than gas turbines or old steam power plants reserved exclusively for peak load demands. Other advantages of ASSET systems is their ability to start fast (about 6 min) and to operate efficiently even at a fraction of their capacity. Unlike hydroelectric pumped-storage systems, they do not create environmental disturbances.

4.1 Principle of Operation

In an ASSET system (Stys, 1983) the pressure of ambient air is raised by compressors to a high value (up to 70 bars). The air is then cooled and subsequently stored in an underground cavity. During the peaking cycle, air is led from the underground store, heated, and then allowed to expand in a turbine, whereby the energy stored is retrieved. Such a system is sketched in Fig. 7.

Numerous variations in the design of such systems have been suggested. Most of the proposals rely on an air storage that can be an aquifer, a mined cavern, or a salt dome. The air storage can be maintained at constant or variable pressure. The heat of com-

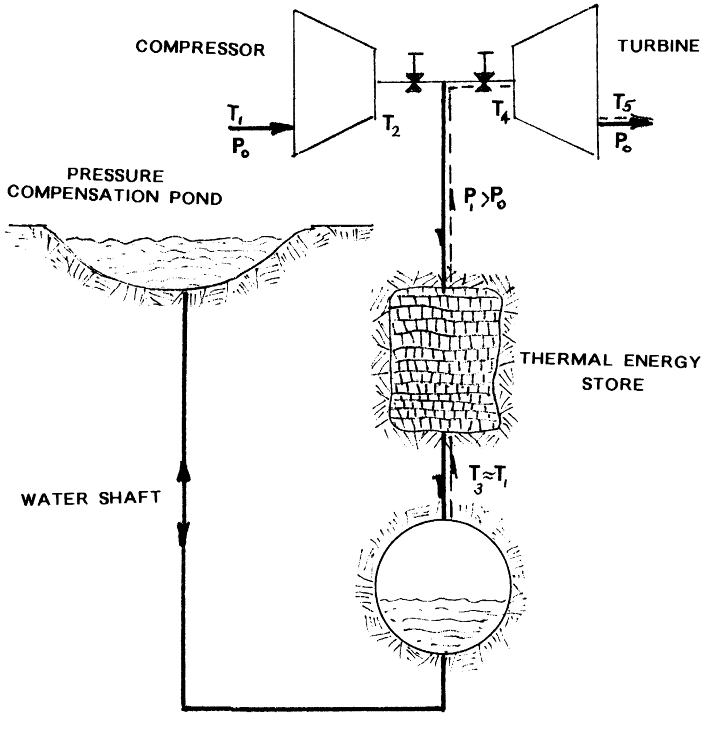

FIG. 7. Operational diagram for an ASSET system (after Stys, 1983). During the charging stage, the motor/generator machine connected to the grid acts as a motor to actuate the compressor. The compressed air raised to 70 atm (≈1000 psi) is stored in an underground cavity. In the discharge phase the high-pressure air is preheated prior to being directed to the two turbines HGT (high temperature) and LGT (low temperature) connected in tandem. The electrical machine attached to the turbines shaft now is run as a generator returning electric power to the grid.

pression may or may not be stored. If it is not stored, combustion of additional fuel is required to make up for the heat lost. When the heat of compression is stored, it is returned to the air upon discharge. The overall process may be considered adiabatic. The advantage of such a system is that it has a high stage efficiency. It is also a stand-alone system that does not require additional fuel (to reheat the air).

The performance advantage of storing the heat of compression was recognized early in the development of this class of storage systems. The proposed procedure included an underground rock-based bed, which allows recuperation in a single (Glendening, 1974) or two-stage thermal cycle (Stephens, 1976), as encountered in the ASSET system. The basic scheme for a single stage is shown in Fig. 8.

4.2 Operational Experience

The Nordwestdeutsche Kraftwerke (NWK) of Hamburg, Germany, installed the first ASSET plant in 1978. A large fraction of NWK generating capacity is from nuclear reactors, which require system management. Since the subsoil of Northwest Germany contains a large number of salt domes, it was the obvious solution for the location of a storage system. Two such caverns with a volume of 150 000 m^3 apiece were combined to provide the air reservoir for the system. The two domes could provide two hours' coverage at full-load peak. The NWK storage system has performed very well, as indicated by the operation parameters given in Table 2.

In the United States, Soyland Power Cooperative, Inc. of Decatur, IL, is a complex of 15 individual Illinois cooperatives. A por-

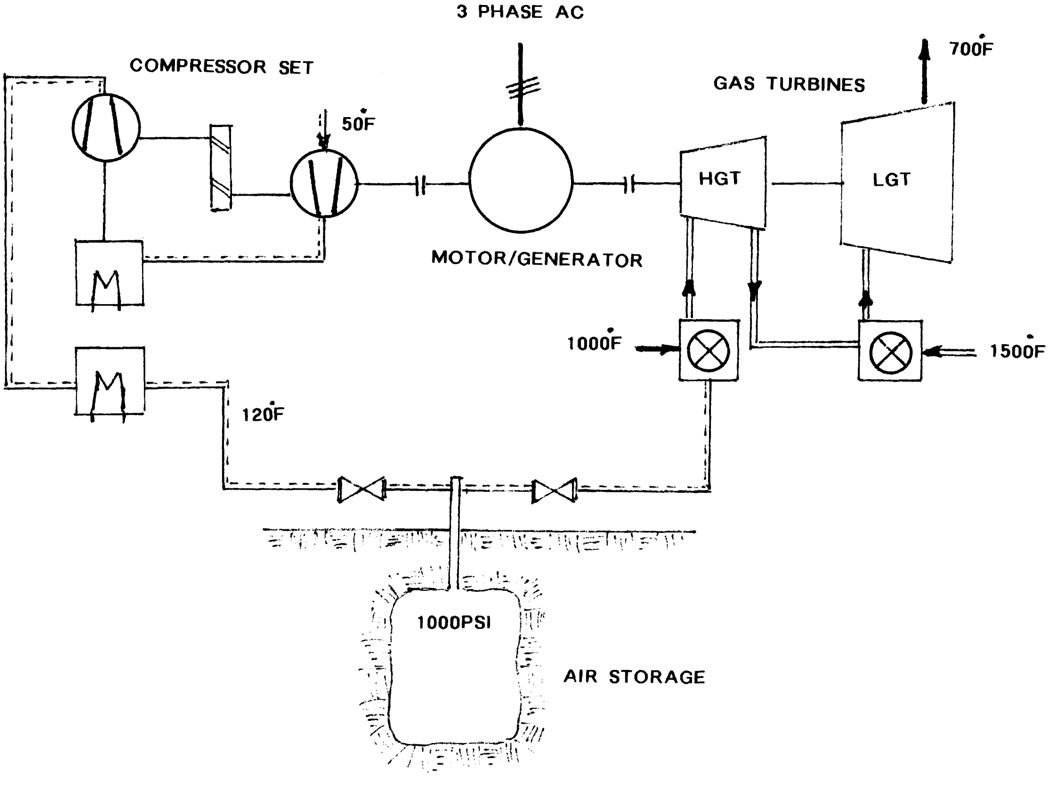

FIG. 8. Single-stage heat-of-compression storage adiabatic compression system (after Glendening, 1974). As the air is compressed, its temperature is raised above its intake temperature. The sensible heat associated with the air is deposited in a thermal store prior to being stored in an underground cavern. The pressure compensation pond maintains the air-pressure constant. Upon discharge, the air is diverted to a turbo-generator to regain the energy stored in the air. The operating temperatures and pressures are indicated on the sketch.

Table 2. Operating parameters of the ASSET plant in Hamburg, Germany (Stys, 1983).

Interval considered	One year
Charging time	1 874 h
Discharging time	840 h
Capital invested (including salt domes)	\$230/kW
Energy delivered	86 475 MWh

tion of Soyland's capacity is nuclear. Following a system analysis of their power generation management, Soyland has decided to include in the planning the addition of an ASSET system. Such a system is being constructed.

5. PUMPED-HYDRO STORAGE

Pumped-hydro storage is based on the principle that the potential energy of water can be increased, if surplus electric power is available, by pumping the water from a lower elevation to a higher one, thus indirectly storing energy. A variation on the conventional pumped storage is the underground pumped-hydro system. The impetus in adapting pumped storage to electric utility systems is attributed to the development of the reversible Francis-type impeller wheel, operating in one direction as a pump and in the other as a turbine. This has reduced the cost of medium-head pumped storage most prevalent in the United States.

Pumped-hydro systems have been in operation for many years in the United States and overseas. Their technology is well established and extensive documentation (Hunt, 1968) on the subject is readily available. This important method of storage will not be reviewed here in detail; it is mentioned only for completeness. Although new pumped-hydro plants are still being installed overseas, pumped-hydro storage plants are losing their popularity in the United States because of their adverse impact on the environment by flooding large tracts of land and altering the level of the underground water table.

6. CHEMICAL ENERGY STORAGE

A basic criterion for a chemical energy-storage system is its ability to be reversible. It should be able to absorb energy from a primary power source, store it, and deliver upon demand this energy in a usable form: usually electricity or heat. As a result of the reversibility requirements, chemical storage systems tend to be elaborate. Chemical reactions offer large energy-storage densities as a result of the highly energetic processes involved in the reversible destruction and reformation of the chemical bonds. Catalytic reactions are particularly attractive because the products of the endothermic reactions contain thermal energy as chemical bond energy that is retrievable over an appropriate catalyst.

The emphasis here has been placed on chemical storage in a broad sense and considers systems more complex than the specific chemical reactions mentioned above. This statement is clarified by two such examples that have been commercialized, namely, the hydrogen-cycle system and electrical batteries.

6.1 Hydrogen-Cycle System

The hydrogen-cycle peak shaving system has received a great deal of attention from the electric utility energy systems. It consists of a complex mix of chemical, thermal, and electromechanical energy conversion components so combined as to optimize performance and cost. A typical hydrogen-storage system is shown in Fig. 9 (Salzano *et al.*, 1974). During the off-peak hours of the utility system the output of the converter–inverter is directed to electrolysis cells. The hydrogen produced by electrolysis is dried first and then stored in an iron–titanium storage tank.

Under peak load conditions the electrolysis cells are disconnected from the network, and the fuel cells are restored on line. The dc output from the fuel cells is processed through the inverter–converter prior to being connected to the ac network. In an alternative scheme one starts with the combustion of hydrogen and recovers the energy stored by means of a gas turbine or a magnetohydrodynamics (MHD) generator operated in an open-cycle mode. The main features of the hydrogen-cycle system are discussed below.

6.1.1 Hydrogen Production. The cost of producing hydrogen by electrolysis represents an important fraction of the capital in-

vestment on the system. One of two competing schemes is used for the electrolysis. The first is a solid polymer sulfonic acid cell developed mainly by the General Electric Co., and the other is an alkaline cell produced by Teledyne Isotopes.

The solid polymer electrolyte is a sulfonic acid plastic membrane (Nultall and Fernandes, 1974) through which ionic conductivity is contributed by hydrated hydrogen ions. The maintenance of the cells is simple because of the absence of free acids or caustic liquids. The membrane acts as a barrier to the hydrogen generated and can withstand pressures as high as 35 bars.

Teledyne electrolysis cells (Murray and Yaffe, 1980) with capacities as high as 4 tons per day have been designed. Unlike the polymer cells, which require an operating temperature of about 300 °F, the alkaline cells function at room temperature and need light catalyst loading.

6.1.2 Storage of Hydrogen. A key to the success of the hydrogen-cycle system is the ability to store hydrogen safely for a long time, at reasonable cost, and to charge and discharge the hydrogen gas quickly. Several solutions have been found acceptable. One is to store the hydrogen in cylinders at high pressure (70 to 105 bars). The recovery performance is close to 98%. A second option is the iron hydride storage scheme (Strickland *et al.*, 1974). In this method the hydrogen is absorbed by iron–titanium in an exothermic reaction described by

$$\mathrm{FeTi} + \frac{x}{2}\mathrm{H}_2 = \mathrm{FeTiH}_x + \Delta, \qquad (9)$$

where Δ, the heat of reaction, is approximately 16 000 kJ/kg. The advantage of this method is that the hydrogen can be stored at room temperature, quite safely and at an efficiency of 95%. Attempts have also been made to store the hydrogen as liquid hydrogen. The process unfortunately is costly and inefficient (66%).

6.2 Electrical Batteries

As a result of a study (Crouch and Perry, 1973) sponsored by the U.S. Department of Energy, the Electric Power Research Institute, and the International Lead Zinc Research Institute Organization, it was found that lead-acid batteries could be used as storage batteries in an electric network. On the other hand, the cost of these batteries designed for the required cycle life is prohibitive as compared to other energy-storage systems such as pumped hydro storage.

The need for electric batteries for use in electric cars or in uninterrupted power supplies has instigated the development of advanced light-weight batteries capable of long life and reasonably priced. The general guidelines in the search for these batteries have been a preference for soluble or liquid reactants to achieve reproducibility in morphology of active materials, and high temperatures for improved reversibility. Some of the most promising systems being considered are sodium–sulfur (and antimony trichloride), lithium-alloy/metal sulfide, and redox. Several research reports on the latest developments of these advanced batteries are reviewed in the proceedings of an annual conference: the IEEE International Power Source Symposium.

A typical example of an advanced battery system is the molten sodium chloride aluminate cell. This battery uses inexpensive materials in its construction; it operates at 200 °C so that one can use Teflon seals and aluminum containers. Furthermore, it has a long cycle life because there are no solid–solid transformations.

7. MAGNETIC STORAGE

In a superconducting magnetic energy-storage system, the energy is stored in the magnetic field associated with a coil. If the coil is wound with superconducting material, then once the coil is "charged" the magnetic energy stored can be preserved indefinitely provided the coil can be maintained in the superconducting state.

Historically, when the art of manufacturing superconductors on a large scale first became a practical reality, applications were quick to start in experimental plasma physics (Robson and Lupton, 1975), solid state, and particle physics (Hammel *et al.*, 1970). Ferrier (1970) was the first to propose the use of a superconducting coil as an energy storage for the Electricité de France. Ferrier's scheme required the installation of a very large central superconducting magnetic energy storage (SMES) for the whole network. Ferrier's concept was judged impractical, and the proposal was abandoned.

In 1971, a program was started in the United States at the University of Wisconsin to re-evaluate the SMES concept and to examine in detail the operation of the components in the system. The project leaders, Boom and Peterson, came to the conclusion (Peterson *et al.*, 1975) that there was great merit in having the SMES interface the electric network through a Graetz bridge. This circuit, discussed in some detail in Sec. 7.1.3, has the attractive feature of effectively stabilizing the system against oscillations while acting as an inverter–converter.

The definitive study for the feasibility of SMES was conducted at the Los Alamos Scientific Laboratory in 1972 (Hassenzahl *et al.*, 1973). This was as a result of a directive by the U.S. Department of Energy to conduct a realistic cost analysis to provide guidelines on the course of action to take on SMES.

One component of the SMES unit, the structure required to deal with the magnetic forces on the conductors, was found to be so expensive as to make the system impractical. However, two concepts developed in 1972 completely changed this picture. The use of warm supports for the superconducting coil (Powell and Bezler, 1973) not only reduced the refrigeration load but also made it feasible to consider a warm structure such as *in situ* rock as a less costly support to take care of the magnetic forces.

Since the reinforcing structure represents by far the major cost of a SMES system, attempts were made to identify coil configurations in which the fields and currents conspire to compensate for the internal forces. Mawardi (1975) proposed a combination of poloidal and toroidal coils that would achieve quasi force-free conditions, thus eliminating the need of external support. The coil, however, deemed not cost-effective per unit of energy stored, was not pursued any further. The scheme, however, is well suited to space applications where different criteria apply and where rock support is not available.

The early estimates of SMES indicated that only very large units (greater than 1000 MW·h) would be economical. It was difficult, therefore, to justify the construction of a smaller unit on which a SMES system could be made economically viable. As a result of a series of conferences and workshops in the United States and Japan (SMES Review Panel, 1976), a suggestion was made to construct a small SMES to stabilize long interties between power plants.

7.1 Components of SMES

Reference designs of a SMES unit of 1 GW·h rating have been compiled by the Los Alamos group (Rogers and Turner, 1980) and by the University of Wisconsin team (Wisconsin Superconducting Energy Storage, 1974). The two designs contained novel ideas for the construction of the superconductors, the coil configuration, the restraining structure, the Dewar vessel, and the inverter–converter interfacing circuit. These findings are summarized below.

7.1.1 The Superconductors. The cost of the superconductors is an important fraction of the capital invested on a SMES system. To evaluate accurately the minimum mass of conductors required, one needs to determine the maximum permissible current density in the conductors, the cooling method, and the heat capacity of the conductors.

Two possible methods of cooling are possible: the pool-cooled conductors (Mullan, 1977) and the force-cooled conductors (Hoening, 1976). In the first method a cable of conductors with many strands (500–2000) is immersed in a bath of liquid helium. In the second the helium is forced through the conductor itself.

Conductors should be designed to be cryostable; i.e., the heat generation, when all the current flows in the stabilizing material, should be less than the heat-removal rate capacity of the system. The ratio of stabilizing material (Cu, Al, . . .) to superconducting material is usually chosen so that the operating current density is one-half of critical. This conservative rule of thumb has been abandoned in favor of the "grading" procedure. This latter procedure, which has been incorporated in the SMES design, rests on the fact that the critical current density increases inversely with the strength of the magnetic field. Accordingly, one adjusts the quantity of superconductors in the cable so that the current density throughout the windings always is at 90% of the critical density. This procedure leads to substantial saving of conductors.

The superconductors used in the SMES are multifilament (Rogers, 1979) extruded copper with a copper-to-NbTi ratio of 1.33. The composite is then drawn to a strand. A flat transposed cable is made of 23 such strands and subsequently surrounded by a stabilizer of aluminum clad with a thin layer of copper. Drawing of the assembly produces a conductor as shown in Fig. 10. The current density in the aluminum is reckoned to be no more than 15 kA/cm^2. At that value of the current, 1% of the stored energy is dissipated in the aluminum, which must not exceed a temperature of 100 K.

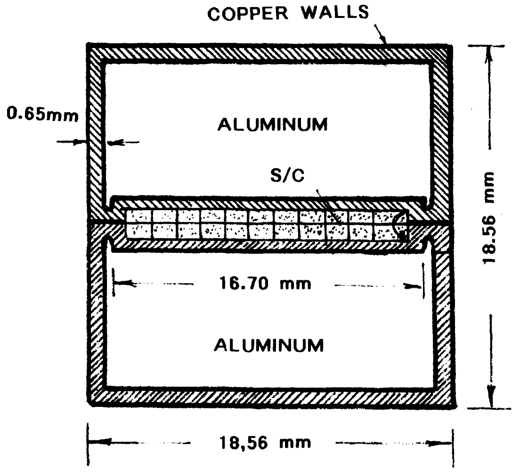

FIG. 10. Cross-sectional view of the conductors used in the windings of the SMES (after Rogers, 1979). The superconductors are located in the center strip. The aluminum bars contribute mostly to the stabilization and to the mechanical strength of the conductors.

7.1.2 The Coil and Its Accessories. The coil is cylindrical and is pool-cooled by liquid helium at 1.9 K. The discharge requirement of the coil is that the maximum turn-to-turn voltage does not exceed 100 V. The coil has accordingly been subdivided into 13 segments, each with its individual Dewar vessel. The coil characteristics are summarized in Table 3.

The layout for the coil is drawn in Fig. 11(a). Figure 11(b), the cross-sectional view across the plane "AA" in Fig. 11(a), illustrates the manner in which the helium vessel is installed. Figure 11(c), on the other hand, gives a detailed view of the construction of the warm supports. The radial and axial forces on the conductors are transmitted through the conductor stack to the helium vessel and to the support. The axial forces accumulate. The windings into each of the segments have been divided vertically into two parts. One abuts against the Dewar vessel and the other on ledges fitted to the inner and outer walls of the Dewars. The coils and their Dewar are installed into an underground excavation whose profile is shown in Fig. 12. The axial pressures (tending to compress the coil) are constant and are evaluated to be 108 bars. The radial pressures vary with height. They are a minimum at the top of the coil (12.5 bars) and reach a maximum about mid-height (100 bars).

Table 3. Characteristics of superconducting coil designed by the Los Alamos Group (after Rogers and Turner, 1980).

Average radius	66 m
Height	44 m
Radial thickness	0.20 m
Inductance	3170 H
Current at full charge	50 kA
Coolant	Helium @ 1.8 K and 1 atm
Number of turns	4280 (in 5 layers)

Cooling of the coil is accomplished by means of a two-fluid system. The heat load is due mainly to losses through the supports and the leads in and out of the SMES coil. To reduce these losses the supports and the leads are vapor-cooled to 63 K by the return helium.

7.1.3 The Graetz Circuit. Some very brief comments will be made on the novel use of this classic circuit in the SMES. This circuit, shown in Fig. 13, behaves as an ac-to-dc rectifier and a dc-to-ac converter. In the charging mode, the direction of the current I_d in the coil is fixed by the SCRs. In the discharging phase, the polarity is reversed, while the voltage across the coil is made null when the storage coil is idle.

The three-phase bridge consists of SCRs, which are controlled by a firing circuit. The firing pulses use for reference the 60-Hz power source. By altering the phase of the firing signal with respect to the 60-Hz reference, the voltage can be made to change in magnitude and polarity. The converter operation is explained along the same lines.

The pulsed bridge generates harmonics, which can be transmitted to the network. The amplitude of the harmonics can be reduced by increasing the frequency of the firing signals or by filtering.

7.1.4 Conclusion. The fast response time, high efficiency, and environmentally safe attributes of the SMES make it a system of great interest to the utilities. Continuous technical improvements in the cost and performance of the components are bound to bring the operation of the SMES to a level that will be competitive with other methods of storage. There is a great deal of expectation that it will happen in the very near future.

7.1.5 SMES and Transmission Stabilization. The Pacific Northwest and southern California are part of the Western U.S. Power System. The electric-generating centers of these regions are connected to the load by two intertie complexes: the 900-mile-long Pacific AC Intertie and the Pacific HVDC Intertie.

Studies completed prior to the installation of the AC Intertie predicted (Cresap and Mittlestadt, 1976) that the line had the potential of exhibiting self-excited oscillations at the frequency of 0.33 Hz. On 7 August 1974 such oscillations did occur with a power amplitude swing of 300 MW and a frequency of 0.35 Hz.

To forestall the occurrence of such oscillations, the Bonneville Power Administration (BPA) installed equipment on the high-voltage direct current (HVDC) line to modulate the power flow and damp the oscillations. Unfortunately, the HVDC line is available for only 89% of the time and furthermore is subject to being down on account of earthquakes.

It had occurred to a number of investigators (Byerly, 1980) that the addition of a SMES to the network would add enough inertia in the system to stabilize it. The SMES is a reliable alternative to and less expensive than a redundent HVDC transmission line. Los Alamos thus was commissioned to build a 30-MJ SMES.

The design of this unit was similar to the 1-GW·h reference unit except for two features. Since the SMES would operate under time-varying conditions, the conductors had to be designed to withstand such conditions. Accordingly, the construction shown in Fig. 14 (Rogers *et al.*, 1983) was adopted. The second variation in the design was the use of a nonmetallic Dewar vessel to avoid the excitation of eddy currents in the walls of the vessel.

7.2 Pulsed Inductive Storage

The transfer of energy from a SMES takes place over times that can be as short as a second and that can extend to periods of the order of hours. On the other hand, for the pulsed homopolar generator, we found that the time constant ranged from milliseconds to a few seconds. The transfer of energy from a charged air-core inductor to a load, however, can take place in times of the order of microseconds or even, with proper care, of nanoseconds. In view of the many applications that are in need of these rapid pulses of energy, it was considered worth while to devote a special section on this class of energy storage.

One of the simplest arrangements for the transfer of energy from a charged inductor to a load is shown in Fig. 15. Initially the switch is closed to charge the storage inductor *L*. Upon opening the switch, energy is transferred from the inductor *L* to the load. As was discussed in Sec. 1.2, if the load is inductive, then adding a capacitance to the circuit improves the efficiency of transfer.

There are several features of the above circuit that must be considered. The voltage *e*(*t*) can climb to very high values that may reach the megavolt range. The design criterion for the inductor is that it can withstand

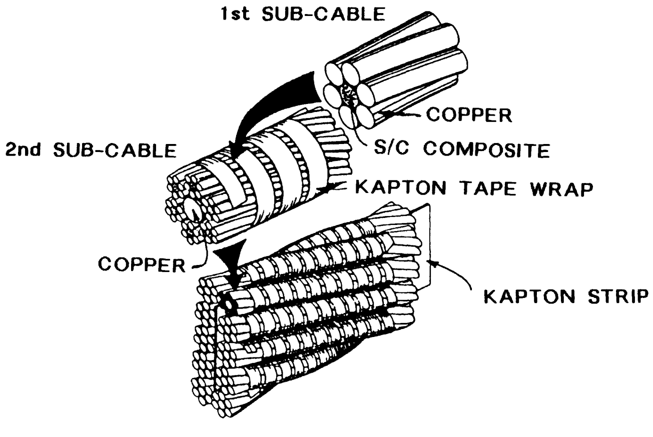

FIG. 14. Superconducting braided conductor used in a SMES unit operating as a stabilizer (after Rogers and Turner, 1980).

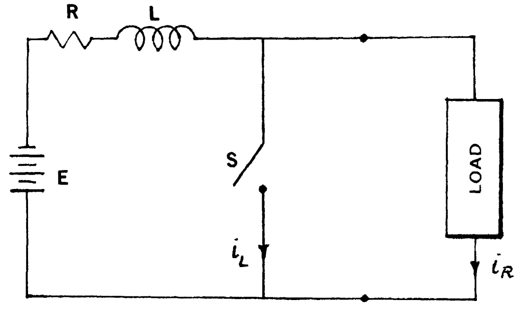

FIG. 15. Classic circuit for a pulsed inductive source. The inductor is charged when the switch S is closed. Discharge takes place upon opening S.

high voltages and avoid electric flashover. The switch is not ideal, i.e., it does not instantly acquire an infinite resistance once it opens. Quite often the switch arcs and the current interruption takes place only after extinction of the arc. Trost *et al.* (1976) calculated the performance of the circuit of Fig. 15 when the ideal switch was replaced with a time-dependent resistor representing an arc. It was shown that the peak voltage was reduced by almost a third (of the ideal case), when the switch "opens" in a time equal to twice the decay period (R/L) of the circuit.

At first glance it would appear that there would be a definite advantage in making inductors out of superconducting materials. This would yield $R/L \rightarrow 0$. Unfortunately, when such conductors are subjected to rapidly varying fields, severe eddy currents are induced in the stabilizing material. As a result the coil may quench to the normal state. Many attempts have been made to construct superconductors for ac fields (Yamamoto, 1986). So far, most of the results have been disappointing.

Several variations on the simple circuit of Fig. 15 have been used with the purpose of shaping the pulse. One such circuit is illustrated in Fig. 16 (Holland, 1984). In it the inductors are successively brought on line. The technology of pulse shaping is highly developed, and the interested reader can find additional information in the literature. Up-to-date information on this subject can be found in the proceedings of the IEEE Pulsed Power annual conferences.

GLOSSARY

ASSET: An acronym for air-storage system energy transfer. This refers to a system comprising both the compressed-air installation and the air turbine to extract the energy from the compressed air.

Force-Free Coil: A coil, first discussed by E. Fermi and S. Chandrasekhar, in which

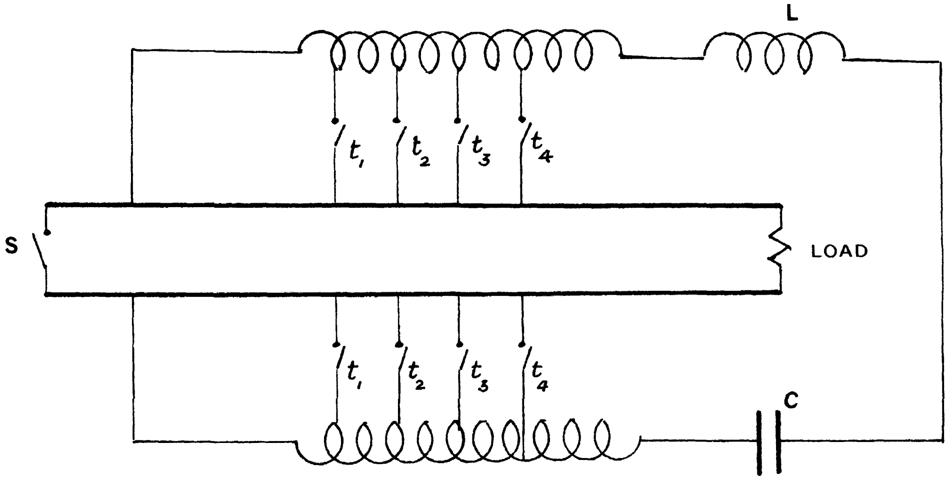

FIG. 16. Pulse-shaping circuit that doubles as an inductive storage system (after Holland, 1984). Charging of the inductor L takes place by closing S and opening the switches t_1, t_2, ... To discharge the inductor and start a current pulse down the transmission line, S is closed first, and subsequently, the switches t_1, t_2, . . . are closed in succession.

the current in the coil windings is everywhere parallel to the induced magnetic field. As a result, there are no net forces on the conductors.

Francis Turbine: A reversible machine that can operate as a pump and as a turbine.

Graetz Circuit: An inverter/converter with very low harmonic content.

Homopolar Generator: Originally invented by Faraday, consists of a solid conductor in the form of a cylinder or disk that is spun in a magnetic field. The device behaves as a generator with a one-turn winding. As a result, large currents can be produced.

Peak Load Shaving: A term applied to the procedure of reducing the output power from a generating plant by relying on a storage system to return stored energy and thus supplement the power plant during the "peak" load.

Pumped Hydro: Short for pumped hydroelectric.

SMES: Superconducting magnetic energy storage.

Stable Superconductor: A composite of superconductors embedded in normal conductors with sufficient heat capacity that they can act as a heat sink and prevent the temperature of the superconductor from rising as a result of a surge inducing eddy currents in islands of normal material in the superconductor.

Ward Leonard: Name given to the combination of a flywheel and motor used mostly in rolling mills and mining shafts.

Warm Supports: Thermally insulated mounts fixed to the rock and to which the vacuum vessel of the SMES is attached.

3.1
Overview

In this chapter, we give an overview of our theory of the strong interactions, *quantum chromodynamics* (QCD) and its properties. We also briefly review the history of the study of the strong interactions, and the discoveries that ultimately led to the formulation of QCD.

The strong force is one of the four known fundamental forces in nature, the others being the electromagnetic, the weak, and the gravitational forces. The strong force, usually referred to by scientists as the *strong interaction*, is relevant at the subatomic level, where it is responsible for the binding of protons and neutrons to atomic nuclei (see Figure 3.1). To do this, it must overcome the electric repulsion between the protons in an atomic nucleus and be the most powerful force over distances of a few femtometers ($1\,\text{fm} = 1\ \text{femtometer} = 1\ \text{fermi} = 10^{-15}\,\text{m}$), the typical size of a nucleus. This property gave the strong force its name.

The first quantitative theory of the strong interactions was proposed by Yukawa (1935). Yukawa postulated that the strong force arises from the exchange of new particles, now called the *pions*, between protons and neutrons. From the known range of the strong interaction, he could estimate the mass of these particles. The pions were, indeed, discovered by Lattes *et al.* (1947). In the following years, many new strongly interacting particles were discovered at new particle accelerators as well as in cosmic ray showers. They are collectively referred to as *hadrons*. It was found that hadrons could be grouped into two classes by whether or not they carried a conserved quantum number called the *baryon number*. Particles that carry baryon number, examples of which are the proton and neutron, are called *baryons*. Among the particles with vanishing baryon number, known as *mesons*, are the pions. Some of the discovered hadrons showed an unexpectedly long (strange) lifetime, like the Λ baryon which had already been observed in 1947 in cosmic ray showers (Rochester and Butler, 1947).

The discovery of the large array of strongly interacting particles implied that Yukawa's theory could not be the fundamental theory of the strong interactions. The pursuit of finding an underlying order and understanding the regularities observed in experiment eventually led to the proposal that there are only a few truly fundamental particles of the strong interactions, of which all hadrons are composed. This proposal was made independently in 1964 by Gell-Mann (1964) and Zweig, and Gell-Mann coined the name

ISBN: 978-3-527-40691-3

quarks for these new particles. To take into account the observed systematics of baryons and mesons, one had to introduce different types, or *flavors*, of quarks. The basic constituents of the nucleus – the proton and the neutron – are built up from three quarks with two different flavors called *up* (*u*) and *down* (*d*) (see Figure 3.1). Mesons consist of a quark and an antiquark. The strangeness of the Λ particle (Gell-Mann, 1956) could be explained through the introduction of a third quark flavor – the strange quark (*s*). Another observation that became crucial for the further development of strong interaction theory was made by Greenberg (1964) and Han and Nambu (1965) soon after the introduction of quarks: to satisfy the Pauli exclusion principle for baryons such as the Δ^{++} or the Ω^{-}, which are made up of three quarks of the same flavor and spin orientation, the spin-$\frac{1}{2}$ quarks had to carry a new quantum number, later termed *color*. It was proposed that quarks came in three different colors.

Quarks were originally introduced simply on the basis of symmetry considerations. A modern rendition of Rutherford's experiment then showed that quarks are real (Bloom *et al.*, 1990). This experiment is the *deep-inelastic scattering* (DIS) of electrons (or, later, muons) off the nucleon, a program that was started in the late 1960s at the Standford Linear Accelerator Center (SLAC). The early DIS results compelled an interpretation as elastic scattering of the electron off pointlike, spin-$\frac{1}{2}$, constituents of the nucleon, carrying fractional electric charge (Bjorken, 1969). These constituents, called *partons* by Feynman, were subsequently identified with the quarks.

In 1974, a new meson, soon called the J/ψ, was observed simultaneously in experiments at Brookhaven National Laboratory (BNL) (Aubert *et al.*, 1974) and at SLAC (Augustin *et al.*, 1974). Its surprisingly long lifetime made it clear that there was yet another quark flavor – now called the *charm* quark (*c*). Currently, we know six different quark flavors. In addition to the *u, d, s*, and *c* quarks, the very heavy bottom (*b*) (Herb *et al.*, 1997) and top quarks (*t*) (Abe *et al.*, 1995) have been discovered experimentally in 1977 and 1995, respectively, at the Fermi National Accelerator Laboratory (Fermilab). There is currently no evidence of the existence of further quark flavors.

Remarkably, quarks have never been observed in isolation, or as free particle states, like those familiar in an atom or the proton. They only seem to exist bound inside hadrons or in larger entities called *quark matter*, which is presumed to have existed in the early universe and may still exist in the interior of compact stars. This striking phenomenon is known as *confinement*. It is clear that a true theoretical understanding of the strong interactions requires a quantitative explanation for the confinement of quarks, which has remained elusive till today.

QCD, the modern theory of strong interactions, is a quantum field theory. It was formulated by Fritzsch, Gell-Mann, and Leutwyler (1973). QCD rests on a number of the concepts and experimental findings just mentioned: QCD specifies the interactions among the quarks introduced in the quark model of Gell-Mann and Zweig. It turns the relatively ad hoc color quantum number into the conserved charge of a local gauge theory, identical in spirit to the electric charge of quantum electrodynamics (QED). And, finally, the features seen in the DIS experiments paved the way to QCD as a viable contender for the theory of the strong interactions. The experimental data pointed to a theory that would have the remarkable

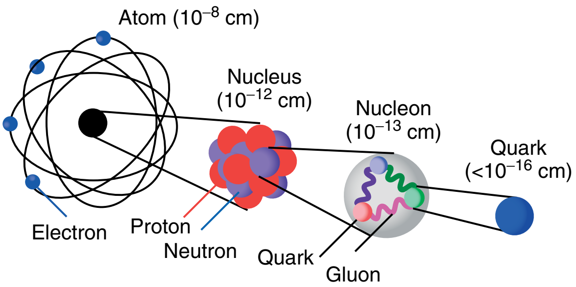

Fig. 3.1 The substructure of matter made of strongly interacting quarks and gluons. They form protons and neutrons that bind through the strong force to form the atomic nucleus.

property of becoming weakly coupled at large momentum transfer or, equivalently, short distances. QCD precisely has this property of *asymptotic freedom* (Gross and Wilczek, 1973).

QCD has been constructed in close analogy to QED, which very successfully describes the electromagnetic forces among electrically charged particles in terms of the exchange of a massless particle, the photon. The force carrier in QCD is called the *gluon*. The structure of the theory demands that there are actually eight gluons. Gluons are responsible, for example, for binding quarks together to form hadrons. Direct evidence for the existence of gluons was found in 1979 at the Deutsches Elektronen Synchrotron (DESY) in Hamburg, Germany, through the discovery of so-called three-jet events (Barber *et al.*, 1979).

The asymptotic freedom of QCD at short distances makes the theory in this regime accessible to standard perturbative calculational techniques and allows for direct comparisons with experiments performed at high-energy accelerators. This has allowed to subject QCD to stringent tests, and to validate it as the correct theory of the strong interactions. Perturbative techniques fail, however, when the theory is probed at lower energies. It is in this so-called nonperturbative regime that the binding of quarks and gluons to hadrons, and that of protons and neutrons to heavier nuclei, occurs. It has so far not been possible to understand and derive the masses of these bound states in detail from the basic Lagrangian of QCD. Among the important phenomena QCD shows here, is, in particular, the confinement of quarks that we have mentioned earlier. A consequence of this is the rich spectrum of hadrons arising as bound states of quarks and gluons. To calculate the properties of these states, for example, their masses, requires calculational techniques that go beyond perturbation theory. A method that allows studies of some aspects of nonperturbative QCD was proposed by Wilson (1974), who introduced a formulation of QCD on a regular discrete four-dimensional space–time lattice. *Lattice QCD* is one of many ways to regularize a quantum field theory. It has the advantage that it makes QCD accessible to numerical calculations. Creutz (1980) could show through numerical calculations that, in an approximation in which only the gluon sector of QCD is taken into account, confinement does indeed occur. Today, lattice QCD calculations are performed mostly on large-scale computers, and many important insights into QCD have been gained in this way.

Another important phenomenon in QCD is *chiral symmetry breaking*, which is believed to be responsible for certain aspects of the observed hadron spectrum, for example, the small value of the pion mass compared to other hadron masses. In the limit of vanishing up and down quark masses, the Lagrangian that describes QCD possesses a certain symmetry in the *u, d* quark sector, known as *chiral symmetry*. This name comes from the fact that one can define left- and right-handed parts of the quark fields, which become independent of one another in the QCD Lagrangian, once the quark masses are neglected. However, it turns out that the chiral symmetry is broken spontaneously by paired quarks, so-called quark condensates, in the QCD vacuum. This again is a nonperturbative feature of QCD that has been verified to exist by lattice calculations. Spontaneous breaking of a symmetry leads to the existence of massless (Nambu–Goldstone, 1961) bosons, in this case, the pions. Since the quark masses are not zero, the pions are not in fact massless, but remain much lighter than all the other hadrons. As the quark masses are small, one can formulate a systematic perturbative expansion that is valid in the vicinity of the massless limit. This *chiral perturbation theory* (Weinberg, 1967) leads to many predictions in the low-energy domain of QCD.

The spontaneous breaking of chiral symmetry as well as confinement are striking nonperturbative aspects of the theory of strong interaction, which are absent in the asymptotically free regime of QCD that can be addressed perturbatively. It has therefore been speculated that QCD has different phases that are separated by phase transitions very much like the ones known to occur in many-body systems. In fact, from QCD one should, at least in principle, be able to derive the properties of bulk matter formed from strongly interacting particles, for example, the properties of nuclei, properties of compact stars as well as of the hot and dense matter that existed in the early universe. In the latter case, there exists strong evidence from heavy-ion collision experiments that at temperatures about 100 000 times larger than that in the center of our sun, that is, under conditions that existed in the early universe at a time of about 10^{-5} seconds after the Big Bang, a hot and dense form of strongly interacting matter can exist in which chiral symmetry is restored and quarks and gluons are deconfined. The exploration of the properties of this so-called quark–gluon plasma is being pursued intensively in relativistic heavy-ion experiments, lattice QCD calculations, as well as analytic calculations that make use of modern perturbative techniques.

3.2
Eightfold Way and Quark Model

Prior to the quark model, it was realized independently by Gell-Mann and Ne'eman (1961) that the observed regularities in the masses, interactions, spin, and charge of hadrons could be explained by grouping them according to rules dictated by the mathematical special unitary group in three dimensions, SU(3). The observed hadron states appear in higher dimensional representations of this group. The proton and neutron, for instance, are members of an octet representation along with other hadrons of similar properties, and a meson octet contains the pions, among others. This organization scheme, which has been called the *eightfold way* (Ne'eman, 1961) owing to the presence of octet representations, is illustrated in Figure 3.2. It was of crucial importance that it predicted the existence of a hitherto unknown hadron, the Ω^-, which was subsequently observed experimentally at BNL (Barnes *et al.*, 1964).

Since the hadrons were related to higher dimensional representations of the SU(3)

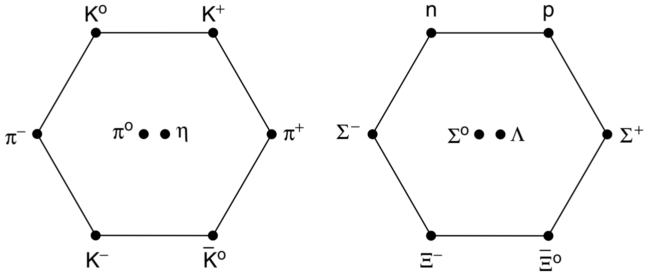

Fig. 3.2 Eightfold way: meson and baryon octets.

group, it was natural to ask what the particles corresponding to the fundamental representation might be. As this is mathematically a triplet representation, there would need to be three elementary particles. These were proposed by Gell-Mann (1964) and Zweig and are known as *up* (u), *down* (d), and *strange* (s) quarks. The quark model explains the eightfold way: the baryons consist of three quarks, while the mesons are made up of a quark and an antiquark. Mathematically, the baryons are products of three-quark triplet representations, while the mesons are the product of a triplet and an antitriplet representation. We have listed the quark content of some hadrons in Table 3.1. Each quark is characterized by a baryon number of $\frac{1}{3}$, spin $\frac{1}{2}$, an electric charge of $-\frac{1}{3}$ or $+\frac{2}{3}$, and a new quantum number called *color* (Greenberg, 1964; Han and Nambu, 1965), which comes in three different variants, say red, blue, and green. This color is the strong charge of a quark, similar to the positive or negative charge of a particle in electrodynamics. The hadrons observed in experiment are color singlets, that is, are white combinations of the colored quarks.

Over the last 50 years, studies at high-energy particle accelerators have led to the conclusion that there exist six different quark flavors (up, down, strange, charm (c), top (t), and bottom (b)). The three additional c, b, t quarks are much heavier than the originally proposed u, d, s quarks. The properties of quarks are summarized in Table 3.2. The six quarks have been grouped into three generations of two quarks with electric charge $\frac{2}{3}$ and $-\frac{1}{3}$, respectively. This ordering principle goes beyond the framework of QCD and indicates the role of QCD in the standard model of particle physics (Glashow, 1961) that unites the strong, electromagnetic, and weak forces. Within the standard model, precision studies of the decay width of the Z-boson, a carrier of the weak force, have established that there are just three generations of particles. Dedicated searches have not produced any evidence for the existence of further quark generations or for a substructure of quarks. We finally note that the quarks are the only known elementary particles that participate in all of the four fundamental interactions.

3.3
Quantum Chromodynamics

QCD incorporates the basic properties of quarks in the framework of a quantum field theory. The structure of a local quantum field theory, its local and global symmetries, have important consequences for the interaction among particles as well as for their properties, which can be tested experimentally.

Tab. 3.1 Some hadrons and their properties. Hadron masses are given in units of giga electron volt divided by the velocity of light squared (GeV/c^2)[1 GeV = 1 billion electron volts]. For further information, see (Yao *et al.*, 2006).

Hadron	Quark content	Mass (GeV/c^2)	Electric charge	Spin
Mesons				
Pion (π^+)	$u\bar{d}$	0.139	1	0
Kaon (K^-)	$s\bar{u}$	0.494	−1	0
Rho (ρ^+)	$u\bar{d}$	0.775	1	1
J/ψ	$c\bar{c}$	3.097	0	1
Upsilon (Υ)	$b\bar{b}$	9.460	0	1
Baryons				
Proton (p)	*uud*	0.938	1	$\frac{1}{2}$
Neutron (n)	*udd*	0.940	0	$\frac{1}{2}$
Lambda (Λ)	*uds*	1.116	0	$\frac{1}{2}$
Xi$_c$ (Ξ_c^+)	*usc*	2.468	1	$\frac{1}{2}$
Lambda$_b$ (Λ_b)	*udb*	5.624	0	$\frac{1}{2}$

QCD has been constructed in close analogy to QED. The basic degrees of freedom are the quarks, and the interaction among them is transmitted by massless bosons, the gluons. In contrast to QED, the three color degrees of freedom of the quarks, however, suggested to formulate QCD in terms of a nonabelian gauge group, the special unitary group SU(3)$_c$. We have used the subscript *c* here to distinguish it from the SU(3) that we used earlier for the quark flavors. Like in QED, the interaction among quarks and gluons is determined by the requirement of local gauge invariance: the theory is invariant under local transformations that rotate the charges of the quarks in the color space defined by the SU(3)$_c$ gauge group. This controls the basic properties of QCD. A direct consequence of this is that gluons not only interact with quarks but also have a self-coupling and interact directly among themselves. This is very different from QED. The existence of these specific self-coupling terms has been verified experimentally through the observation of high-energy jets (see Section 3.4). The self-interaction of gluons is responsible for much of the complexity of QCD and the richness of its phenomena.

3.3.1
Asymptotic Freedom

One of the peculiar consequences of the self-interaction of gluons is that QCD becomes *asymptotically free* at short distances, which means that the coupling among quarks and gluons becomes weaker with decreasing distance. This property of QCD was discovered by Gross and Wilczek (1973). The precise behavior of the coupling between quarks and gluons as a function of distance (or momentum transfer between them) follows from the renormalization properties of QCD. One finds that the coupling vanishes as an inverse logarithm of the momentum

Tab. 3.2 The six quark flavors. All quarks are fermions that have spin $\frac{1}{2}$, baryon number $\frac{1}{3}$, and an additional color charge red, blue, or green. For each quark, there exists an antiparticle (antiquark) with opposite quantum numbers. Their properties are given in Yao *et al.* (2006).

Flavor	Mass (GeV/c^2)	Electric charge
Up (u)	$0.0015 - 0.003$	$\frac{2}{3}$
Down (d)	$0.0025 - 0.0055$	$-\frac{1}{3}$
Strange (s)	0.095 ± 0.025	$-\frac{1}{3}$
Charm (c)	1.25 ± 0.09	$\frac{2}{3}$
Bottom (b)	4.2 ± 0.07	$-\frac{1}{3}$
Top (t)	174.2 ± 3.3	$\frac{2}{3}$

transfer. This behavior has been exquisitely verified by a variety of measurements and has been confirmed in lattice QCD calculations.

Large momentum transfer may be realized in particle collisions at high energy or in media at very high temperature where the average momentum transfer in a reaction is proportional to the temperature of the medium (see Section 3.5). When the coupling becomes weak, processes in QCD can often be analyzed well in terms of *perturbation theory*. This led to numerous predictions for the properties of high-energy processes that have been tested experimentally (see (Bethke, 2007; Ellis, Stirling and Webber, 1996) and Section 3.4). The good agreement found between theoretical predictions and experimental results found here cemented our belief that QCD is the correct theory of the strong interaction. A recent compilation of determinations of $\alpha_s(Q)$ is given in Figure 3.3.

3.3.2
Confinement

As one can see from Figure 3.3, the QCD coupling $\alpha_s(Q)$ appears to become large for small momentum transfer. However, the result shown in the figure is based on a perturbative calculation and is therefore no longer self-consistent when $\alpha_s(Q)$ becomes large. Nonetheless, it is consistent with the fact that QCD phenomena become strongly coupled and confining. The analysis of heavy-quark (c, b) bound states and the sequence of their excitations suggests that the potential between quarks rises linearly at large distances. This gave rise to nonrelativistic potential models that describe the spectrum of heavy-quark bound states like the J/ψ and its excitations and the Υ family. The origin of the linearly rising potential again can be attributed to the self-interaction among gluons, which allows them to build up an almost one-dimensional color flux tube (string) that transmits the interaction between quarks over large distances. Thus, it would cost an infinite amount of energy to completely separate a quark antiquark pair. The qualitative picture behind confinement is that after separation by a certain distance the energy contained in the field between the quark and the antiquark becomes so large that a further quark–antiquark pair can be created from the vacuum, so that two color singlet hadrons – for

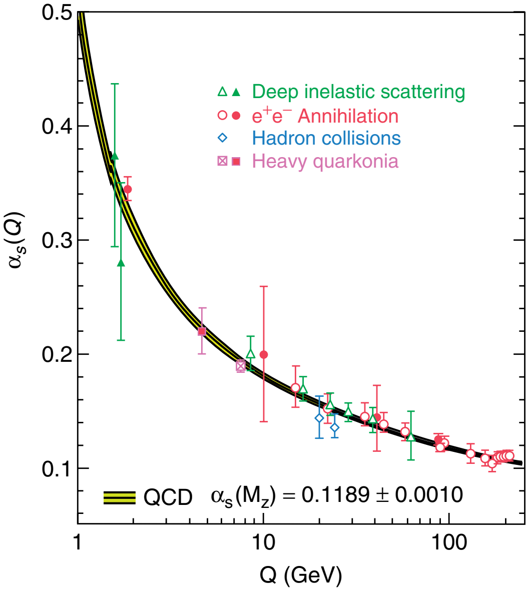

Fig. 3.3 Summary of experimental results on the QCD running coupling constant $\alpha_s(Q)$ as function of the momentum transfer, Q, in an elementary interaction. To determine the running coupling, experimental data are compared with calculations performed in leading (open symbols) and next-to-leading (filled symbols) order of QCD perturbation theory. The figure also includes a purely theoretical data point obtained from lattice calculations (boxed square). The figure is taken from Bethke (2007).

example, pions – can be formed. This explains why free quarks are not observed experimentally and why observed hadrons only appear as color singlet states.

Unlike the short-distance properties of QCD, which can be studied using perturbative techniques, the long-distance properties are entirely nonperturbative. An appropriate tool for performing calculations in this nonperturbative regime is provided by lattice QCD, a formulation of QCD on a discrete four-dimensional space–time grid (lattice) that makes the analysis of large-distance properties of QCD, or equivalently of processes with low momentum transfer, accessible to numerical calculations. Quarks occupy the sites of the lattice, while the gluons, as the mediators of the strong force, correspond to the links from one lattice site to another. Lattices used for modern calculations typically have a few million sites. Currently, this allows to analyze physics in a spatial volume of about (10–20) fm^3 and to resolve details on a distance scale of about 0.05 fm. Ideally, one would like the volume to be as large as possible, and the distance between the lattice sites to be as small as possible, to match the true continuum. This requires large computational resources. Progress in lattice QCD calculations thus is closely coupled to the rapid development in computer technology. Lattice QCD allows to calculate the potential between static quark sources. These calculations indeed demonstrate that the potential between quarks increases linearly at large distances, as shown in Figure 3.4(a). Lattice QCD also allows a direct calculation of hadron masses. A comparison of lattice calculations for the light hadron spectrum with experimental results is shown in Figure 3.4(b). Although this calculation has been performed in an approximation that only takes into account the contribution of valence quarks and gluons (quenched QCD), the agreement with experimental results is striking. It is expected that this agreement will further improve once calculations that also include sea quark contributions become feasible and accurate enough.

3.3.3
Chiral Symmetry

If some, say n_f, of the quark flavors had vanishing masses, QCD would have an additional exact symmetry property. It would be possible to interchange different spin components (chiralities) of the quark fields without changing physical properties of the theory. In fact, the left and right chiral components of quark fields could be transformed independently in flavor space by a nonabelian rotation with $\mathrm{SU}(n_f)$ matrices. This chiral symmetry is broken owing to the nonvanishing quark masses. However, this explicit breaking is rather mild for the two lightest (up and down) quarks, which have a very small mass. The QCD Lagrangian thus has an almost exact $\mathrm{SU}(2)$ chiral symmetry for each of the two quark chiralities.

A symmetry of a physical system is said to be *broken spontaneously* when its ground state (or, vacuum) does not obey the symmetry. The chiral symmetry of QCD is spontaneously broken by a nonvanishing *chiral quark condensate* in its vacuum, which connects left and right quark chiralities. If an exact global symmetry is spontaneously broken, it gives rise to massless particles in the theory – the Goldstone bosons. If the symmetry is only almost exact, these Goldstone bosons will acquire a mass, but typically remain light. The fact that the light pseudoscalar pions have a mass that is small on the scale of all the other hadron masses suggests that they are the Goldstone bosons arising from the spontaneous breaking of chiral symmetry in QCD. Indeed, a nonvanishing chiral condensate is found in lattice QCD calculations. As chiral symmetry is broken explicitly in QCD owing to the presence of small quark masses, the pions have a mass. There are many consequences of this spontaneous symmetry breaking and the small perturbations that arise owing to the small, nonzero up and down quark masses. They can be analyzed systematically in terms of an expansion in the small quark masses known as *chiral perturbation theory* (Weinberg, 1967). Among these results is the famous (Gell-Mann–Oakes–Renner, 1968) relation that connects the chiral condensate and light quark masses with the pion mass and the pion decay constant.

3.3.4
Glueballs

As discussed above, an essential property of QCD, which distinguishes the strong force from the electromagnetic one, is that its force carriers can interact among themselves. As a consequence of this, even in the absence of quarks, the pure-gauge sector of QCD already is a complex nontrivial theory that shows many of the features of full QCD. It is asymptotically free and leads to a linearly rising potential (confinement) between static external color sources. Self-interacting gluons should also be able to form bound states, so-called glueballs. QCD predicts that in addition to the experimentally well-explored hadron spectrum there should be further bound states, predominantly built up from gluons, with no valence quarks. These glueball states have been analyzed extensively in numerical studies of QCD on the lattice, and quite accurate predictions exist for the masses of these states. Experimentally they are, however, difficult to identify as the glueball states can mix with

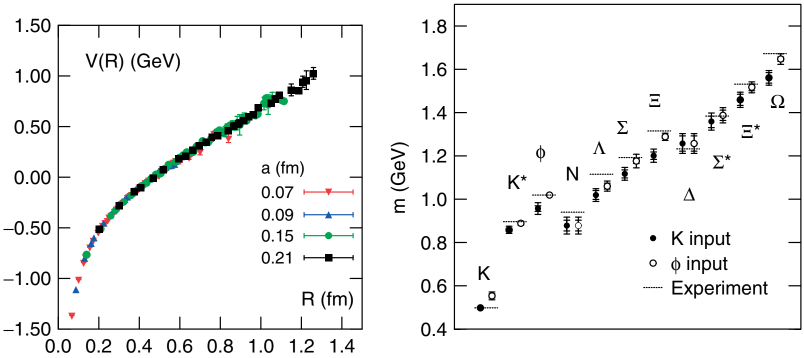

Fig. 3.4 The potential energy between a pair of static quark and antiquark sources as a function of their separation (a). Shown is the result of a lattice calculation performed for several values of the discretization length scale, that is, the lattice spacing "a" (from Cheng *et al.* (2008)). (b). ordinary mesons with the same quantum numbers. Large experimental programs are being set up at the Thomas Jefferson National Accelerator Facility (Jefferson Lab) and the Facility for Antiproton and Ion Research at the Gesellschaft für Schwerionenforschung (GSI FAIR) to search for glueballs.

3.4
Experimental Evidence for QCD

3.4.1
High-Energy Collisions

Experiments at particle accelerators carried out over the past three decades have established that QCD is the correct theory of the strong interactions (Yao *et al.*, 2006; Bethke, 2007; Ellis, Stirling and Webber, 1996). Particle accelerators allow the collision of high-energy particles such as electrons, protons, or heavier atomic nuclei. One can, for example, accelerate a beam of particles and scatter it off a stationary target of other particles. This is known as a fixed-target experiment. Higher collision energies are typically reached when two separate accelerated beams of particles are collided. The result of individual particle collisions can be observed and reconstructed using arrays of detector systems around the collision point. These detectors record, for example, the species and momenta, or perhaps decays, of particles receding from the collision.

The basic unit that characterizes accelerator energies is the electron volt (eV), the kinetic energy acquired by an electron accelerated through a potential difference of 1 V. Major technological breakthroughs have been made to achieve the acceleration of particles to ever higher energies. In the 1950s, it became possible to accelerate protons to energies of a few billion electron volts (one 1 billion eV = 1 giga electron volt = 1 GeV), at the cosmotron machine at BNL. Soon after, new techniques allowed to reach proton energies of 25 GeV at the proton synchrotron at the European high-energy physics laboratory CERN, and of 33 GeV at Brookhaven's alternating gradient synchrotron. At such energies, a proton with its rest mass of 938 MeV/c^2 is already less than 0.1% away from the speed of light. In many of today's accelerators, energies are even much higher. At the DESY in Hamburg, Germany, one routinely studied head-on collisions of protons and electrons with a collision energy of about 300 GeV. The Tevatron at the Fermi National Accelerator Laboratory in Batavia, Illinois, has colliding beams of protons and antiprotons (their antimatter partners) at a total energy of nearly 2000 GeV. Finally, the *Large Hadron Collider* (LHC) at CERN, whose construction has just been completed in 2008, will have proton–proton collisions at 14 000 GeV.

In the study of the strong interactions, essentially all types of particle collisions have played an important role. Electrons (e^-) and their antimatter partners, positrons (e^+), do not participate in the strong interactions. The creation of strongly interacting particles in the annihilation of electrons with positrons therefore offers a particularly pristine environment for studying QCD. The experiments that first paved the way to QCD were performed in scattering of electrons off protons in the process known as *deep-inelastic scattering DIS*. Finally, collisions of two hadrons, such as two protons or a proton and an antiproton, has brought further important information about the strong interactions. In the following, we briefly review some of the most important insights into QCD that have been brought by these three basic types of collisions.

3.4.2
QCD in Electron–Positron Annihilation

A lot has been learned about QCD from measurements at high-energy electron–positron colliders. A graphical representation of the production of strongly interacting particles in e^+e^--annihilation is given in Figure 3.5. The fundamental underlying reaction is $e^+e^- \to \gamma \to q\bar{q}$, that is, the electron and positron annihilate into a photon (γ), which then decays into a quark–antiquark pair. If the electron–positron collision happens at energies in excess of several tens of giga electron volts, the intermediate particle will also often be the Z boson of the weak interactions, instead of the photon γ. The process by which the conversion of the color-charged quark and antiquark into colorless hadrons happens, involves QCD in the confinement regime described in Section 3.3 and is known as *hadronization*.

The simplest strong interaction observable in e^+e^--annihilation is the total rate for the production of hadrons such as pions,

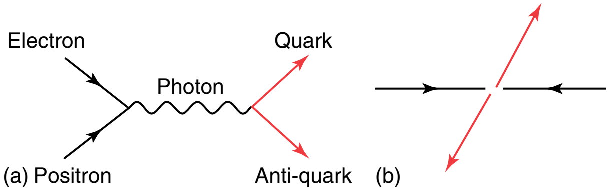

Fig. 3.5 Lowest-order diagram for the production of strongly interacting particles in e^+e^--annihilation. (a) shows a Feynman diagram, used in the theoretical computation of the process and (b) depicts the situation in an actual experiment where the electron and the positron collide head-on. The wiggly line represents the intermediate particle, photon, or Z-boson, created in the annihilation of the electron–positron pair. Because of confinement, the quark and the antiquark will eventually hadronize, that is, convert to colorless hadrons that are seen in the detector.

kaons, and so on. For this, one counts any event with hadrons in the final state. It is customary to normalize the rate to the one for the simple QED annihilation into muons, $e^+e^- \rightarrow \mu^+\mu^-$. The corresponding ratio is denoted by R_{QCD}. At sufficiently high energy, the process $e^+e^- \rightarrow q\bar{q}$ shown in Figure 3.5 becomes the main source for the generation of hadrons. One then finds $R_{\text{QCD}} = 3 \cdot (\frac{4}{9} + \frac{1}{9} + \frac{1}{9})$, where the factor 3 is the number of colors that quarks have in QCD (see Section 3.1), and where the terms in brackets are the squares of the fractional quark electric charges for the light up quarks (fractional charge $\frac{2}{3}$), down quarks $(-\frac{1}{3})$, and strange quarks $(-\frac{1}{3})$ (see Table 3.2). If the collision energy is above the threshold for charm production, another term $\frac{4}{9}$ will need to be added, and if bottom quarks can be produced, an additional $\frac{1}{9}$. The early e^+e^--annihilation experiments performed in the mid-to-late 1970s had already been able to establish the need for the color factor 3, as well as for the factor associated with the fractional quark charges that increased by a step when the charm threshold was crossed. However, the simple form of R given above is only an approximation and is, for example, modified by the radiation of energetic gluons from the $q\bar{q}$ pair. Over the years, it became possible to develop a controlled framework, known as *QCD perturbation theory* that allows very precise calculations of R_{QCD} and in fact of many other observables in high-energy scattering.

At high e^+e^- collision energies, the produced quark and antiquark will also be very energetic, and when they recede from one another in opposite directions, they are expected to each produce a spray of hadrons, termed *jets* (Sterman and Weinberg, 1977). Again, such jet structures had already been seen in the early experiments. The underlying process $e^+e^- \rightarrow q\bar{q}$ predicts a particular pattern of angular distribution of these jets with respect to the initial beams, which depends on the spin of the produced quark and antiquark. The distribution found in experiment has confirmed that quarks and antiquarks have spin-$\frac{1}{2}$, as they should have if QCD is right. The use of jet final states has gone yet further. If the quark or antiquark radiates an energetic gluon, one typically expects a third jet in the detector. Three-jet events were first seen in 1979 at the PETRA machine at DESY (Barber *et al.*, 1979), marking the discovery of the force carriers of QCD, the gluons. Again, detailed studies of angular distributions in three-jet events confirmed that gluons have spin 1, as in QCD. If yet another hard gluon is radiated, one may have four jets in the event. Some of these four jets will arise from a gluon itself radiating a gluon. This is possible in QCD thanks to the fact that the gluons themselves are color charged and hence have a self-coupling, as described in Section 3.1. This markedly distinguishes QCD from abelian theories like QED. Experimental studies of four-jet events have confirmed the presence of the gluon self-interaction. They have also allowed to verify the color charges that quarks and gluons have in QCD.

Finally, these, and related, studies in e^+e^--annihilation have produced very precise measurements of the strong coupling constant and have verified its running with the energy scale predicted by QCD, as shown in Figure 3.3.

3.4.3
Deep-Inelastic Scattering

Electron–positron annihilation has been of great importance in subjecting QCD to precision tests. The DIS process (Bloom *et al.*, 1990), a modern-day Rutherford

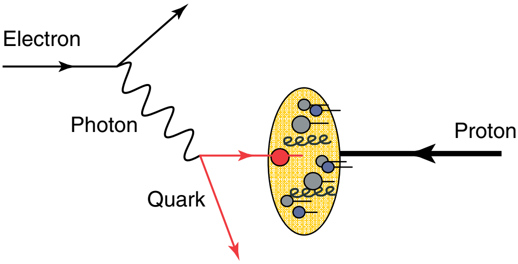

Fig. 3.6 Diagram for deep-inelastic scattering of an electron off a proton, seeing a quark inside the proton.

scattering, has been pivotal in identifying the asymptotically free QCD as our theory of the strong interactions. It also gave us fundamental insights into the internal structure of the proton through the discovery of quarks as its fundamental building blocks. Figure 3.6 shows a graphical representation of the DIS process. An electron scatters off the proton by exchange of a photon with very high momentum transfer. The electron is deflected at a large angle, and the proton breaks apart in the course of this interaction. In typical DIS experiments, the momentum transfer is so large that, according to Heisenberg's uncertainty principle, one probes distances from 0.2 down to 0.002 fm or so, far smaller than the size of the proton.

In the parton model (Bjorken, 1969), the DIS process is viewed as a scattering of the electron off a quark inside the proton, as indicated in Figure 3.6. The struck quark carries a fraction x of the proton's momentum. As such, DIS allows to map out the momentum distributions of quarks in the proton. As discussed in Section 3.2, in the simple quark model, the proton is made of just two up quarks and one down quark. However, a relativistic probe – which, in effect, takes a snapshot of the proton – is expected to also reveal quark–antiquark pairs and gluons inside the proton. These must be present because of QCD interactions that, for example, hold the proton together. In the context of high-energy scattering, all constituents of the proton are collectively referred to as *partons*. The parton model predicts that the distributions of quarks, antiquarks, and gluons depend only on their momentum fraction x, and not on the momentum transfer in the DIS process. The early DIS data were consistent with this so-called scaling behavior. However, it was soon realized that QCD predicted a gentle logarithmic dependence on momentum transfer, known as *scaling violation* (Christ, Hasslacher and Mueller, 1972). The effect of scaling violation can be reliably calculated in QCD and has subsequently been verified with great precision in fixed-target experiments at SLAC and CERN, and at DESY's collider HERA. In this way, DIS has led to one of the best direct tests of QCD (Bethke, 2007). Another early finding of the DIS program was that the quarks and antiquarks carry roughly half of the proton's momentum. The conclusion was that the other half must be carried by gluons (which are not directly seen by the photon since they do not carry electric charge) to be regarded as first indirect evidence for the existence of the gluons of QCD. Figure 3.7 represents the information on the parton distribution functions of the proton extracted from DIS measurements by the H1 and ZEUS experiments at HERA Cooper-Sarkar and Gwenlan. They are shown as functions of the fraction x of the proton's momentum carried by the parton. One can see that two

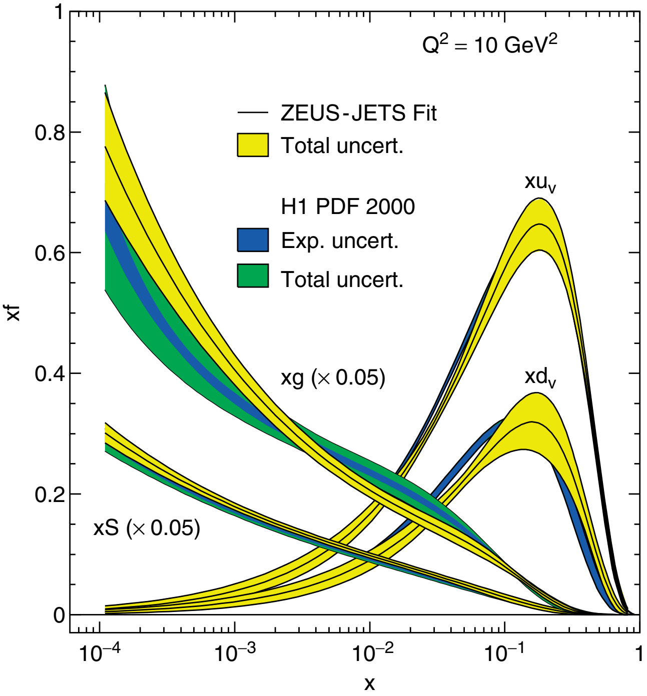

Fig. 3.7 Compilation of parton distribution functions extracted from DIS measurements at HERA. Taken from Cooper-Sarkar and Gwenlan.

distributions, referred to as u_V and d_V have their maximum at rather high x. These are the so-called valence distributions, which represent the two up quarks and the one down quark in the proton as specified by the quark model. For example, one can see that indeed the u-valence distribution is roughly twice as large as the d-valence one. The other distributions, the gluon distribution $g(x)$ and the antiquark distribution $S(x)$, are mostly concentrated at small momentum fractions. This reflects the fact that, in contrast to the valence quarks, it is quite unlikely that gluons or antiquarks carrying a large momentum fraction are found in the proton. All distributions shown have an uncertainty band, which is indicative of the uncertainties in the experimental measurements.

Starting from the late 1970s, DIS measurements were performed with spin-polarized electrons and protons. The electrons and the proton are both spin-$\frac{1}{2}$ particles, and one can set up DIS measurements in such a way that their spins have fixed relative orientations in the scattering, for example, parallel or antiparallel. An important question that one may address in this way is how the quarks, antiquarks, and gluons inside the proton conspire to provide the spin of the proton. After all, these particles themselves have spin, and may also have orbital angular momenta thanks to their motion in the proton. A spectacular discovery made by the European Muon Collaboration (EMC) experiment at CERN was that the quarks and antiquarks combined carry only a small fraction of the proton spin (Ashman *et al.*, 1988), now established to be about a quarter. This came as a surprise to many researchers in the field, because models of the proton predicted a much larger contribution. It clearly means that other contributions to the proton spin, for example, by gluons and/or orbital motion, must be very significant. The resolution of this proton spin puzzle is still an open issue and currently the focus of a number of experiments in this field.

3.4.4
Hadron–Hadron Scattering

The scattering of two hadrons, such as two protons, is another important process in QCD. A typical diagram is shown in Figure 3.8. Certain final states may be selected for which the interaction is very inelastic and both protons break apart in the interaction. Like in DIS, one may then use the parton model concepts to describe the cross section in terms of the distributions of quarks, antiquarks, and gluons in each proton, and their short-distance interaction. Thanks to the asymptotic freedom of QCD (see Section 3.3), the latter may be evaluated in QCD perturbation theory. So-called factorization theorems (Collins, Soper and Sterman, 1988) make this relation quantitative in QCD and show that the distribution functions relevant here are the same as those measured in DIS. In other words, the structure of the nucleon is universal in all these very inelastic reactions.

The prototype for inelastic proton–proton scattering is the Drell–Yan process (Drell and Yan, 1970), in which an electron–positron (or, muon–antimuon) pair is produced. This pair may be created by a quark from one proton annihilating with an antiquark from another. As such, the underlying reaction $q\bar{q} \to \gamma \to e^+e^-$ is the inverse reaction to the e^+e^- process discussed earlier. The Drell–Yan process gives evidence for the presence of antiquarks in the proton. One may also consider final states produced at very high momentum perpendicular to the beam axis, so-called high-$p_\perp$ processes.

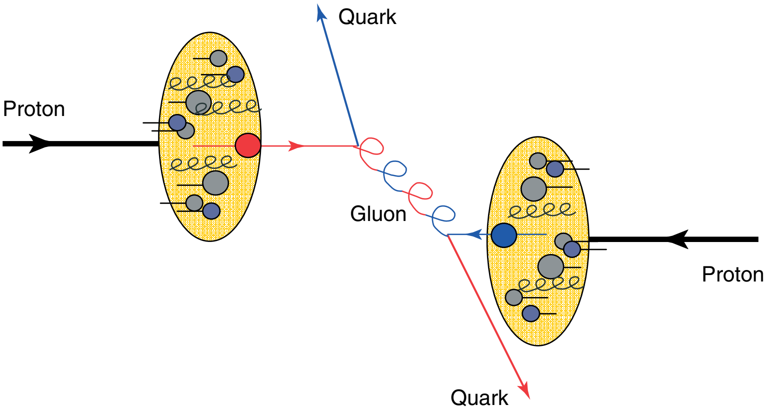

Fig. 3.8 Diagram for an inelastic reaction in proton–proton scattering. Two quarks, one from each proton, scatter by exchange of a colored gluon and produce two jets with large momentum, perpendicular to the directions of the initial protons.

An example is shown in Figure 3.8. The outgoing quarks will lead to high-$p_\perp$ jets, similar to the ones we described in the case of e^+e^- annihilation. Such reactions can serve as probes of the gluon distribution in the proton. For example, at the Relativistic Heavy-Ion Collider (RHIC) at Brookhaven, one studies high-$p_\perp$ reactions in collisions of spin-polarized protons. In this way, it becomes possible to explore the contribution by gluons to the proton spin, helping to solve the proton spin puzzle described above.

Today, our overall knowledge of the distributions of quarks, antiquarks, and gluons inside the proton, as Figure 3.7 shows, is quite good. In fact, we know them so well that we have confidence that we can use the information to make quantitative predictions for signals and background processes at the present and future high-energy colliders, Tevatron and LHC, which try to find and explore phenomena beyond our standard model of particle physics.

3.5
Phases of Strongly Interacting Matter

As has been discussed above, one of the most remarkable properties of QCD is that it incorporates asymptotic freedom as well as confinement: while quarks and gluons behave as almost free particles once they are close to each other, they are never observed individually as free particles. To reach conditions that allow quarks and gluons to behave as almost free particles, one has to ensure that their average separation is small or the average momentum exchanged during their interactions is large. These conditions are met in the high-energy experiments discussed in the previous section. They also existed in the early universe and may occur even today in the interior of dense stellar objects – the neutron stars.

In the early universe, just after the Big Bang, the temperatures were high enough and the density large, so that quarks and gluons were asymptotically free. They carried momenta of the order of a few times the temperature (times the factor k/c with k the Boltzmann constant and c the speed of light), and their average separation was of the order of the inverse of the temperature (times the factor $\hbar c/k$ with $\hbar$ the Planck constant). Unlike in collision experiments performed with protons or electrons, where only a few partons participate, quarks and gluons in the early universe formed large systems of hot and dense matter that has been called the *quark–gluon plasma*. Modern-day experiments with colliding heavy ions, for example, lead or gold nuclei, aim at recreating conditions necessary for the formation of the quark–gluon plasma.

In the interior of neutron stars, the density may also become sufficiently large for quark matter to form. Unlike that in the early universe, however, this matter has quite different properties. While in the early universe the temperature was high and the excess of matter over antimatter (the net baryon number density) was small, the situation is just the opposite inside dense stars: the baryon number density is high but the temperature is rather low.

Much like other many-body systems, macroscopic systems of quarks and gluons have thermodynamic properties. In particular, matter made of quarks and gluons can also exist in different states of aggregation. These different states of matter may be separated through phase transitions, like the liquid–gas phase transition in ordinary fluids. Again, very much like in other many-body systems, the properties of various phases of matter are controlled by

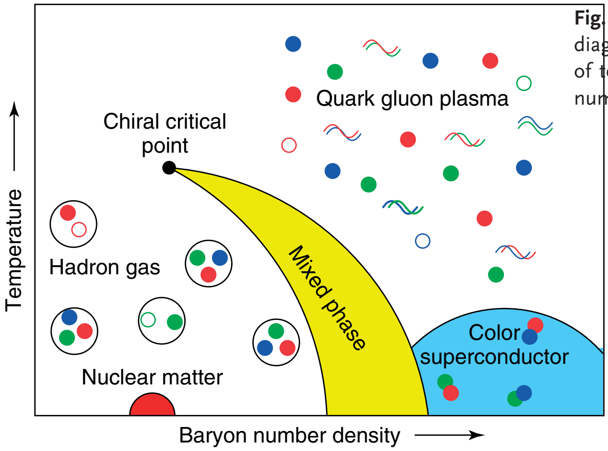

Fig. 3.9 Schematic phase diagram of QCD as function of temperature and baryon number density.

global symmetries of the system, and the transition from one phase to another is controlled by the spontaneous breaking or restoration of these symmetries. In QCD, it is the chiral symmetry that plays a central role for the understanding of the phase structure of strongly interacting matter. A schematic phase diagram of QCD as we think of it today is shown in Figure 3.9.

3.5.1
Quarks and Gluons at High Temperature

To be answered quantitatively, many of the questions related to the phase structure of QCD require nonperturbative techniques. Lattice-regularized QCD and numerical calculations that use this formulation thus play a central role in the theoretical exploration of the phase structure of QCD. These calculations are successfully used at vanishing baryon number density. They thus allow an exploration of QCD thermodynamics under conditions appropriate to describe the hot and dense matter formed in the early universe (Karsch, 2002). These calculations yield evidence for the existence of a rapid transition from a gas phase, where quarks and gluons are still confined inside hadrons and chiral symmetry is broken, to a plasma in which quarks and gluons are the most relevant degrees of freedom and become indeed asymptotically free at very high temperature. The transition between both regimes would indeed be a true phase transition, related to the restoration of chiral symmetry, if chiral symmetry were an exact symmetry of QCD, that is, if the light up and down quarks were massless. The slight explicit breaking of the chiral symmetry due to the nonvanishing up and down quark masses makes the QCD transition a rapid, but continuous, crossover from one phase to the other. Lattice calculations indicate that the transition to the quark–gluon plasma occurs at a temperature of roughly $2 \cdot 10^{12}$ K or almost 200 MeV/k (where k is the Boltzmann constant), which is a temperature about 100 000 times larger than that in the center of our sun. Such conditions have been met in the early universe at about 10^{-5} seconds after the Big Bang.

Although it is not yet confirmed by direct calculations, several theoretical considerations suggest that the continuous transition at vanishing baryon number density becomes a true phase transition with long-range correlations and a divergent correlation length at some critical value of the baryon number density (Stephanov, 2004). At densities larger than that indicated by this chiral critical point, the transition becomes a first-order phase transition, that is, it is expected that an intermediate mixed phase exists in which hadrons can coexist with already deconfined quarks and gluons.

Hot and dense elementary particle matter can be studied experimentally in heavy-ion experiments. In the collision of relativistic heavy ions, that is, the nuclei of heavy atoms such as gold or lead whose electrons have been stripped off, dense matter is generated that rapidly expands, but also seems to interact strongly enough to form an equilibrated hot medium. Experiments at the SPS collider at CERN found first indications for the formation of a quark–gluon plasma in such collisions Heinz and Jacob. The RHIC at BNL provides ground-breaking insights into the properties of strongly interacting matter under these extreme conditions. While it is difficult to establish direct evidence for the restoration of chiral symmetry, there is evidence for the formation of hot and dense quark–gluon matter with striking properties (Arsene *et al.*, 2005). The matter is very opaque: jets that are created in the collision are strongly obstructed and often absorbed while traversing the produced medium, a phenomenon known as *jet quenching*. In addition, the matter shows remarkable elliptic flow properties: an initial spatial anisotropy that is present when the two colliding nuclei hit each other not completely centrally is translated by the medium into a strong momentum anisotropy that persists all the way out to the detectors. Among other important signatures of a quark–gluon plasma that are under investigation at RHIC are the suppression of heavy-quark bound states like the J/ψ, which are expected to no longer be able to form in dense matter because of the strong modification (screening) of the heavy-quark potential, and the thermal radiation of photons, which leads to an enhancement of the photon spectrum at low transverse momenta.

One of the most important scientific discoveries of the past few years, which follows from the observations of jet quenching and elliptic flow, was that the hot matter that is formed when gold nuclei collide in RHIC appears to have the properties of an almost perfect liquid, characterized by a ratio of viscosity to entropy that is lower than that for any other known liquid. This indicates that the quark–gluon plasma formed in the collisions at RHIC is strongly coupled and not a dilute gaseous plasma as originally expected. Further exploration of this new state of matter is currently under way at RHIC and will also be an important task for heavy-ion experiments at the LHC.

3.5.2
Quarks and Gluons at High Baryon Number Density

A change from the low-temperature, low-density hadronic matter to forms of matter in which quarks are the relevant degrees of freedom is also expected to occur at large baryon number density. Again, it is asymptotic freedom that dictates the interactions of quarks at very high baryon number density and low temperatures. As quarks are fermions, they will, at low temperatures, show the characteristic properties of a Fermi gas. At high density, they cannot all occupy the ground state but must fill up higher energy levels, that is, states where individual quarks carry a large momentum. The highest momentum states near the Fermi surface will behave as almost free particles since they have to transfer large momenta when interacting with other quarks. Because of asymptotic freedom this interaction is weak. It can be analyzed systematically within perturbation theory and, in fact, is found to be attractive. An attractive interaction among fermions is the prerequisite for the occurrence of superconductivity through the formation of Cooper pairs. Just like in electrical superconductivity, the attractive color force between quarks leads to color-superconductivity in cold but dense quark matter. Such form of matter may exist in the interior of neutron stars.

As we discussed in Section 3.2, in addition to color and spin, quarks also carry a flavor degree of freedom. This introduces new possibilities for the pairing of quarks into Cooper pairs, which do not exist in ordinary superconductors. The high-density, low-temperature phase diagram of QCD thus may lead to several different phases that are characterized by different pairing mechanisms. In the idealized case of three degenerate light quark flavors, that is, in a limit where it is ignored that the strange quark is much heavier than the light quarks, it is well understood that the so-called color-flavor locked phase, in which quarks of all different colors and flavors can form Cooper pairs, is the preferred state of quark matter at high density. As the density is lowered, other symmetry breaking patterns may become more relevant. In reality, as the u, d, s quarks have different masses, flavor symmetry is not exact. This may lead to a rather complicated phase diagram of QCD at high density (Rajagopal and Wilczek, 2001).

3.5.3

QCD at High Energy

The exchange of gluons between quarks mediates the color force that binds all hadrons. A major discovery of the last decade, made in DIS at the HERA collider, is the dominant role of gluons in protons when viewed by a high-energy probe. The number density of gluons grows extremely rapidly as one probes them at progressively smaller fractions x of a proton's momentum. We have seen this strong rise of the gluon distribution in Figure 3.7. The growth reflects a QCD cascade in which higher momentum (harder) parent gluons successively split into two or more lower momentum (softer) daughter gluons. According to Einstein's theory of relativity, a high-energy proton appears strongly length contracted, or compressed, along its direction of motion, looking much like a disk to a stationary observer. At very high energies, the density of the gluons on this disk is seen to increase greatly. But, if this growth were to continue without moderation, it would eventually lead to probabilities for the scattering process in excess of unity, which is physically impossible. Instead, one expects the growth to be tamed because, once sufficiently high gluon densities have been reached, softer gluons will start to recombine again into harder ones. This competition between splitting and recombination processes should stop the growth of the density of gluons, a phenomenon known as *saturation*.

At very high gluon density, all gluons begin to act collectively and their color forces add coherently. At the same time, typical distances between the gluons become small, where QCD becomes weakly coupled thanks to its asymptotic freedom. As a result, the gluons behave like a very strong classical field. An important recent realization has been that a systematic solution becomes feasible in this domain. The theory describing this high-density gluon matter arising at high energies is called the *color glass condensate (CGC)* theory Iancu, Leonidov and McLerran. Here, the word "color" refers to the fundamental charge of QCD which the gluons carry. "Glass" is borrowed from the term for silica and other materials that are disordered and act like solids on short timescales, but as liquids on long timescales. In the "gluon disk" the gluons themselves are disordered and do not change their positions rapidly because of time dilation. Finally, "condensate" alludes to the very high density of the gluons. A striking prediction of the CGC theory is that eventually all hadrons and all nuclei should appear the same when viewed at high enough energy, that is, should be predominantly made of a universal form of gluonic matter. Possible hints of gluon saturation phenomena have been found in measurements of electron–proton collisions at HERA and of deuteron–nucleus and nucleus–nucleus collisions at RHIC. Saturated gluon densities could have a profound influence on heavy-ion collisions planned at the LHC. The CGC theory predicts that for heavy nuclei the onset of saturation phenomena would already have occurred at lower energies than for the proton. It is believed that a definitive search for universal gluonic matter would become feasible at a future high-energy electron–ion collider.

INTRODUCTION

Physical geology is the study of the physical processes, both internal and surficial, that function upon and within the Earth and other planetary bodies. They include mantle and lithospheric convection processes that drive plate motion (see Plate Tectonics) that in turn produces volcanism, plutonism (a process whereby molten rock is generated and emplaced into the crust of the Earth and crystallized beneath the surface), and deformation within plates, but particularly concentrated at plate boundaries. Structural geology is a branch of geology that deals with the origin, geometry, and kinematics of emplacement of tectonic structures—folds, faults and other fractures, foliations, and microstructures—produced by deformation processes within the Earth. In addition, impact structures and structures formed near the surface by gravity-related processes are sometimes included in the collection of geologic structures. Historical geology places these processes in the continuum of geologic time. Internal processes are driven largely by thermal energy derived from radioactive decay, with smaller components from residual primordial heat, friction, and gravity. Surficial processes are driven primarily by solar and gravitational energy.

Many of the individual processes studied by geologists are components or steps in natural cycles or subcycles that absorb and utilize thermal energy released from the Earth's interior to bring about physical or chemical transformations. The tectonic cycle embodies all of the processes that produce the phenomena associated with both internal and surficial processes and incorporates the rock or geochemical cycle that also contains the hydrologic and biological cycles (Figs. 1 and 2). The article outline is constructed primarily around the rock cycle, with the addition of increments of the tectonic cycle and rock deformation.

1. TECTONICS

Tectonics is the study of large-scale structural features on the Earth ranging from the scale of a few square kilometers to continent or whole-Earth-scale features (also see Plate Tectonics). The dividing line between structural geology and tectonics is not clear because many attributes of structural geology contribute to the interpretation of tectonic features and conversely.

The lithosphere—the 100-km-thick outer shell of the Earth, including all the crust and the uppermost rigid part of the mantle—can be divided into a number of large and several smaller plates (Fig. 3). Plate tectonics is the major paradigm by which we explain many of the processes of the evolution of

continents, ocean basins, mountain chains, and other features that dominate the surface of the Earth today. The continents are composed of light (quartz- and Na-feldspar-rich, commonly $>65\%$ SiO_2) materials with an average granitic composition and, as a consequence, tend to float and not be consumed in subduction zones, regions where crustal or lithospheric material is conveyed downward into the mantle. Oceanic crust that has an average basaltic composition (Mg- and Fe-rich minerals plus Ca-rich feldspar; commonly $<45\%$ SiO_2), in contrast, because of its higher density, is consumed at convergent plate boundaries and is generated at divergent plate boundaries (Fig. 2). The present-day cycle for consumption of ocean crust appears to be about 200 million years, because no ocean crust is identifiable in the present-day oceans that is older than mid-Mesozoic ($\sim$180 Ma), but the time required for the reappearance of individual atoms or ions on the surface may be on the order of billions of years (Anderson, 1995).

Continental crust, because of its lower density, floats and is not consumed. Therefore, it is a scorekeeper that records events through time; it has recorded the plate tectonic history of the Earth since the first continental crust was formed about four billion years ago, and it is still evolving today. The older parts of the continents consist of isostatically adjusted crust that formed the continental nuclei to which younger and younger crust was added through time. This younger continental crust is still being formed today at the western margins of both North and South America and in other parts of the world where plate convergence and collision are taking place and crust-forming processes are active.

Ocean crust forms at the oceanic ridges—spreading centers—where two plates are being pulled apart and new crust is generated as upwelled molten rock derived from melting at lower pressures crystallizes to form basalt. The oceanic ridges commonly have a high topography because the crust beneath them is warm and thus of slightly lower density. The deeper abyssal plains of the oceans form as the crust cools, becomes denser, thickens, becomes more rigid, and sinks. Ocean crust is destroyed by being consumed in trench-subduction zones.

Mountain chains are the product of continental convergence and the completion of Wilson cycles (opening and closing of ocean basins), provided the convergence process involves continent–continent collision (Figs. 2 and 4). Modern mountain chains that involve

FIG. 4. Ideal mountain chain. Masses of continental or oceanic crust or island arcs may be accreted by either head-on or oblique collision, producing a variety of deformational styles, metamorphism, and plutonism. The external massif is a block of basement caught up and transported in the thrust stack. Continental basements A, B, and C represent parts of different continents now amalgamated by collision. T—movement toward observer; A—movement away from observer. Curve is a hypothetical gravity profile of the kind observable in most mountain chains. (From Hatcher and Williams, 1986.)

the completed Wilson cycles include the Alps and the Himalayas. Other mountain chains that are still active today, like the Andes and North American Cordillera, either involve Wilson cycles that are incomplete or the concept of the Wilson cycle is inapplicable to consideration of these mountain chains. This may be the case with all of the island arc and mountain chains around the Pacific margin because there is no indication that continent–continent collision will take place any time in the near- or far-distant geologic future.

Mountain chains have a number of features in common that form during the mountain building cycle (Fig. 4). These include a foreland fold-thrust belt that occurs in most mountain chains produced by deformation of the sediments deposited on the continental margin during the rift-to-drift transition following the opening of a new ocean. Rifted-margin clastic (mechanically deposited sands and muds) sediments are succeeded by carbonate rocks that formed when the margin consistently bounded open ocean. This is followed by the initiation of closing, recognized in the sedimentary record by a reversal of the source of sediments from the old continent to the newly rising mountain chain that is forming offshore or near shore as plate convergence becomes dominant. Island arcs frequently form during this process, and they too contribute sediments to the nearby forearc and backarc regions (the regions toward and away from the open ocean, respectively) and frequently are accreted to continental margins as subduction consumes the intervening ocean crust.

Foreland fold-thrust belts are commonly deformed during the latter stages of mountain building, a statement not true everywhere even in the same mountain chain (that in the northern Appalachians formed during the Ordovician, whereas that in the southern and central Appalachians formed at the end of the cycle). Farther into the chain is commonly a metamorphic core composed of the metamorphosed equivalents of continental rifted-margin sediments, along with oceanic components, either accreted arc material, ocean-floor material, ocean crust, ophiolites (mantle, ocean crust, and overlying ocean-floor sediments), or even rifted pieces of continent that were accreted to the original continental mass, as well as exotic elements derived from volcanic arcs and pieces of distant continents. Pluton generation (a pluton is the mass formed by crystallization of magma) accompanies subduction, and, as the molten material moves or is forced upward into the crust, it intrudes the mountain chain as part of the formation of island or continental arcs. Some late plutons are sometimes considered anorogenic. Plutons that were derived from continental crust commonly have a greater than 0.706 $^{87}Sr/^{86}Sr$ initial ratio, whereas plutons that formed in island arcs, in oceanic material, in the lower crust, or in mantle have a less than 0.706 $^{87}Sr/^{86}Sr$ ratio.

The plate convergence process that involves the accretion of both suspect and exotic terranes—blocks of crustal dimensions whose source either is questionable or is demonstrably alien to the block to which it is presently attached—to the continental mass may involve lateral, oblique, or head-on accretion or a combination of all of these. There may also be rotational components involved in the accretion process.

2. MINERALS

Minerals are naturally occurring, crystalline, inorganic compounds with a composition that is constant or varies within definable limits. Exceptions include water and mercury, which are liquids or gases at normal surface conditions, and several minerals, like opal, that are amorphous or have very open structures like liquids. The most common elements in the crust are mostly light elements, including O, Si, Al, Fe, Ca, Na, K, Mg, and Ti, in order of decreasing abundance. The cations are mostly strongly electropositive, while oxygen is strongly electronegative, and so the bonds in many minerals have a large ionic component. Bonding in minerals varies from pure end-member types of metallic (native metals), ionic (halides), and covalent (quartz, diamond) to complex mixed-bond types, such as the micas that contain covalent, ionic, and weak electrostatic (mostly van der Waals) bonds.

Minerals are commonly grouped according to chemical composition and crystal structure. They are also broadly grouped into silicate and nonsilicate minerals. Silicates are the most common rock-forming minerals in the crust, with the carbonate minerals, principally calcite ($CaCO_3$) and dolomite [$CaMg(CO_3)_2$], forming a small but significant proportion of the minerals in sedimentary rocks. Clay minerals consist of poorly crystallized, weakly bonded, sheet silicate minerals.

Among the silicate minerals (Fig. 5), the feldspars (potash feldspars, $KAlSi_3O_8$, and the plagioclase feldspars where compositions range from $NaAlSi_3O_8$ to $CaAl_2Si_2O_8$) are the most common in the crust, with quartz (SiO_2) second in abundance. Both feldspars and quartz have strongly bonded polymeric three-dimensional network structures in which SiO_4 tetrahedra are linked to each other. If Al is substituted for one of four Si atoms, a negative charge imbalance results that is neutralized by a positive cation of Na, K, or Ca to form the feldspars, feldspathoids, and zeolites. In addition, other important rock-forming minerals include the micas—mostly biotite and muscovite, which have sheet structures; the chain silicates (also called inosilicates); amphiboles [most commonly hornblende, less commonly tremolite, glaucophane, and anthophyllite, based on the composition $X_2Y_5(Si_8O_{22})(OH)_4$, where, if X is a divalent cation (Ca,Mg,Fe^{II}), Y is also, but if X is univalent (mostly Na), Y will be a trivalent cation (Fe^{III}, Al)]; pyroxenes (most commonly augite, hypersthene, and diopside); double tetrahedra including epidote, $Ca_2(Al,Fe)Al_2O(SiO_4)(Si_2O_7)(OH)$; isolated tetrahedra, such as garnet [$X_3Y_2(SiO_4)_3$, where X is a divalent cation like Fe^{II}, Mg^{II}, Mn^{II}, or Ca^{II}, and Y is a trivalent cation like Al^{III}, Cr^{III}, and Fe^{III}]; and olivine [$(Fe,Mg)_2SiO_4$].

Common minerals in oceanic crust are silicates rich in Mg, Fe, and Ca, in contrast with those in continental crust, which are rich in Na, K, and Al. Moreover, the most common minerals in oceanic crust have structures that are less complex with respect to SiO_4 linkages and polymerization than minerals in continental crust, which has an abundance of strongly polymerized three-dimensional structure silicate minerals (mostly quartz and feldspars). The minerals in oceanic crust (pyroxene, plagioclase, and olivine) have simpler silicate structures, and higher densities (average density 3.0 g/cm^3) and seismic velocities (6.0–7.2 km/s), than those in continental crust (average density 2.6 g/cm^3, seismic velocities <6.0 km/s), trends that become even more pronounced in the mantle where even simpler silicate structures (olivine, pyroxene, very little feldspar) and higher densities (average density 4.0 g/cm^3) and seismic velocities (≥ 8.0 km/s) prevail.

3. IGNEOUS ROCKS

Magma—molten rock—is generated by partial melting of crust in subduction zones and by pressure decreases accompanying

Feldspar (e.g., orthoclase, KAlSi$_3$O$_8$, and albite, Na AlSi$_3$O$_8$), feldspathoid [e.g., nepheline, (Na, K)(AlSiO$_4$), and leucite, K(AlSi$_2$O$_6$)], and zeolite [e.g., natrolite, Na$_2$(Al$_2$Si$_3$O$_{10}$) · 2H$_2$O] structures consist of the quartz structure modified by substituting one Al for every four or fewer Si in the 4-coordinate position requiring an additional univalent or divalent cation to be incorporated for charge balance. The symmetry of both the structures and crystals of these "stuffed" derivatives is lowered, but remains a framework structure.

Framework silicate structure (quartz, SiO$_2$)

FIG. 5. Common silicate structures and representative examples. Silicate structures, with the exception of the isolated tetrahedral structures (a), consist of tetrahedra linked in various ways from double tetrahedra (b), to four- and six-membered rings (c), to single and double chains (d and e), to sheets (f), and three-dimensional framework structures (g). Solid dots represent Si atoms, open circles are oxygen atoms, dark-shaded dots represent OH ions, light-shaded small circles are Al atoms, T identifies a tetrahedral (four-coordinate) layer in the phyllosilicates, and O identifies an octahedral (six-coordinate) layer in the phyllosilicates. The shaded triangles in the plan view sheet structure represent the sites to which octahedral layers are attached to the tetrahedral layers throughout the phyllosilicate structures. Large, light-shaded dots with K$^+$ in them represent large cation sites in the phlogopite and muscovite structures that provide increased bond strength to permit large sheets to form; divalent cations (e.g., Ca^{2+}) in these sites further increase bond strength between layers so that more equant crystals form (these are the "brittle micas," such as margarite and ottrelite).

crustal extension (at mid-ocean ridges or by extension of continental or oceanic crust). Magma moves upward by pushing aside the rocks above, driven by the lower density of the magma; by melting, removal, and assimilation of solid blocks of wallrock (rock adjacent to an igneous body or a mineral deposit)—a thermally inefficient process; and by magma fracturing (analogous to hydrofracturing) whereby magma is forced into zones of lower pressure by forming tension fractures that provide a conduit system into which magma flows. Physical properties of the magma, such as viscosity, volume, temperature, water content, and composition, control the emplacement mechanism.

While temperature has a strong influence on viscosity of magma, silica content of magma also controls the viscosity. The higher the percentage of SiO_2 in the magma, the higher the viscosity and the lower the melting temperature. Thus granitic magmas have much higher viscosities than basaltic magmas. The higher water and other gas content of granitic magmas also lowers the viscosity. Granitic magma that reaches the surface as rhyolitic volcanic rocks, however, commonly flows very slowly because the water and other gases that were dissolved in the magma under pressure at depth then are exsolved as pressure decreases near the surface. As a result, glasses of granitic composition (obsidian, pitchstone, and pumice) are much more common than basalt glass. Basalt, low-silica volcanic rock, has a much higher melting temperature (~1000 °C) than granitic magma at minimum-melting conditions (~650 °C, water saturated). Near-surface water provides a source for much of the water in magmas and is also responsible for much of the explosive volcanic activity observed. High-silica magmas, however, are more likely to produce explosive activity than low-silica magmas if there is no surface-water contamination.

Contamination of magmas by melting and assimilation of wallrocks provides a way for alteration of the composition of magmas. Assimilation and melting of appreciable quantities of wallrocks can significantly modify magma composition, but this also is thermally a very inefficient process, because of the heat energy necessary for assimilation. Turcotte and Emerman (1985) concluded that, because of the heat-exchange requirements of melting, assimilation, and related processes, magma-induced fracturing is a much more efficient process for intrusion into a cold crust.

Initial ratios of $^{87}Sr/^{86}Sr$ may be used to determine the source of the original magma. The upper continental crust commonly has an average $^{87}Sr/^{86}Sr$ of >0.706; the lower continental crust and the mantle have $^{87}Sr/^{86}Sr$ <0.706, so it is possible to distinguish broadly magmas derived from the upper continental crust from those derived from the mantle and lower crust. Ocean crust also has low initial $^{87}Sr/^{86}Sr$ ratios, because of its derivation from the mantle.

Crystallization of magma begins as soon as enough heat is lost for the temperature to fall below the melting temperatures of the highest–melting-point constituents and proceeds until the last remaining liquid is solidified. The original composition of the magma largely determines the range of constituent minerals and rock types that will crystallize from the magma. Additional factors include the amount of water present, oxidation state of the magma, and, to a lesser extent, other dissolved gases. Dissolved gases accumulate in the magma as the high–melting-point constituents crystallize, lower the viscosity of the residual magma, permit greater element mobility, and allow larger crystals to form. During this process, if the magma is basaltic, crystals of olivine and calcium-rich plagioclase will be the first to crystallize. These crystals will sink toward the bottom of the magma chamber, and, as the temperature decreases, some will react with the liquid to form clinopyroxene and plagioclase that contain less Ca and more Na, respectively (Fig. 6). This reaction process, called Bowen's reaction series, will continue until all of the liquid is consumed and the outer rims of plagioclase crystals are dominated by Na-rich plagioclase, and the hydrous phases hornblende and biotite dominate the mafic constituents—those composed of Mg- and Fe-rich minerals—that crystallize. If any liquid remains, a small amount of K-spar, quartz, and muscovite may crystallize.

An original magma of granitic composition likewise would crystallize the highest-melting constituents first: amphibole and/or biotite and plagioclase of intermediate composition (but still with Na > Ca). Crystallization of K-spar and quartz would consume

the remaining magma, forming rock of granitic composition.

Variation in crystallization rate determines the texture of the resulting igneous rock. Uniform texture usually indicates a uniform crystallization rate. Presence of megacrysts (large crystals) in a finer groundmass, yielding a porphyritic texture, usually indicates that the crystallization rate changed during crystallization of the magma. Because of the lower viscosity of basaltic magmas (despite their lower water content), porphyritic textures are less common, except in mafic (basaltic) volcanic rocks. Glasses commonly indicate quenching of magma but also indicate faster cooling (not necessarily quenching) of very high-silica (high-viscosity) magma producing obsidian (glass of granitic composition). Basalt glass is relatively uncommon, despite the overall greater abundance of basalt than the more felsic (granitic) volcanic rocks, but obsidian and other glassy rocks are much more common in areas of felsic volcanism.

Large volumes of gases are released during volcanic eruptions. Some of these are primordial gases from the interior of the Earth; the majority of the water in volcanic eruptions since the late Proterozoic, however, is water vapor derived from surface water or near-surface ground water that comes into contact with the rising magma. During the original cooling of the Earth into a solid mass, the atmosphere and hydrosphere may have been derived from outgassing of the water and other gases trapped in the interior. The primordial atmosphere and hydrosphere are thus probably originally by-products of igneous processes.

4. SURFICIAL PROCESSES

Surficial processes modify topographic features that occur above sea level by in-place weathering of rocks and sediments formed in different environments and by moving surficial materials into transport and subsequent deposition. Subsea processes operating on and near the ocean bottoms modify the shape of ocean-floor topography and the distribution of sediments. Geomorphology is the study of surficial processes and features.

4.1 Subaerial Processes

Weathering and erosion are processes that go hand in hand on the surface of the Earth. Weathering may be either chemical or mechanical or a combination of both, determined mostly by climatic conditions and also determined in part by the locations on slopes of the affected materials. Erosion involves the removal and transportation of weathered materials. Rocks weather at different rates, depending on their composition and the weathering environment; they also erode at different rates. For example, the same materials, such as limestone, produce valleys in the humid environment of the eastern United States, but form ridges in arid to semiarid climates of the West, where mechanical weathering and erosion processes dominate.

Chemical weathering, or decomposition, involves chemical breakdown of minerals and the formation of new minerals. Intuitively, one might predict that minerals that form at high temperatures should break down most readily in the surface environment, because high-temperature minerals are far removed from the environment in which they formed. An additional variable is involved, however, so that many high-temperature minerals survive in even intense tropical weathering conditions. This variable is the amount of energy involved in the formation of these minerals, forming strong chemical bonds, and the amount of activation energy needed to transform them to other species under surface conditions. Some minerals, such as quartz (SiO_2), form and are stable in both surface and high-temperature conditions. Feldspars also form under surface conditions in the marine environment but readily break down under tropical weathering conditions to form kaolinite [$Al_2Si_2O_5(OH)_4$] and quartz. Ferromagnesian minerals (e.g., biotite, hornblende, and pyroxene) break down into other clays, quartz, and iron oxides under tropical weathering conditions. The rate of chemical weathering is increased by presence of water with a high or low *p*H, warm temperatures, and a large available surface area (fine grain size).

Mechanical weathering involves the breaking apart—disaggregation—of rock masses into smaller particles without a change of chemical composition of the constituent minerals. For example, a limestone or a granite may ideally be broken apart by frost wedging and plant roots without any change in the amount of calcite ($CaCO_3$) or feldspar, quartz, and biotite, respectively, present in any of the resulting smaller particles. Although mechanical weathering occurs in all environments and aids chemical weathering by increasing surface area, mechanical weathering dominates in arid regions where little water is available for decomposition of minerals, and in arctic and alpine regions where water freezes and thaws frequently, or remains frozen much of the year.

4.2 Gravity-Related Slope Processes

Slope processes driven by gravity may be divided into two groups: those that move slowly and those that move rapidly. Slow-moving processes involve downslope movement under the influence of gravity. The rates of these processes vary from thousands to millions of years and involve the transport of materials from places where they are derived to the site where they are deposited on lower slopes. In a humid climate, soil, including suspended partially decomposed rock, may move slowly downslope. It may move at a very slow rate, producing a tongue of colluvium (unsorted, unconsolidated, nonglacially derived slope material), or rapidly—even catastrophically—if the toe of the colluvial tongue is removed and the slope oversteepened either naturally (e.g., by stream erosion) or artificially (e.g., by highway construction). In dry regions, transport occurs during short but intense rainfall events that move large amounts of material, but the water becomes dispersed on the lower slopes forming an alluvial fan. In arid to semiarid regions, water accomplishes most of the work of erosion and transportation of materials, and, although a desert region may appear static to the casual observer, large amounts of energy are expended over short periods of time to effect erosion, transportation, and deposition. The desert landscape may thus be changed gradually by the effects of many catastrophic events over a period of several thousand years.

Rapid processes in humid regions involve the catastrophic movement of material from upper to more gentle lower slopes. There, oversteepened slopes may occur on the upper slopes and earthquakes, freeze–thaw, or other mechanisms may trigger landslides, wedge failures, rock falls, rock and snow avalanches, and other rapid types of motion.

Glaciers are gravity-driven slow downslope-moving masses of ice that occur either in Alpine regions or as icecaps—continental glaciers. Glaciers are less important agents of erosion, transportation, and deposition today than they have been in the recent geologic past (the Pleistocene epoch). They were also important during the late Paleozoic (Carboniferous deposits in the Gondwanan continents) and early Paleozoic (Ordovician deposits in North Africa and southern South America) as well as during the Upper and Middle Proterozoic. Relict continental glaciers occur in Greenland and Antarctica, and numerous Alpine glaciers exist today mostly in high mountains in different parts of the world. These are remnants of the most recent Pleistocene glacial maximum (actually four maxima separated by four interglacial events) that began to retreat from the northern hemisphere some 8 000–10 000 years ago. A large amount of evidence has been cited by climate model research that "global warming" has occurred during the past several decades and that this is attributable principally to increases of CO_2 and other gases released into the atmosphere from combustion of coal and hydrocarbons (e.g., Houghton *et al.*, 1990, 1992; Jager and Ferguson, 1991). Rigorous climate models, however, span less than two decades—an instant in geologic time. Therefore, it is still not possible to say whether or not the small increases in global climate measured in the last several decades will form a long-term warming trend toward interglacial (or postglacial) times wherein all glacial ice will melt and present climatic zones will be significantly altered, or if the Earth has gone through a short interglacial period, and the climate will return to a glacial maximum during the next 10 to 20 ka. Regardless of the outcome of the debate about the present and near-term scenario, there is little doubt that continued combustion of hydrocarbons producing a buildup of CO_2 and other harmful gases in the atmosphere will be destructive in the long term.

4.3 Stream Processes

Streams erode, transport, and deposit material, continuously change their channels and floodplains, and finally reach the primary base level, or sea level, as they empty into an ocean or sea. Temporary base level may be established naturally where streams flow into larger streams, into natural or artificial lakes, or onto alluvial fans (Fig. 7). These attributes change the dynamics of streams and permit them, at the outlets from lakes or reservoirs, to erode their channels and increase the amount of sediment being transported, because water emerging from natural or artificial lakes normally contains very little sediment but does possess a great deal of potential energy. Therefore, the large amount of potential energy can be converted to kinetic energy to erode the channel and transport sediment below a dam where no energy is presently being consumed by transportation of sediment by water above the dam.

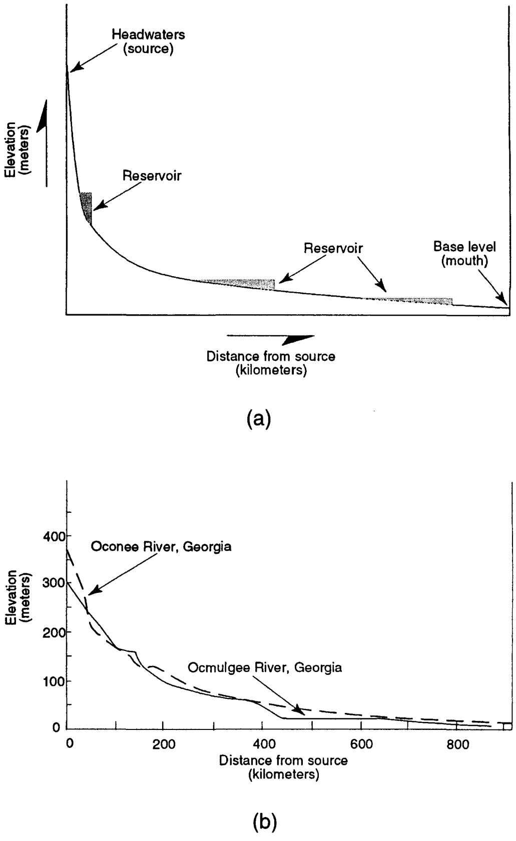

FIG. 7. (a) Equilibrium stream profile showing the superposition of temporary base level by construction of reservoirs. (b) Examples of actual stream profiles of two streams in the Blue Ridge and Piedmont of Georgia. (From Hack, 1982.)

Stream discharge (Q) at a point on a stream is described by $Q = VA$, where V is velocity and A is cross-sectional area. The cross-sectional area, velocity, and discharge of a stream increase downstream, but the stream gradient decreases, a floodplain develops, and the stream channel becomes more sinuous, or meandering. The channel becomes more asymmetric in cross section, deposition occurs on the inner arcs of the channel, and erosion occurs on the outer arcs, thus causing the channel to migrate both laterally (increasing the amplitude of meanders) and downstream. Erosion, transportation, and deposition become linked more to the local dynamics of the stream. A delta may form at the mouth of the stream if the body of water into which the stream empties does not have enough energy to remove the sediment as it is deposited. Deposition is accelerated if the stream flows into the ocean or other body of saltwater, because saltwater flocculates suspended clays and other fine sediment. Large accumulations of sediment occur in deltas of major rivers where strong currents are not present; proportionally smaller deltas form where strong currents do exist or at the mouths of streams with smaller discharge.

5. SEDIMENTATION

Sediment derived from the continents and smaller land masses, such as islands, is ultimately dispersed into the marine environment. This sediment is then dispersed in the ocean by longshore currents, or, as currents build unstable sediment accumulations along the continental slope, gravity-driven turbidity flows may carry sediment for long distances down the continental slopes and into the abyssal plains of the oceans. Most of the sediment deposited in this way is mechanically derived—clastic sediment. It is dispersed and accumulates to varying depths on the continental shelves, slopes, and in the deep-ocean basin.

Shallow seas under the right conditions of temperature, lack of clastic sediment, and low latitude will deposit carbonate sediment. This carbonate sedimentation, if voluminous and assisted by organisms like coral and algae, forms reef-dominated carbonate banks that commonly face the open ocean. In the back-reef area where poor circulation exists, the limestone will be converted to dolomite [$CaMg(CO_3)_2$].

Deep-ocean sediments are predominantly clastics at depths of greater than 4000 m, because the water at greater than these depths is commonly undersaturated with respect to carbonate, and carbonate minerals will redissolve. Most of the sediments of the deep-ocean basins are also relatively fine-grained because of the processes that transport, disperse, and deposit them. In some cases, however, large blocks derived from nearby areas of high topographic relief on adjacent continents or islands, or along even the submarine parts of the oceanic ridges, occur in the deep-ocean basins. Active faults may produce topographic relief and cliffs that will shed blocks into the deep-ocean basins either in island arc systems or along the oceanic ridges. Icebergs that are carried by currents southward or northward from the polar icecaps also transport large blocks that are dropped and become part of the deep-ocean sediments as the icebergs melt. These are relatively easy to identify either from the source material or from the dynamics of accumulation where they disturb the sediment around them and contrast markedly in grain size and otherwise with the enclosing sediments.

6. METAMORPHISM

Metamorphism is a process that involves solid-state recrystallization of minerals largely under the influence of increased temperature. Increased pressure, both lithostatic (confining) stress and simple shear (deviatoric or nonlithostatic) stress, and pressures from minor amounts of fluids (e.g., water and CO_2) can also influence the products of metamorphism, along with the original composition and grain size.

Recognition of the grade, or degree, of metamorphism—assessment of the T and P conditions of metamorphism—is made by means of characteristic minerals and mineral assemblages recognized either in the field, under the microscope, or both, as well as determination of the compositions of particular minerals in metamorphic rocks in the laboratory (Fig. 8). Determination of metamorphic grade can be most easily accomplished in metamorphosed shales because they form characteristic assemblages over a broad range of temperatures and pressures. For example, the suite of characteristic minerals formed in shale from lowest to highest grade under conditions of increasing temperature and pressure is chlorite, biotite, garnet, stau-

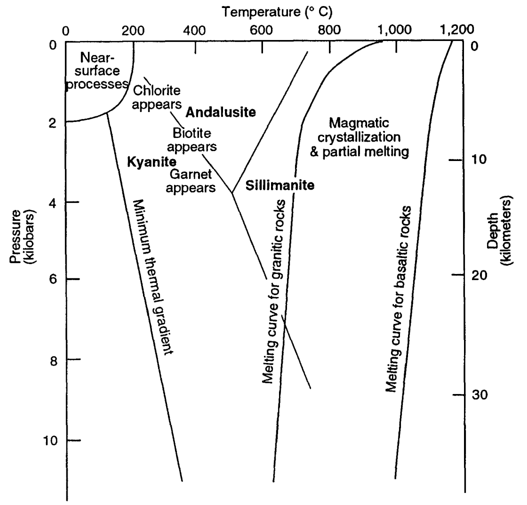

FIG. 8. Relationships between pressure (depth), temperature, and the formation of several characteristic mineral assemblages in metamorphic rocks.

rolite, kyanite (Al_2SiO_5), sillimanite (a high-temperature moderate-pressure polymorph of kyanite), and sillimanite-K-spar. If only temperature increases, the suite is chlorite, biotite, garnet, andalusite (another high-temperature, but low-pressure, polymorph of kyanite), cordierite [$Mg_2Al_3(AlSi_5O_{18})$], and K-spar. Impure carbonate rocks are nearly as useful as shales. Sequences of characteristic minerals in other rock types are not as diverse, so where shales are absent or rare it may not be possible to determine the metamorphic grade as exactly. Regardless of the rock types present, assessment of metamorphic grade is best made using the minerals and mineral compositions present in the entire assemblage under investigation.

In addition to the suites and conditions outlined above, low-temperature (<300 °C), high-pressure regimes exist in the near-surface parts of subduction zones that produce other characteristic minerals like the Na-amphibole glaucophane. Very high-pressure, high-temperature metamorphism of basalt, like that in the upper mantle, produces an assemblage of Mg–Al garnet (pyrope) and a pyroxene (omphacite) that does not form in the near-surface regimes of the middle to upper crust. Moreover, there are ultrahigh-pressure polymorphs of quartz that form in impact structures at near-surface temperatures.

As metamorphic grade (*T*,*P*) increases, dehydration increases the number of anhydrous phases and decreases the number of hydrous minerals, until at the highest grades (high *T*, ±*P*) only a few hydrous minerals, like biotite, are stable. At lower grades (low *T*, ±*P*), micas and amphiboles are abundant; as the grade increases, however, micas are converted to feldspars, and the aluminum silicates (kyanite, andalusite, and sillimanite, Al_2SiO_5) and amphiboles (e.g., actinolite, tremolite, and hornblende) are converted to pyroxenes (e.g., diopside and hypersthene). Feldspars and quartz persist at all grades, with quartz being either the product of several metamorphic reactions or consumed as a starting material in many reactions. An example of a common metamorphic reaction involves impure dolostone as a starting material, composed of dolomite, quartz, and clay minerals, which reacts to form wollastonite ($CaSiO_3$), diopside [$(Ca,Mg)_2Si_2O_6$], and either grossularite [$Ca_3Al_2(SiO_4)_3$] or andradite [$Ca_3Fe_2(SiO_4)_3$]; both of the latter are garnets. Water released from clay minerals may initially form hydrous minerals like phlogopite (a mica) or tremolite (an amphibole), but these too dehydrate at higher temperatures.

Regional metamorphism, the most widespread metamorphic process, involves recrystallization under conditions of increased temperature, both confining and directed (simple or pure shear) stress, and the presence of fluids. Water produced by dehydration of clays is commonly a product of metamorphic reactions and can affect greater mobility of elements, particularly during the early stages (lower grades) of metamorphism. Because regional metamorphism and deformation are linked in the formation of mountain chains during subduction, terrane accretion, and collisional processes, numerous structures, ranging from foliations (textures imparted by the parallel orientation of platy or elongate minerals) and lineations to folds and ductile faults, form during metamorphism.

Contact metamorphism is thermally driven and is commonly related to zones where magma and the host rocks are in closest contact. Zones of contact metamorphism range from a few centimeters to several kilometers thick, depending on the amount of heat and fluid available, and the bulk compositions of both the magma and the host rocks. Basaltic magmas are hotter but are commonly dry and less voluminous; granitic magmas are cooler but usually contain more water and are more voluminous. Impure carbonate and fine-grained clastic rocks, because of their diverse composition and fine grain size, produce the most extensive contact metamorphic zones, whereas pure sandstones and intrusive igneous rocks produce the least.

7. DEFORMATION PROCESSES

Most rock deformation within the Earth or the other planets is the product of tectonic forces. Within the Earth, deformation is driven by plate tectonic processes (Figs. 2 and 3; also see PLATE TECTONICS), which are in turn driven by processes (ultimately thermally driven flow) that produce convection in the mantle. Deformation can be defined in terms of strain: the change in length of reference lines (elongation strain, $\epsilon = dl/l$), change of volume ($\Delta = dV/V$), or distortion of the angular relationships within a reference object (shear strain $\gamma = \tan\psi$, where ψ is the rotation angle). It can also be defined in terms of displacement. In the simplest sense, forces affecting deformation can be thought of as occurring in two forms: compression, in which particles are forced closer together, and tension, in which particles are pulled farther apart. Compression may be produced by gravity-driven vertical forces related to depth of burial either beneath the atmosphere (atmospheric pressure, 1 bar at sea level), under water (hydrostatic pressure that varies with water depth), or within the Earth (lithostatic, related to the thickness of the column of rock above). Compression may also be produced by laterally directed tectonic forces related to plate motion. Tension (tensile deviatoric stresses) may be produced tectonically in parts of the crust, such as at the midocean ridges or the Basin and Range in western North America, where the crust is being pulled apart, and by gravitational forces that produce near-surface readjustments in the upper crust (such as the north-dipping detachment related to gravitational collapse of the high Himalaya), flow in glaciers, and in meteorite impact structures related to elastic rebound following impact.

Deformation in the shallow crust is commonly brittle and produces only granulation (cataclastic deformation) or pressure solution (diffusive mass transfer at grain boundaries) without any recrystallization or other internal deformation of constituent grains composing the rock. Granulation is commonly the product of linear-elastic behavior described by Hooke's law,

$$\epsilon \propto \sigma \quad \text{or} \quad \epsilon = Y\sigma,$$

where ϵ is strain, σ is stress, and Y is Young's modulus, one of several elastic constants that may be used to convert the proportionality to an equality.

Pressure solution is another process important in deformation below 400 °C in the presence of fluid. Quartz and calcite are generally the most soluble common rock-forming minerals. Under shallow-burial conditions of less than 1 km, irregular surfaces called stylolites form in limestones, with the orientation of the surfaces generally parallel to bedding, indicating the force that produced the dissolution was oriented vertically. Similar structures form in sandstones at greater depth and in both rock types under tectonic compression at greater depth. Tectonic stylolites are differentiated from those forming under static burial load by forming at a high angle to bedding. A flow law for pressure solution (assuming Newtonian behavior) is

$$\dot{\epsilon} = \frac{KD_{gb}\Omega C_0}{x^3 kT\rho}\tau_d,$$

where $\dot{\epsilon}$ is strain rate (rate of deformation; geologic rates are commonly on the order of 10^{-6} to 10^{-9} sec^{-1}), K is a material constant, D_{gb} is the coefficient of grain-boundary diffusion, Ω is molar volume, C_0 is concentration of the solution outside the grain boundary, x is grain size, k is Boltzmann's constant, T is absolute temperature, ρ is density, and τ_d is differential (shear) stress (Rutter, 1976). This, and the other flow law presented below, relates strain rate to deviatoric (shear) stress rather than to normal stress because of the complex nature of geologic systems.

Deformation in the lower crust, the mantle, and slow deformation of ice and rock salt at the surface occur plastically where the constituent minerals in a rock undergo recrystallization and the rock flows by a variety of mechanisms (most commonly dislocation creep within individual grains). A flow law that describes the most common recrystallization mechanism in rocks, or dislocation creep, is

$$\dot{\epsilon} = \dot{\epsilon}_0 \tau^n e^{-(Q/RT)}$$

where $\dot{\epsilon}_0$ is the initial strain rate for the crystal being deformed, n is the stress exponent, defined as $d\ln\dot{\epsilon}/d\ln\tau$, Q is the apparent activation energy for the process, R is the universal gas constant (1.987 $\text{cal/deg}^{-1}/\text{mol}^{-1}$), and T is absolute temperature (Poirier, 1985).

The change from brittle to ductile deformation in the crust and mantle is partially a function of composition but is more a function of temperature (Fig. 9). The boundary is not sharp but is a transition zone where the change gradually takes place, and it is called the ductile–brittle transition, or DBT.

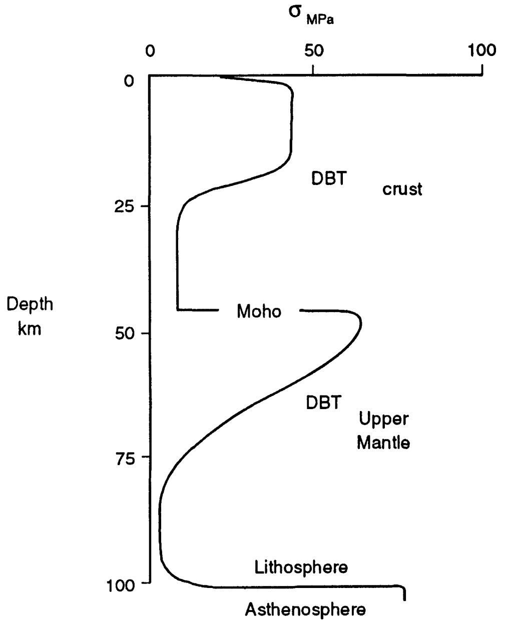

FIG. 9. Stress vs. depth curve showing possible relationships of behavior of quartz (in the crust) and olivine (in the mantle) as a model for brittle-plastic behavior of crustal and mantle rocks. Variation in differential stress is directly related to the strength of the material. DBT: ductile–brittle transition. (From Hatcher, 1995, © 1995 Prentice Hall Inc.)

7.1 Physical Properties of Rocks

Mineral composition of a rock (mineralogy) is a primary control of the physical properties of rocks, but grain size and shape, layering, composition of layers (all layers the same or different), layer thickness, temperature, confining pressure, size and interconnectedness of pore spaces between grains, and presence or absence of fluids all determine the physical properties of rocks. In order to minimize and control as many of these variables as possible, until recently most experimental work has been conducted using monomineralic rocks, rocks with uniform grain size and texture, and rocks without many other anisotropies.

Massive rocks—rocks that have properties that are largely isotropic—deform differently than rocks that contain anisotropies (e.g., bedding or foliation). Layer thickness also has a strong influence on properties, as does the presence of layers of contrasting composition.

Deformation itself may play a role in the subsequent properties of rocks, particularly shallow depths where brittle deformation dominates. Limestone, sandstone, and shale have markedly different properties under most conditions. If, however, each is deformed dry at surface (or near-surface) conditions under ideal (experimental) conditions, and then the products deformed a second time, the strength of the shale would remain nearly constant, and the strengths of both the limestone and sandstone would be much lower for the second cycle of deformation. The reason for this marked change in behavior under surface conditions is that neither the grain size nor porosity of the shale change markedly, whereas the average particle size of the limestone and sandstone both decrease markedly, and the porosity increases. Additional changes may be noted with the addition of fluid during these experiments.

7.2 Folds

Folds are wavelike structures that result from the distortion of originally planar structures—bedding, foliations, faults, joints, or other surfaces—into a curved shape (Hudleston, 1986). They occur on all scales and form in all deformational environments, from brittle to mixed brittle–ductile to ductile environments. Factors that affect the formation of folds, fold wavelength, amplitude, and fold mechanisms include the inherent properties of the rocks (composition, texture, and anisotropy), layer thickness, whether or not layers will slip past one another, and the ambient pressure–temperature conditions of the rock mass. Stress orientation that produces the folds is also a factor, wherein forces may be applied parallel to (producing buckle folds) or across the layering (producing bending folds). Whether or not layers are confined, layer contrast—the relative viscosity of layers—and the thickness of layers can also affect the shapes and mechanisms of the folds that form (Johnson, 1977). Changes in temperature, pressure, and presence of fluids also change the rheological state of the rocks. The most commonly recognized mechanisms include buckling (Currie *et al.*, 1962), where the stresses are applied from the ends of a layer or beam; bending, in which the stresses are applied perpendicular to the beam; kinking, in which the stresses are applied from the ends but the layering cannot slip past itself (Johnson and Ellen, 1974); and various flow mechanisms in which layering either participates to effect the shape of the structures or does not participate.

Folds produced by bending of a layer that is pinned at both ends can be described by $dM/dx = V_a x$ or $M = V_a x +$ constant, where M is deflection, V_a is vertical force, and x is amount of shortening.

A direct relationship exists between the wavelength of folds formed by buckling and the thickness of the dominant strong layer in the sequence (Currie *et al.*, 1962) and can be expressed by

$$\lambda_d = 2\pi t(\mu_1/6\mu_2)^{1/3},$$

where λ_d is the dominant wavelength (of folds in the strong layer), t the thickness of the strong layer, μ_1 the viscosity of the strong layer, and μ_2 the viscosity of the weak supporting medium or matrix.

Depending on the properties of the rocks, nature and properties of layers, temperature, and pressure, folds may form that have a very uniform, gently curved geometry, or they may form as very tight and closely spaced structures. Within the same fold there may be layers that change thickness, while others do not, depending on the relative ductility of individual layers. Other folds may exist where all layers either change thickness by the same amount (similar folds) or do not change thickness at all and produce folds in which the layers are all parallel to one another.

The nucleation and propagation of folds in initially undeformed layers have been the subject of numerous investigations and experiments (Dubey and Cobbold, 1977). Again, depending on conditions, the folds that form may transfer motion to another, they may involve the formation of additional folds, or, if the deformation proceeds far enough, they may be superposed by folds having the same trend or crossing trends if the orientation of the strain field changes. Most folds change properties and geometry along their length, providing evidence of a component of simple shear involved in formation of most folds. Where a large component of simple shear is directed perpendicular to the initially formed fold hinges (the hinge is the part of the fold that has the greatest curvature), a large amount of transport commonly develops in the direction from which the original strain was applied, producing folds that are very elongate parallel to the direction of transport called strongly noncylindrical to sheath folds (Fig. 10).

Depending on the orientations of principal strain axes ($X > Y > Z$, related to the strain ellipsoid) through time, deformation may produce folds that interfere with one another like waves on a water surface and produce the combined effects of two or more events. Many different options arise for creating different geometric variations in the shapes of folds based on the angular relationships between the first and second deformations. Ideally, there are three fundamental fold-interference types (Ramsay, 1967):

1. Type I: The axial surfaces of folds were vertical in both cases with respect to each other, and the deformation occurred at right angles, producing fold hinges at right angles to each other; the interference pattern resembles an egg carton or a series of domes and basins.
2. Type II: The axial surfaces of the first folds are nearly horizontal, and those of

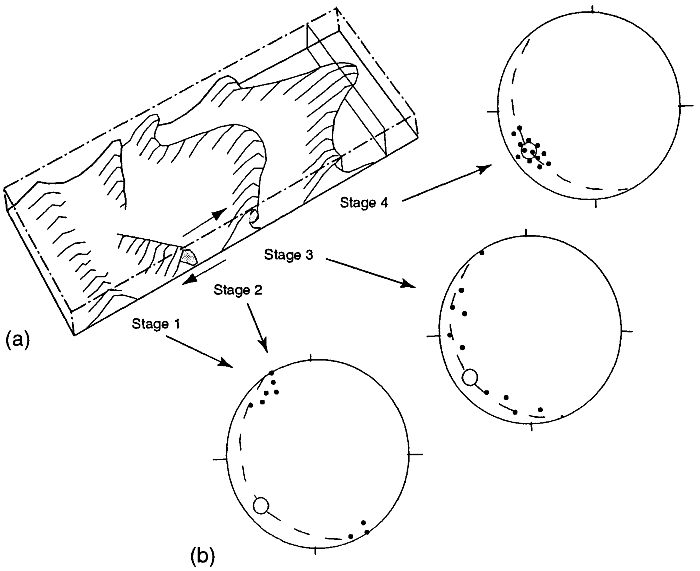

FIG. 10. (a) Progressive amplification of folds (stages 1–4) from cylindrical to sheath geometry in a shear zone, with (b) the corresponding fabric diagrams for each fold. Note the clustering of hinges of the noncylindrical folds about great-circle girdles (dashed lines) that approximate the shear plane. The open circles represent the sheath-fold axes. (Modified from Hudleston, 1986; from Hatcher, 1995, © 1995 Prentice Hall Inc.)

the second set of folds are nearly vertical with respect to the first; the hinges are oriented at right angles to each other, producing a boomerang pattern.

3. Type III: The fold hinges both have the same trend, and the later folds continue to fold and refold the first folds, producing a hook pattern in outcrop, or jellyroll structure, as the layering simply is rolled about itself.

Thiessen and Means (1980) determined that there are at least 16 possible alternative geometries that might be produced with variations in the three basic types described above.

7.3 Fractures and Faults

Geologists use the term fracture in ways different from the usage employed by physicists, probably more akin to that employed by materials scientists: We call any surface across which a rock has lost cohesion a "fracture" (a crack). Following that usage, geological fractures include joints, shear fractures, and faults. Fractures are thought to form by three different mechanisms (Fig. 11): Mode 1 involves opening and therefore a tensional field (joints); mode 2 involves sliding parallel to the fracture surface; and mode 3 involves tearing, again parallel to the fracture surface, but the motion is perpendicular to that in mode 2 (Pollard and Aydin, 1988). Both mode 2 and mode 3 fractures are analogs to the three classes of faults, although there is no requirement here of significant displacement parallel to the fracture surface. There is also another analog with the propagation of a dislocation surface that involves comparing motion of an edge dislocation to mode 2 fractures and the motion of mode 3 fractures to the propagation of screw dislocations (Fig. 12).

Faults are fractures along which there has been appreciable movement parallel to the plane of the fracture. Fractures (mode 1 joints) are structures that form in the brittle realm that have no displacement parallel to the plane of the fracture and have all of the movement perpendicular to it. We recognize three basic types of faults—thrust, normal, and strike-slip—but combinations with

oblique slip are probably more common than the pure end-member types. In an attempt to understand rigorously the mechanics of faults and how they form, Anderson (1942, 1951) defined the three groups of faults and the mechanical conditions that would be required to produce each one. Inherent in each of his definitions is a standard state that he defined as a "condition of stress which is the same in all directions at any point and equal to that which would be caused by the weight of the superincumbent material [the overlying rock mass, lithostatic stress] across a horizontal plane, at the particular level in the rock." It is assumed in this definition that the surface is flat and that the strata are of uniform specific gravity. He also made several other assumptions that are applicable to understanding the mechanics of how faults form. These assumptions oversimplify the Earth or other planets but are essential for a uniform definition of mechanics:

1. The crust was initially intact and unfractured.
2. One of the principal stresses is vertical.
3. The two other principal stresses must be horizontal and are perpendicular to the first and to each other. They also probably maintain a constant orientation for a long period of time.
4. Forces must balance each other in a body in equilibrium (Newton's third law).

In Anderson's ideal model, he defined three basic stress conditions that would produce the deviatoric stresses necessary to produce faulting:

1. Thrust faulting: Principal stresses σ_1 and σ_2 are horizontal, the least principal stress σ_3 is vertical, and the dip on the fault plane will be $45° - \phi/2$ (about 30°; ϕ is the angle of internal friction, tan ϕ is the coefficient of internal friction).
2. Strike-slip faulting: The maximum and minimal principal stresses σ_1 and σ_2 are horizontal, implying that the intermediate stress σ_2 is vertical and that the fault plane will have a near-vertical dip.
3. Normal faulting: Principal stress σ_1 is vertical; therefore, the fault plane will dip $45° + \phi/2$ (about 60°).

In a classical sense, thrust faults and strike-slip faults are thought to form in compressional environments and normal faults to form in tensional environments. While this conclusion is generally correct, we know that most faults are not ideal thrust, normal, or strike-slip faults but have components of each with one dominating in the fault system. We also know that the other types may form within a fault system that is dominated by one fault type simply by changing the orientation of the fault plane, changing the position of the fault relative to external blocks, or causing the fault to step over from one segment to another, thereby producing a zone of tension or compression in an otherwise compressional or tensional environment.

We commonly think of the motion on faults as being the product of frictional sliding involving either stick-slip or stable sliding. Both are produced by the requirement that the fault will move if the stresses applied are sufficient to overcome the coefficient of friction (μ) of the fault surface or to break the rock if the rock mass was not previously broken. Renewed movement on the fault is produced by overcoming the coefficient of friction again and again. Faults may move by sudden motion that produces earthquakes, called stick slip, where the energy that is accumulated along the fault zone is relieved catastrophically and elastically so that the rebound of the blocks on either side of the fault produces a sudden release of elastic energy in the form of an earthquake. The alternative is stable sliding, where a fault moves continuously to relieve the accumulated elastic strain so that the deformation occurs uniformly through time and the accumulated strain is released without catastrophic rebound. Both mechanisms may occur in segments of the same fault, or one may dominate along the entire length of a fault, although movement does not occur along the entire length of a fault at the same time. Large faults such as the San Andreas commonly have segments that are undergoing stick-slip–type deformation and other segments that undergo stable sliding (Sylvester, 1988).

The motion on faults may be enhanced by the presence of fluid along the fault zone. Fluid pressure generally reduces the coefficient of friction on the fault and promotes motion at lower values of accumulated elastic strain than would otherwise occur. Terzaghi (1923) first recognized the importance of fluids in his studies of soil mechanics and introduced the concept of effective normal stress ($\sigma_n - P_w$, where P_w is the buoyant pressure of water in the material or along a fault) to modify Amontons' first law to $\tau = \mu \times (\sigma_n - P_w)$. In detail, motion on a fault occurs whenever the coefficient of friction is overcome, which physically means that the fault is moving. For this to occur, sometimes microscopic, sometimes visible, irregularities called asperities serve as barriers to motion and must be either broken or bypassed for the fault to move. If fluid is present in the fault zone, the stress may be borne by the fluid and fewer asperities broken for movement to occur.

Faults in the outer several kilometers of the crust move by breaking asperities, and deformation proceeds by a brittle mechanism. Movement along faults in the deeper crust occurs along zones of ductile deformation below the DBT. The position of the DBT is a function of temperature, combinations of temperature and fluid pressure, or these combined with other factors. Ironically, we are learning today that many large earthquakes, such as the deep-focus (640 km) magnitude 8.2 Bolivian earthquake in June 1994, are nucleated at depths where rocks are quite hot and should be relieving strain by aseismic creep, indicating that Amontons' law (brittle failure) is not the only mechanism by which earthquakes may be generated. For example, earthquakes between 75 and 300 km in depth may be produced by rapid (catastrophic) dehydration of serpentine [$(Mg,Fe)_3Si_2O_5(OH)_4$] to olivine [$(Mg,Fe)_2SiO_4$] (Meade and Jeanloz, 1991). Earthquakes at depths greater than 300 km are today thought to occur by nucleation of anticracks (lensoidal microfractures that form perpendicular to the greatest principal stress, σ_1) during the phase change from olivine to an equivalent Mg (–Fe) silicate with a much denser spinel ($MgAl_2O_4$) structure (Green *et al.*, 1990).

Direction of motion on a fault may be determined by several means. At the map scale, faults may be identified by displacements of rock units, or generation of earthquakes if the fault is active today, and by displacement of topographic features and other structures. On the microscopic to hand-specimen scale, features are developed within fault zones that also indicate motion. Grooves or other features on a brittle fault surface may indicate direction of motion; rotation sense on small folds that are developed in association with the fault zone are very good indicators of motion sense on the fault. In addition, the presence of rotated porphyroclasts (relicts of mechanically resistant minerals, such as feldspars and garnets) and other features has been used to some advantage, but it must be used with care in the determination of motion. In addition, shear foliations may develop in fault zones at an angle to existing foliation that will indicate the sense of motion on the fault. The angular relationships of the shear foliation relative to the original foliation indicate shear sense on the fault.

7.4 Foliations

Foliations consist of one or more structures that permit rocks to split along planes other than bedding. These include cleavage, schistosity, gneissic banding, and the general term foliation. Foliations may be divided into two different groups. One group consists of structures that do not permeate the entire rock mass. These are called nonpenetrative foliations and consist of structures that are developed within fault zones only locally or that have a wide spacing in a rock mass. The other kind—penetrative—is pervasive throughout the entire rock mass on all scales and includes slaty cleavage, schistosity, and the foliations observed in gneisses and consisting of parallel alignment of nonequant minerals (e.g., micas, amphiboles, and quartz). This is the classic foliation of most rocks and has been known for several hundred years. On the microscopic scale, many foliations become spaced and are separated by small areas of undeformed rock. Therefore, they are nonpenetrative on the microscopic scale. There are, however, structures that permeate the rock on the scale of a hand specimen, a road cut, or a map. Slaty cleavage is the foliation that occurs in fine-grained rocks at low metamorphic grade; gneissic banding and schistosity dominate at high grades. All kinds of foliations, except those associated with flow during the latter stages of crystallization of an igneous body, are tectonic structures. Once again, the properties of the rock determine to some extent the spacing and the angular relationships of the cleavage or foliation in adjacent layers. Fine-grained rocks produce very closely spaced penetrative cleavage, whereas coarser-grained rocks involve cleavage at much greater spacing. In addition, the angle of cleavage to some other reference plane such as bedding may change drastically at the interface between one layer composed of a coarse-grained rock like sandstone and another layer composed of a different rock type like shale.

Most foliations that are pervasive throughout large rock masses were traditionally thought to form by pure shear—flattening. Williams (1976), however, challenged this view by demonstrating, because of the variable distribution of strain in folds, that there must be components of simple shear present.

GLOSSARY

Amphibole: Group of orthorhombic and monoclinic, double-chain (SiO_4 tetrahedra) silicate minerals that contain divalent cations (Mg^{II},Fe^{II},Ca^{II}) in particular sites. Some also contain large univalent cations (Na,K) in other sites in structures where Al^{III} has substituted for Si^{IV}, leaving a charge imbalance. Amphiboles form at high temperatures and pressures and thus are common in igneous and metamorphic rocks. Hornblende is one of the more complex amphiboles; tremolite has a simpler structure and composition. Glaucophane is one of the Na-rich amphiboles.

Basalt: Fine-grained, dark-colored igneous rock (commonly volcanic) composed of calcic plagioclase and pyroxene, sometimes with lesser amounts of olivine, amphibole, and biotite.

Clinopyroxene: Pyroxene group mineral that crystallizes with monoclinic symmetry.

Dolostone: Sedimentary rock composed predominantly of the mineral dolomite [$CaMg(CO_3)$].

Fabric Diagram: An equal-area projection of a hemisphere onto a plane circle to represent orientations of plot lines or planes that represent structures in rocks, such as foliations, lineations, or small folds, that contribute to the fabric (texture plus structure) in rocks.

Felsic: Light-colored igneous rock composed of quartz, plagioclase, and potassium feldspar, and one or more micas (occasionally hornblende).

Fold: Geologic structure defined by layering in rocks that is continuously curved. Folds may be very tight, gentle, or disharmonic, with different curvature from layer to layer.

Foliation: Texture in deformed and metamorphosed rocks imparted by the parallel orientation of platy or elongate minerals. Schistosity, gneissic banding, and slaty cleavage are all foliations.

Garnet: Group of silicate minerals that contain isolated SiO_4 tetrahedra and trivalent (Fe^{III},Al^{III},Cr^{III}) and divalent cations (Mn^{II},Mg^{II},Fe^{II},Ca^{II}) in particular sites. Almandine (Fe) is the most common garnet; other common garnets include grossalurite (Ca), spessartine (Mn), and pyrope (Mg).

Gondwana: Supercontinent that existed during the Paleozoic and the latest Precambrian, consisting of Africa, Antarctica, Australia, India, and South America.

Granite: Coarse-grained igneous rock composed of potassium and plagioclase feldspar (K-spar dominant), quartz, and minor amounts of biotite (and/or hornblende, or muscovite).

Hinge: Part of a fold that has the greatest curvature.

Laurentia: North America.

Plagioclase: Silicate mineral group with a composition that ranges continuously from $NaAlSi_3O_8$ to $CaAl_2Si_2O_8$. Structures consist of three-dimensional polymeric networks of SiO_4 tetrahedra, with one Al^{III} substituting for every third Si^{IV} in a four-coordinate site, requiring a univalent or divalent cation to neutralize the charge imbalance. Mostly forms in igneous and metamorphic rocks.

Pyroxene: Group of single SiO_4 tetrahedra chain silicate minerals that commonly contain Mg^{II}, Fe^{II}, and Ca^{II} as principal cations.

Ultramafic: Igneous rock rich in Mg and Fe, poor in K and Na, and containing <40% by weight of SiO_2. The mantle is composed mostly of ultramafic rocks.

INTRODUCTION

It is now nearly 50 years since the phenomenon of nuclear magnetic resonance (NMR) was first discovered. For much of that time NMR has, arguably, been regarded as the single most important tool for obtaining detailed information about chemical structures. The continuing development of NMR has resulted from a series of step changes. NMR was first developed using continuous-wave (cw) methodology. By the late 1960s the development of pulsed Fourier-transform (FT) techniques extended the scope of NMR, enabling many low-abundance nuclei such as ^{13}C to be observed. By the late 1970s two-dimensional solution NMR techniques were allowing ever more complex molecules to be studied. In the last two decades NMR techniques have been developed that obtain solution-type spectra from solids. Over the same time scale the technique of magnetic resonance imaging (MRI), which has revolutionized diagnostic medicine, has also been developed. This is described in a separate article, MAGNETIC RESONANCE IMAGING.

The first part of this article contains a very brief summary of the principles of NMR and the NMR experiment. Reflecting the major role that solution NMR plays in the determination of chemical structures, the main part is concerned with high-resolution solution NMR. The parameters measured, the nuclei studied, the experiments used, and some applications are discussed. The final section covers NMR of solids. This briefly introduces the additional interactions observed in the solid state and summarizes the type of information that can be obtained from both low- and high-resolution experiments.

1. PRINCIPLES OF NUCLEAR MAGNETIC RESONANCE

To exhibit magnetic resonance the system concerned must have a magnetic moment. For NMR this is provided by a nucleus with a nonzero nuclear spin. The nuclear spin I of an atomic nucleus has one of the values 0, $\frac{1}{2}$, 1, $\frac{3}{2}$, etc. in units of $h/2\pi$, where h is the Planck constant. The mass and atomic numbers of nuclei constrain the possible nuclear-spin values as shown in Table 1. Thus some important, common nuclei such as ^{12}C and ^{16}O that have both even mass and atomic numbers have zero spin. Nuclear magnetic moments μ_N are proportional to the magnitude of the spin, i.e.,

Table 1. Nuclear properties.

Mass number	Atomic number	Nuclear spin I
Odd	Even or odd	$\frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \ldots$
Even	Even	0
Even	Odd	1, 2, 3, . . .

$$\mu_N = \gamma_N hI/2\pi, \tag{1}$$

where γ_N is the magnetogyric ratio of the nucleus. In SI units μ_N is in ampere meter^2 and γ_N in radian tesla^{-1} second^{-1}. Alternatively, the magnetic moment can be expressed as

$$\mu_N = g_N \beta_N I, \tag{2}$$

where g_N is a dimensionless constant, the nuclear g factor, and β_N the nuclear magneton,

$$\beta_N = eh/4\pi Mc, \tag{3}$$

where e and M are respectively the charge and mass of the proton and c is the velocity of light. g_N and I are the quantities that distinguish nuclei from one another.

1.1 Nuclei in a Stationary Magnetic Field

When a nucleus with nonzero spin is placed in a strong magnetic field B, the orientation of the spin becomes quantized, each possible orientation having a different energy. A nucleus of spin I has $2I + 1$ possible orientations, with associated spin quantum numbers m_I of $-I, -I + 1, \ldots, I - 1, I$. The energy of interaction is proportional to the nuclear moment and the applied field. For a nucleus this can be written as

$$E_I = -g_N \beta_N m_I B = -\gamma_N h m_I B/2\pi. \tag{4}$$

Energy-level diagrams for nuclei with spins of $\frac{1}{2}$ and $\frac{3}{2}$ are given in Fig. 1. The selection rule governing transitions for a single nucleus is $\Delta m_I = \pm 1$. Thus

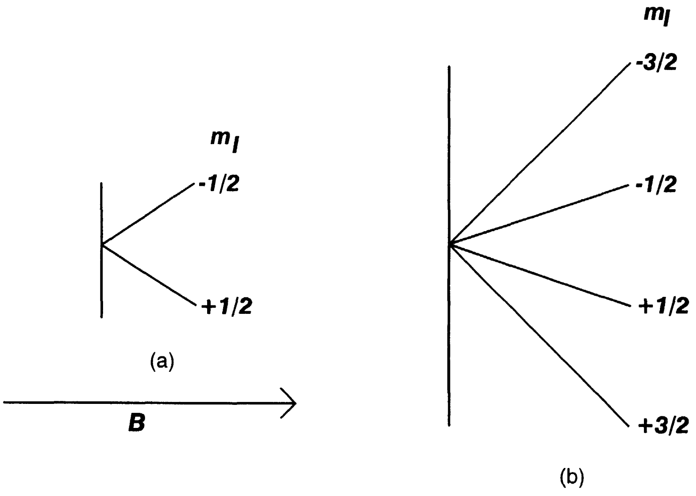

FIG. 1. Energy levels for (a) a nucleus with $I = \frac{1}{2}$, (b) a nucleus with $I = \frac{3}{2}$.

$$\Delta E_I = g_N \beta_N B = \gamma_N hB/2\pi. \tag{5}$$

1.2 Basic Principles of the NMR Experiment

To observe transitions, radiation given by $\Delta E = h\nu$ must be applied. The fundamental resonance condition for the NMR experiment is

$$h\nu = g_N \beta_N B = \gamma_N hB/2\pi, \tag{6}$$

where ν is the resonance frequency. For a proton in a magnetic field of 2.349 T, ν is 100 MHz.

Resonance absorption can only be detected if the spin levels involved differ in population. Consider a spin-$\frac{1}{2}$ nucleus, where the lower, more stable energy level is denoted by α and the higher one by β. In thermal equilibrium the Boltzmann distribution of energies is maintained and

$$N_\beta/N_\alpha = \exp(-h\nu/kT). \tag{7}$$

For NMR the excess of spins in the lower state is only ca. 1 in 10^5. This is one reason for the low sensitivity of NMR compared with IR and UV spectroscopy and even electron spin resonance.

The magnetic-resonance experiment itself is best explained and visualized in classical as opposed to quantum-mechanical terms. How is the energy transferred to nuclei that are in a magnetic field, and how is the energy absorbed measured? The following description is for nuclei of spin $\frac{1}{2}$. In a magnetic field B_0, applied in the z direction, the nuclei will precess in random phase around the z axis with a frequency ω_0 known as the Larmor frequency, where $\omega_0 = 2\pi\nu$. For a spin-$\frac{1}{2}$ nucleus there are two precessional cones, as shown in Fig. 2, one with and the other against B_0. There is a slight excess of nuclei processing with B_0, which gives rise to a small net magnetization vector M_0 along

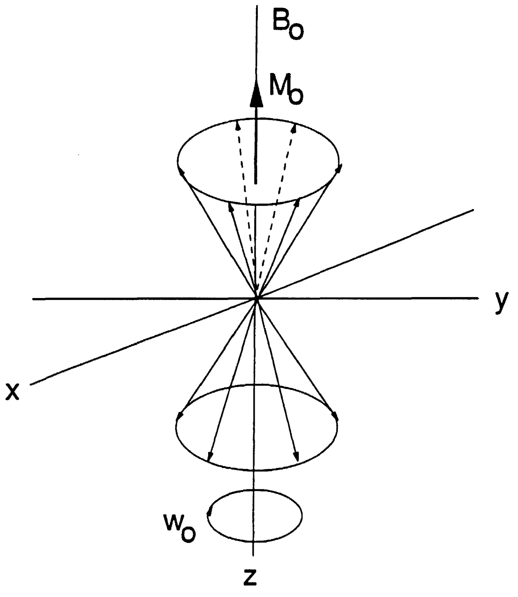

FIG. 2. Motion of spin-$\frac{1}{2}$ nuclei in a magnetic field.

the *z* axis but not in the *x*-*y* plane. The quantum description of the lower- and higher-energy levels can be equated with the classical description of nuclei processing with and against the applied field.

In the magnetic-resonance experiment, the net magnetization M_0 is tipped toward the *x*-*y* plane. Radio-frequency (rf) electromagnetic energy is applied such that its magnetic component, B_1, is at right angles to B_0 and is rotating with the processing nuclei. The rf irradiation is applied along the *x* axis, and at the resonance frequency it tilts the net magnetization toward the *x*-*y* plane. Conventionally, the receiver is located on the *y* axis of the Cartesian coordinates.

To obtain an NMR spectrum, which may contain more than one peak at slightly different resonance positions, either the rf frequency or the magnetic field B_0 can be scanned over a narrow range to bring the various peaks into resonance. Historically, this mode of excitation, known as continuous wave (cw), was used by NMR instruments. It has now been almost completely superseded by the more sensitive pulsed FT method. For more detailed descriptions of the NMR experiment and instrumentation, the reader is referred to the articles NUCLEAR MAGNETIC RESONANCE AND QUADRUPOLE RESONANCE and MAGNETIC RESONANCE SPECTROMETERS, respectively, and books by Harris (1986), Shaw (1984), and Farrar (1987). In particular, the reader should consult these sources for information on the FT experiment since this knowledge is assumed in the description of multiple-pulse experiments later in this article. In such experiments, "pulse angles" are specified. A pulse whose duration is exactly adjusted to turn the double cone of precession through 90° is called a 90° pulse. When the cone is turned about the *x* axis, it is a 90°_x pulse.

In the absence of any mechanism enabling the nuclear spins to return to the ground state, the populations of the lower- and higher-energy levels will become equal, and no more energy will be absorbed. However, two such mechanisms do exist. One is the spin–lattice or longitudinal relaxation process, characterized by a rate constant T_1, which occurs by the loss of energy from excited nuclear spins to the surrounding molecules. The other is the spin–spin or transverse relaxation process with a rate constant T_2, which involves a transfer of energy from one nucleus to another. An important feature of spin–spin relaxation is that it determines the natural linewidth of the signals in a spectrum.

2. HIGH-RESOLUTION SOLUTION NMR SPECTROSCOPY

In general, solids give broad NMR signals devoid of the fine structure usually of interest to the chemist. The interactions (see Sec. 3.1) that cause the broadness are generally averaged to zero in the gas phase or in solution as a result of the random motion of the molecules.

The magnetogyric ratio (γ) of a nucleus enables the resonance frequency to be calculated from Eq. (6) for any magnetic-field strength. Table 2 lists useful, commonly studied nuclei and their magnetic properties. The frequencies are for a 2.35-T applied magnetic field, i.e., relative to ^1H at 100 MHz. Table 2 gives the relative sensitivity for equal numbers of each nucleus and their relative receptivities, i.e., the product of the relative sensitivity and natural abundance.

The abundant nuclei, ^1H, ^{19}F, and ^{31}P, with $I = \frac{1}{2}$ were the first to be studied by cw NMR. On account of sensitivity problems, less abundant isotopes of important spin-$\frac{1}{2}$ nuclei such as ^{13}C and ^{15}N require FT techniques for their observation in natural abundance. Nuclei with spin $I \geq 1$ have an electric quadrupole moment in addition to their magnetic dipole moment. The interaction of the nuclear quadrupole moment with the electric field gradient at the nucleus provides a very efficient process for nuclear relaxation and can result in very broad signals.

The sample, normally a solution in a deuterated solvent in a 5- or 10-mm glass tube, is placed in the instrument probe between the poles of an electromagnet or permanent magnet or inside the solenoid of a superconducting magnet. The probe contains the rf transmitter and receiver coils and a spinner to spin the tube about its vertical axis. Sample spinning is used to average out magnetic-field inhomogeneity across the sample. High-resolution NMR requires both the magnetic field and the rf source to be homogeneous and stable to better than 1 part in 10^8.

The ideal NMR solvent should dissolve

Table 2. Magnetic properties of some nuclei.

Isotope	Spin	Natural abundance %	NMR frequency at B = 2.35 T (MHz)	Relative Sensitivity	Relative Receptivity
^{1}H	$\frac{1}{2}$	99.98	100.000	1.00	1.00
^{2}H	1	0.015	15.351	9.65×10^{-3}	1.45×10^{-6}
^{11}B	$\frac{3}{2}$	80.42	32.084	0.17	0.13
^{13}C	$\frac{1}{2}$	1.108	25.144	1.59×10^{-2}	1.76×10^{-4}
^{14}N	1	99.63	7.224	1.01×10^{-3}	1.01×10^{-3}
^{15}N	$\frac{1}{2}$	0.37	10.133	1.04×10^{-3}	3.85×10^{-6}
^{17}O	$\frac{5}{2}$	0.037	13.557	2.91×10^{-2}	1.08×10^{-5}
^{19}F	$\frac{1}{2}$	100	94.077	0.83	0.83
^{23}Na	$\frac{3}{2}$	100	26.451	9.25×10^{-2}	9.25×10^{-2}
^{29}Si	$\frac{1}{2}$	4.70	19.865	7.84×10^{-3}	3.69×10^{-4}
^{31}P	$\frac{1}{2}$	100	40.481	6.63×10^{-2}	6.63×10^{-2}

the sample, be inert, nonpolar, liquid over the temperature range of interest, and inexpensive, and not give rise to large interfering peaks in the spectrum being recorded. Deuterated solvents such as deuterochloroform ($CDCl_3$) and deuterodimethylsulfoxide (D_6DMSO) are most commonly used. They offer the advantage of being "transparent" in proton spectra and provide a deuterium signal that can be used to stabilize and lock the spectrometer system. A clear mobile solution is required for a high-quality spectrum. Solid particles or viscous solutions will degrade the resolution. Traces of paramagnetic impurities in a solution can dramatically reduce relaxation times and cause peak broadening.

The amount of sample required depends on the method of detection (cw or FT) and the receptivity of the nucleus being studied. For most routine cw proton spectrometers, 10–20 mg of compound of molecular mass 200–300 Da [1 Da (dalton) = 1/12 the mass of a ^{12}C atom], dissolved in 0.4 mL of solvent, should give a reasonable proton spectrum. On a 500-MHz FT instrument it should be possible to obtain a proton spectrum from a few micrograms of such a compound. The low receptivity of nuclei such as ^{13}C means that it is important to use as concentrated a solution as possible in order to obtain a spectrum in as short a time as possible. Larger-diameter sample tubes (10 and 15 mm) and consequently larger sample volumes can be used to increase the amount of sample used.

2.1 Spectral Parameters

All applications of solution NMR spectroscopy to structure determination make use of one or more of the spectral parameters chemical shift, spin–spin coupling, and signal intensity. In the following sections, examples from ^{1}H and ^{13}C NMR are used, but the concepts described apply to magnetic nuclei in general. Books by Harris (1986), Abraham *et al.* (1988), and Emsley *et al.* (1965) will provide further information.

2.1.1 Chemical Shift Equation (6) might suggest that only a single peak would be obtainable from each magnetic isotope. However, when the molecule under observation is placed in the magnetic field, the electrons in the molecule shield the nuclei from the applied magnetic field to a small extent. For a particular nucleus within a molecule, the degree of shielding depends on the density of the electrons circulating about that nucleus. Protons in different chemical environments therefore have different shieldings. Figure 3 shows diagrammatically what happens to spherically symmetrical *s* electrons at a nucleus under the influence of an external magnetic field B_0. They circulate around the nucleus, producing their own magnetic field that opposes the applied field. The effective field B at the nucleus is then given by

$$B = B_0(1 - \sigma). \qquad (8)$$

Thus to obtain the resonant condition, Eq. (6), it is necessary to increase the applied

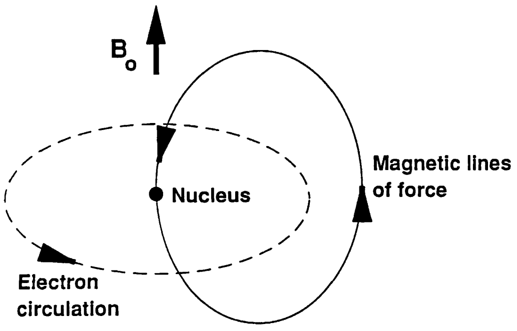

FIG. 3. Electronic shielding of a nucleus by circulating electrons.

field above that for an isolated nucleus. The shielding constant σ is a small fraction, usually of the order of parts per million. For electrons in *p* orbitals where there is no spherical symmetry, the situation is more complex since shielding and deshielding effects depend on the orientation of the molecule with respect to the applied field. Such effects are considered in more detail in Sec. 2.2.1.

The magnitude of the nuclear shielding is proportional to the applied magnetic field. The difference in the peak position of a particular nucleus from the peak position of a reference nucleus is called the chemical shift. In ^{1}H NMR, if two peaks are separated by 100 Hz in a magnetic field corresponding to 100 MHz, they will be separated by 400 Hz in a field corresponding to 400 MHz. Chemical shifts can be expressed in dimensionless units δ as parts per million of the applied frequency as follows:

$$\delta = \frac{(\nu_{\text{sample}} - \nu_{\text{reference}}) \times 10^6}{\text{applied frequency}} \,. \qquad (9)$$

Thus for the example given above, at 100 MHz,

$$\delta = \frac{100 \times 10^6}{100 \times 10^6} = 1.0;$$

at 400 MHz,

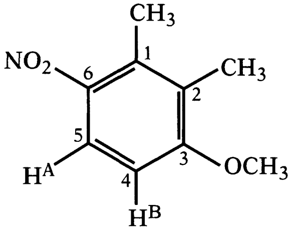
$$\delta = \frac{400 \times 10^6}{400 \times 10^6} = 1.0.$$

The chemical shift δ is therefore a molecular parameter that does not depend on the spectrometer frequency. ^{1}H and ^{13}C nuclei in different environments in organic molecules give peaks that cover ranges of approximately 20δ_H and 220δ_C, respectively.

Tetramethylsilane (TMS) is the most commonly used chemical-shift reference compound for ^{1}H and ^{13}C NMR. In both types of spectra, TMS gives a single sharp resonance at lower frequency than most other proton or carbon resonances. The TMS is usually added to the sample solution as an internal reference. The accepted sign convention is for chemical shifts to high and low frequency of the reference peak to be positive and negative, respectively. Figure 4 shows the 250-MHz ^{1}H spectrum of methylacetate, CH_3COOCH_3, referenced to TMS, the peaks at 2.0δ and 3.6δ arising from the protons of the acetyl and methoxy groups respectively, respectively.

2.1.2 Spin–Spin Coupling

Chemical shift is one source of information on fine structure in NMR spectra. The second is spin–spin coupling. Figure 5 shows the resonances from the aromatic protons in the 4 and 5 positions of 3-methoxy-6-nitro-o-xylene,



One might expect two peaks from the two different aromatic protons in the molecule. In fact four peaks are observed. This results from the indirect coupling of proton spins through the intervening bonding electrons. Thus the magnetic field experienced by nucleus A has a small component arising from nucleus B. Nucleus B has two equally probable orientations in the magnetic field, $m_B = +\frac{1}{2}$ or α and $m_B = -\frac{1}{2}$ or β. As a result nucleus A gives two equally intense peaks corresponding to the two orientations of B. By the same reasoning B itself also gives two equally intense peaks with the same separation as those for A. This splitting is called the spin–spin coupling *J*, where J_{AB} is the

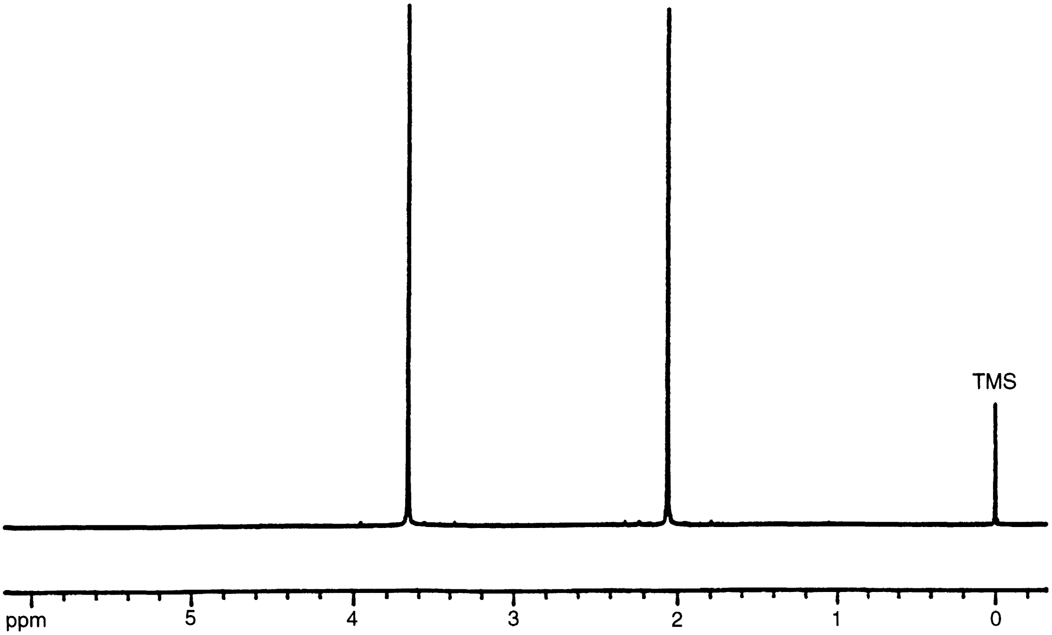


FIG. 4. 250-MHz ^{1}H NMR spectrum of methylacetate.

coupling between nuclei A and B. The magnitude of the coupling, which is measured in hertz, is independent of the applied magnetic field. Couplings between protons may be observed from nuclei separated by up to four bonds. Their magnitude rarely exceeds 20 Hz.

If more than two nuclei are interacting with each other, all the possible orientations of the coupling nuclei must be considered. Figure 6 shows the splitting patterns from two different combinations of three interacting nuclei. When all three nuclei have different chemical shifts, as for the olefinic protons of vinyl acetate, $CH_2=CHOCOCH_3$, then each nuclear signal is split by coupling to both of the other nuclei. Thus each resonance can be envisaged as being split into a

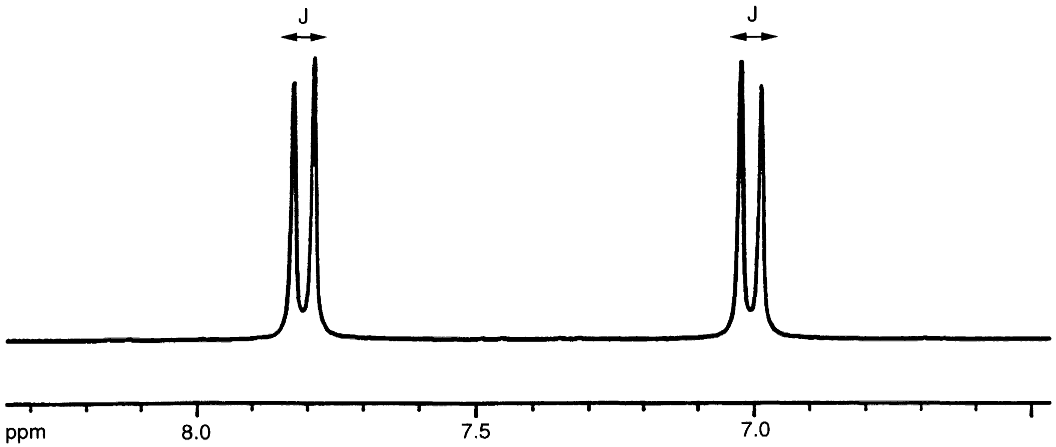

FIG. 5. Aromatic region of the 250-MHz ^{1}H NMR spectrum of 3-methoxy-6-nitro-orthoxylene.

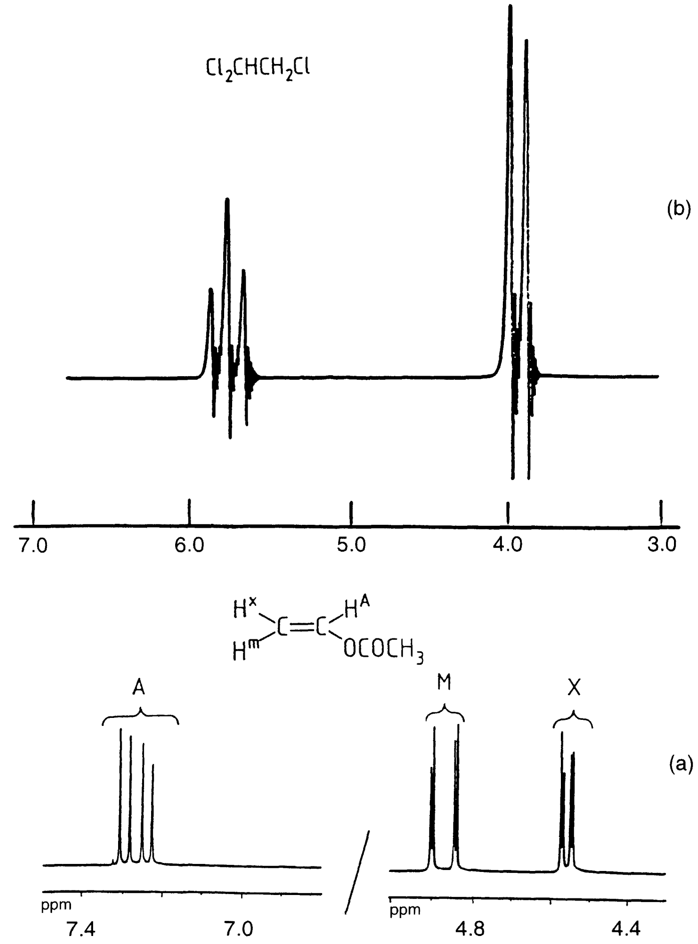

FIG. 6. (a) Olefinic region of the 250-MHz ^1H NMR spectrum of vinyl acetate; (b) 60-MHz ^1H NMR spectrum of 1,1,2-trichloroethane.

doublet by the first coupling, each line of which is further split into a doublet, to give a quartet pattern for each nucleus. When two of the three nuclei are equivalent as in 1,1,2-trichloroethane, Cl_2CHCH_2Cl, the total number of lines in the spectrum is reduced because some of the couplings are identical. The methylene resonance is split into a doublet with a coupling J to the methine resonance. However, the methine resonance is a 1:2:1 triplet pattern with the same splitting J. This arises because the two equivalent methylene protons have three possible orientations ($\alpha\alpha$, $\alpha\beta$ and $\beta\alpha$, $\beta\beta$). Note that the two chemically equivalent methylene protons do not exhibit any splitting from coupling to each other.

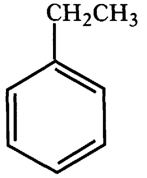
Simple splitting patterns such as these, for nuclei of spin $\frac{1}{2}$, obey the following general rules:

1. If a nucleus interacts with n other nuclei with a different coupling to each, then the signal will consist of 2^n lines of equal intensity.
2. If a nucleus A couples to n equivalent nuclei B, then the pattern for A comprises $n + 1$ lines with relative intensities given by the coefficients of the binomial expansion of $(1 + x)^n$.

These simple rules are only strictly applicable to so-called "first-order spectra." For a spectrum to be first order, a single criterion must be obeyed: The chemical shift difference $\Delta\nu$ for the coupled nuclei must be much larger than the coupling between them ($\Delta\nu/J > 10$). If this condition is not met, the spectrum may show more lines than the rules predict, and their intensities are distorted, with a buildup of intensity toward the middle of the coupling pattern. It is beyond the scope of this article to describe second-order spectra. In the limit where two coupled nuclei have exactly the same chemical shift, either because they are chemically equivalent or because they just happen to have the same chemical shift, the coupling is not observed, and in the absence of coupling to other nuclei, a single peak is observed.

Because the magnitude of the spin–spin coupling interaction is independent of the applied magnetic field whereas the chemical shift separation is proportional to it, a complex NMR spectrum can be simplified by going to higher applied fields.

All the above examples of spin–spin coupling involve homonuclear coupling in proton spectra. In natural-abundance ^{13}C spectra homonuclear coupling is not normally observed since the probability of two adjacent ^{13}C atoms is extremely low, viz., 10^{-4}. For organic molecules the most commonly encountered couplings are those to protons. One-bond couplings range from about 110 to 250 Hz. Most longer-range couplings are <10 Hz. Proton-coupled ^{13}C spectra often show complex overlapping multiplets. In the interests of simplifying the spectra and obtaining a spectrum in a shorter time, routine ^{13}C spectra are usually proton-noise decoupled (see Sec. 2.3.2). Thus in the absence of other coupling nuclei such as ^{31}P or ^{19}F, a single sharp peak is observed for each chemically inequivalent ^{13}C atom. Figure 7 shows both the proton coupled and decoupled ^{13}C spectra of ethyl benzene,



.

2.1.3 Signal Intensity NMR is an inherently quantitative technique. For any nucleus the NMR signal obtained, at least for a single-scan cw experiment or a single-pulse FT experiment, is directly proportional to the number of nuclei producing it. For FT experiments in general to be quantitative, the spin system must be given sufficient time to relax completely between successive pulses. Most proton spectra are recorded under essentially

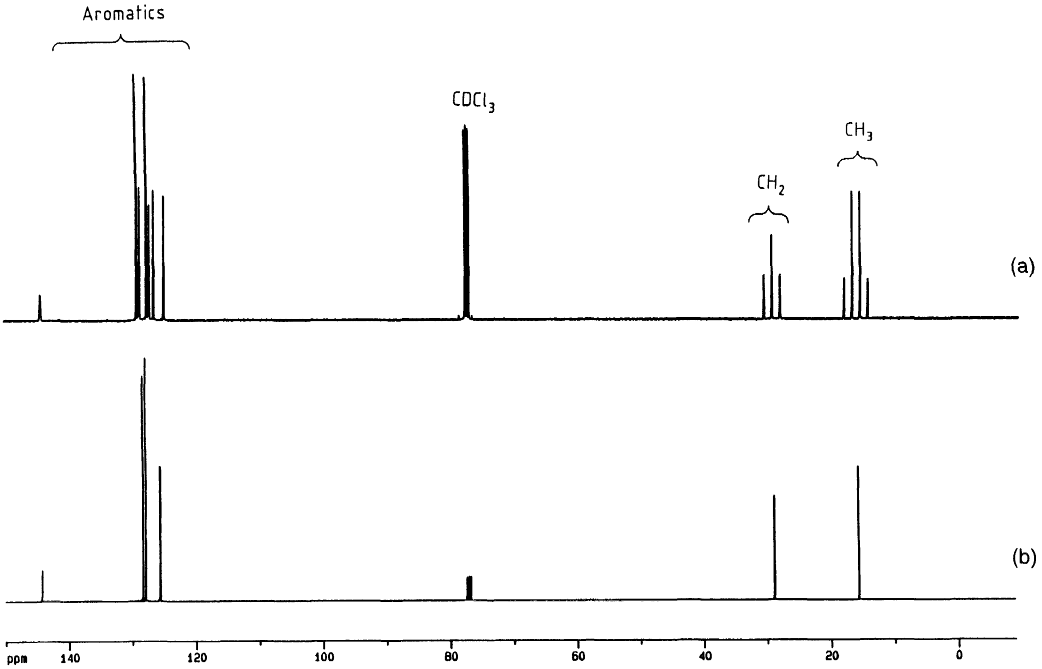


FIG. 7. (a) Proton-coupled and (b) proton-broadband decoupled 100-MHz ^{13}C NMR spectrum of ethylbenzene in deuterochloroform ($CDCl_3$).

quantitative conditions and are integrated to give the relative number of protons contributing to each resonance. Figure 8 shows the integrated proton spectrum of ethylbenzene with the integral traces and relative peak areas of 5:2:3 displayed for the aromatic, methylene, and methyl protons, respectively.

^{13}C spectra and those of other low-natural-abundance nuclei are not normally recorded under quantitative conditions. For structural identification work with such nuclei, conditions are usually selected for optimum sensitivity, not quantification. There is an additional problem in spectra such as ^{13}C where broadband proton decoupling is usually used. Apart from collapsing the multiplet structure, the decoupling irradiation causes an increase in signal intensity due to a phenomenon known as nuclear Overhauser enhancement (NOE—see Sec. 2.3.2). The enhancement factor is often different for the various ^{13}C resonances in the spectrum. Quantitative ^{13}C work is possible, but the experimental conditions have to be carefully selected.

2.2 NMR and Structure

In this section the relationship between chemical structure and the NMR parameters of chemical shift and spin–spin coupling are discussed for some of the more commonly studied nuclei. Information about other nuclei can be found in books by Harris and Mann (1978), Akitt (1983), and Mason (1987).

2.2.1 Hydrogen (^1H and ^2H) The two naturally occurring isotopes of hydrogen are the proton and the deuteron, with natural abundances of 99.985% and 0.015%, respectively. While the former with $I = \frac{1}{2}$ is the most commonly studied of all magnetic nuclei, the latter with $I = 1$ is much less frequently studied in natural abundance and then only for a few specialist applications. One such application is the determination of deuterium levels in samples. If small isotope effects are disregarded, corresponding ^1H and ^2H chemical shifts are the same. Resonances in ^2H spectra are less well dispersed than the corresponding ^1H spectra by a fac-

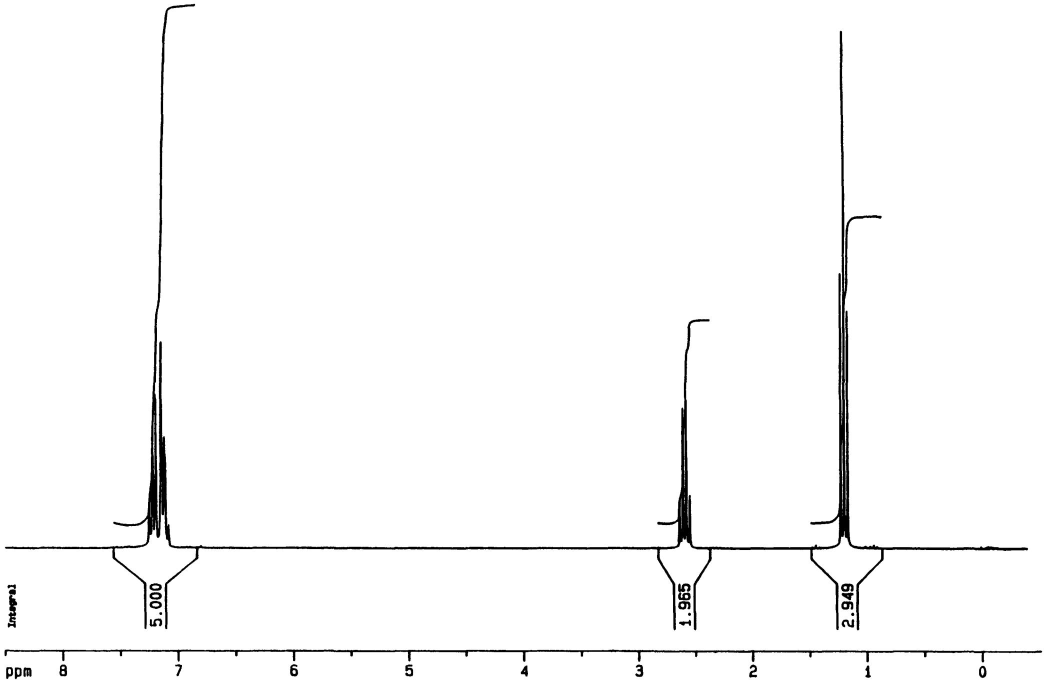

FIG. 8. Integrated 250-MHz ^1H NMR spectrum of ethylbenzene.

tor of 6.51, the ratio of the magnetogyric ratios. The smaller magnetogyric ratio also results in correspondingly smaller coupling constants. While the following discussion is exemplified by reference to the proton, most of the content is equally applicable to the deuteron. However, since deuterium homonuclear coupling constants are very small, ^{2}H spectra with broadband ^{1}H decoupling (see Sec. 2.3.2) give a single peak from each chemically inequivalent deuteron even for deuterium-enriched samples.

2.2.1.1 Chemical Shifts. The shielding effect of spherically symmetrical *s* electrons was discussed in Sec. 2.1.1. This diamagnetic upfield shift affects all nuclei since every molecule has *s* electrons. For electrons in *p* orbitals there is no spherical symmetry, and the phenomenon of diamagnetic anisotropy is used to explain some otherwise anomalous chemical shifts. Diamagnetic anisotropy results in shielding and deshielding, which depend on the orientation of the molecule with respect to the applied magnetic field.

The hydrogen atom is a special case since it is the only commonly studied nucleus with no *p* electrons. A consequence of this is that in proton NMR the direct influence of the diamagnetic term can be seen. For example, in substituted methanes CH_3X, as X becomes more electronegative, the electron density around the protons decreases, and they resonate at lower fields. For the same reason, acidic protons in carboxylic acid groups resonate at very low fields. Figure 9 shows the chemical-shift ranges for a selection of organic groups.

While the electronegativity concept can be used to explain chemical shifts for saturated aliphatic compounds, the effects of diamagnetic anisotropy must also be considered for some other classes of compounds. For example, aromatic compounds such as benzene are strongly deshielded, the protons of acetylene are much more strongly shielded than those of ethylene (acetylene 1.48δ compared with ethylene 5.31δ), and aldehydic protons resonate at low fields. In the case of benzene the deshielding results from the so-called "ring current effect." When a molecule of

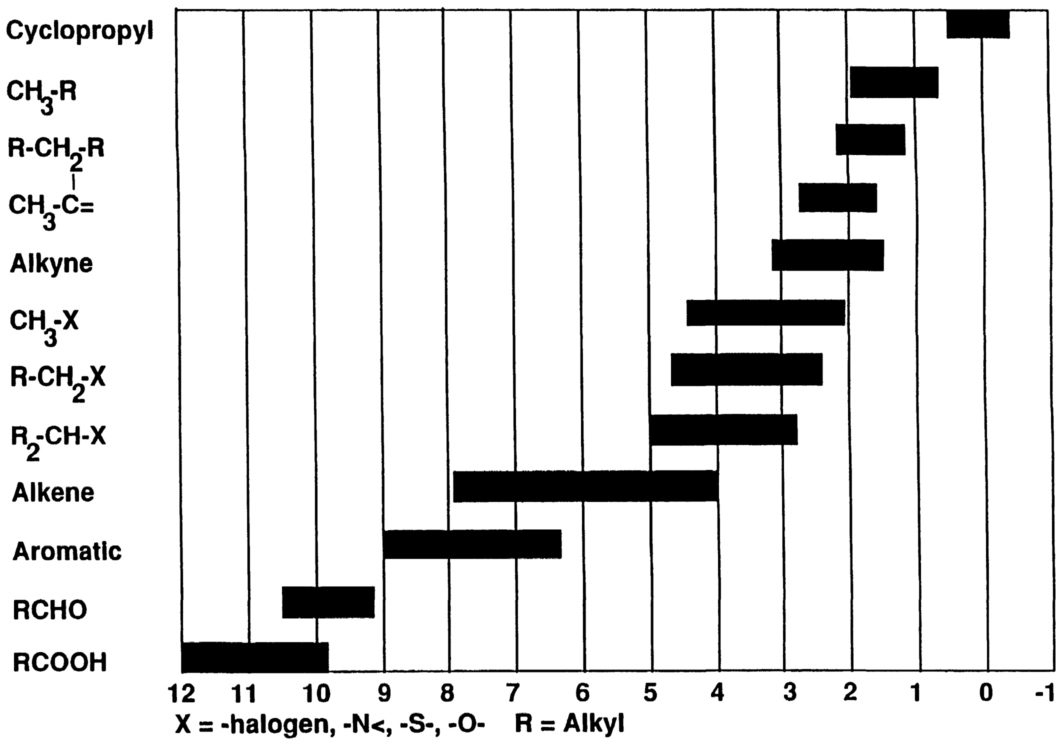

FIG. 9. ^{1}H NMR chemical-shift ranges.

benzene is oriented perpendicular to the applied magnetic field B_0, there is a molecular circulation of electrons about the field as shown in Fig. 10. The resulting ring current produces an additional field that opposes the applied magnetic field along the sixfold axis of the benzene ring but adds to it at the protons on the benzene ring, giving a low field shift. The ring current is only induced when the applied magnetic field is perpendicular to the benzene ring. In practice only a proportion of the rapidly tumbling molecules are perpendicular to the magnetic field, but the overall averaged shift is affected by them. Similar arguments can be invoked to explain the apparently anomalous shifts of acetylenic and aldehydic protons.

The effect of substituents on the proton chemical shifts of hydrocarbons has been extensively investigated. Schoolery's rules enable the prediction of the chemical shift of any CH_2XY and $CHXYZ$ proton. The chemical shift is the shift for methane plus the sum of substituent contributions that are largely determined by the electronegativity of the substituent. In aromatic compounds, strongly electron-withdrawing groups such as nitro and carboxyl deshield all the protons, but the effect is largest at the ortho and para positions. The opposite is true for strongly electron-donating groups such as NH_2 and OH, while the halogens show smaller effects.

2.2.1.2 Spin–Spin Coupling. The origin of spin–spin coupling and the resulting multiplet structure in proton NMR spectra was introduced in Sec. 2.1.2. The magnitude of couplings plays an important role in chemical structure determination, particularly in differentiating between isomeric structures. In proton NMR couplings are observed between protons and to other magnetic nuclei in the molecule such as ^{19}F and ^{31}P. A vicinal proton–proton coupling between protons separated by three bonds is denoted by $^3J_{HH}$, whereas $^1J_{PH}$ represents a one-bond coupling between a proton and a phosphorus atom.

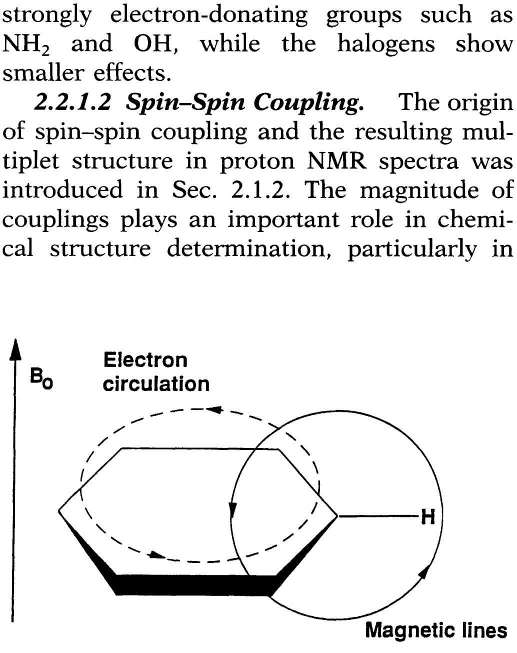

FIG. 10. Ring-current effects in benzene.

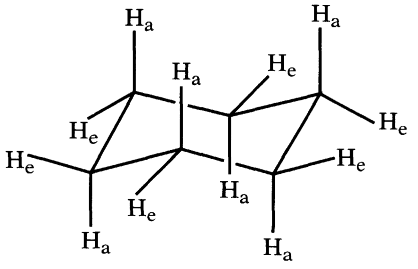
The most commonly encountered coupling in NMR is the vicinal proton–proton coupling. For protons on adjacent carbon atoms in saturated aliphatic groups, this depends primarily on the dihedral angle ϕ between the CH bonds. The angular dependence may be written approximately as

$$^3J(\mathrm{CH\cdot CH}) = 10\cos^2\phi\ \mathrm{Hz} \qquad (10)$$

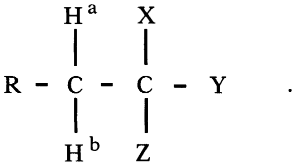
and is best exemplified by couplings in six-membered rings of fixed geometry, such as the chair conformation of cyclohexane,



.

Thus an axial–axial coupling $^3J_{aa}$ in a cyclohexane ring where $\phi = 180°$ would be ca. 10 Hz. Experimentally, $^3J_{aa}$ varies from 8 to 13 Hz, the axial–equatorial coupling $^3J_{ae}$ from 2 to 4 Hz, and the equatorial–equatorial $^3J_{ee}$ from 1 to 3 Hz depending on the nature of the substituents present. In acyclic systems the same angular dependence exists with *gauche* and *trans* couplings typically in the ranges of 2–4 and 8–12 Hz, respectively. However, in systems where there is free rotation about the intervening C–C bond, an average coupling of ca. 7 Hz is observed.

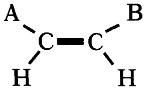
The magnitude of geminal couplings $^2J_{HH}$ over two bonds depends to a first approximation on the H–C–H angle between the coupled protons. For tetrahedrally substituted carbon atoms, a coupling in the range of 12–15 Hz is typical. In aliphatic systems where there is free rotation about bonds, geminal couplings are only observed where methylene protons are diastereotopic, that is, when the molecule contains a chiral center:



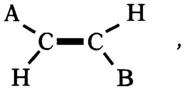
$$\begin{array}{ccccccc} & & H^a & & X & & \\ & & | & & | & & \\ R & - & C & - & C & - & Y \\ & & | & & | & & \\ & & H^b & & Z & & \end{array}$$

In such compounds, protons H^a and H^b cannot be interchanged by symmetry operations or by rapid rotation and therefore may have different chemical shifts and exhibit coupling to each other.

In olefinic compounds the $^3J_{HH}$ coupling constant is used to differentiate *cis* and *trans* isomers, e.g. of a disubstituted ethylene with substituents A and B,

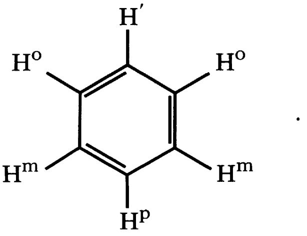


CIS



TRANS

since $J_{trans} > J_{cis}$. Ranges for *trans* and *cis* couplings are 12–18 and 6–12 Hz, respectively. Geminal couplings from terminal $=CH_2$ groups in olefins lie in the range 0–3 Hz. In aromatic compounds the observed couplings are also characteristic of the disposition of the hydrogen atoms. For benzene derivatives the following ranges are typical: $^3J_{\text{ortho}} = 6\text{–}10$ Hz, $^4J_{\text{meta}} = 1\text{–}3$ Hz, $^5J_{\text{para}} = 0\text{–}1$ Hz, where the ortho (o), meta (m), and para (p) protons relative to the proton of interest, H′, are shown for the benzene molecule,



Couplings of protons to other nuclei are discussed in the sections concerned with those nuclei.

Further information about proton chemical shifts and coupling constants can be found in books such as Abraham *et al.* (1988) and Silverstein *et al.* (1991) as well as data collections that include "The Sadtler Collection of High Resolution Spectra," Pouchert (1983) and Brugel (1979).

2.2.2 Carbon (^{13}C) Although present in natural abundance at only 1.1%, the ^{13}C nucleus has, since the advent of FT methodology, been extensively studied. Only ^{1}H NMR is more widely used. In organic chemistry the information obtained from the two nuclei is often complementary for solving structural problems. As mentioned in Sec. 2.1.2, proton–carbon spin–spin couplings in ^{13}C spectra are usually removed by broadband proton decoupling.

2.2.2.1 Chemical Shifts. For organic chemicals most shifts are spread over a range of 0–200 ppm, about 20 times that for the proton. Figure 11 shows chemical-shift ranges for some common organic groups. By comparison with Fig. 9 it can be seen that there is an overall similarity in ordering on going downfield from TMS to that observed for proton chemical shifts. However, in ^{13}C NMR the effects of substitution are often significant several bonds away from the point of substitution. In simple alkanes, α and β carbons result in deshielding effects of approximately 9 ppm each while a γ carbon shields by about 2.5 ppm. As a result the C-1 shifts for methane (CH_4), ethane (CH_3CH_3), and propane ($CH_3CH_2CH_3$) are -2.3, 5.7, and 15.4 ppm, respectively. For alkanes the effects are additive, and a set of rules has been derived by Lindeman and Adams (1971). Similar analyses have been developed for alkenes.

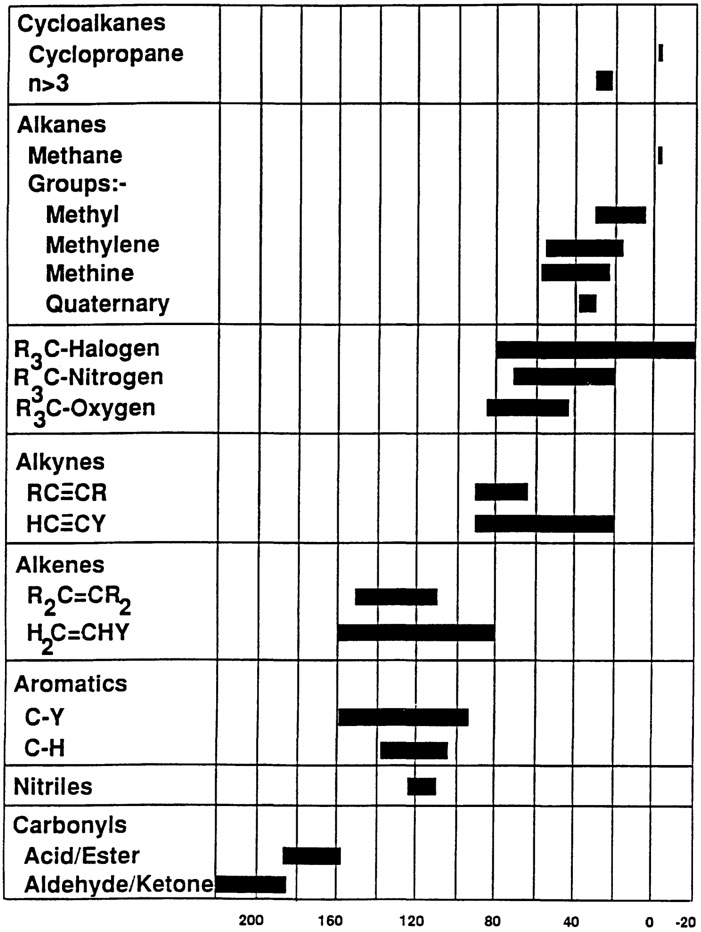
Polar substituents have large effects as can be seen by comparing the shifts for *n*-pentane and 1-pentanol:

$$\begin{array}{ccccccccc} 13.7 & & 22.6 & & 34.5 & & 22.6 & & 13.7 \\ CH_3 & - & CH_2 & - & CH_2 & - & CH_2 & - & CH_3 \end{array}$$

$$\begin{array}{ccccccccccc} 13.9 & & 22.9 & & 28.5 & & 32.7 & & 62.0 & & \\ CH_3 & - & CH_2 & - & CH_2 & - & CH_2 & - & CH_2 & - & OH \end{array}$$

Substituent chemical shifts in benzene derivatives have been collated by Ewing (1979).

2.2.2.2 Spin–Spin Coupling. Carbon–proton couplings are usually sacrificed by broadband proton decoupling in the interests of spectral simplification and obtaining an acceptable spectrum more quickly. However, such couplings can provide valuable structural information.



Where R = H or alkyl, Y = all substituents

FIG. 11. ^{13}C NMR chemical-shift ranges.

One-bond carbon–proton couplings $^1J_{CH}$ are of particular interest. At the simplest level the resulting multiplet provides information about the type of carbon atom; for example, a methyl group gives a quartet resulting from coupling to three equivalent hydrogen atoms. However, such information can be more conveniently obtained from editing experiments (see Sec. 2.4). $^1J_{CH}$ values vary from ca. 110 to 320 Hz, increasing with increasing *s* character of the C–H bond. Thus the couplings for methane, CH_4 (sp^3), ethylene, $CH_2{=}CH_2$ (sp^2), and acetylene, $CH{=}CH$ (sp) are 125, 156, and 248 Hz, respectively. Polar substituents also have significant effects on the magnitudes of couplings.

$^2J_{CH}$ values in aliphatic hydrocarbons range from 5 to 60 Hz. Couplings are often very characteristic of substitution and/or bond hybridization. Thus while $^2J_{CH}$ for ethane is 4.5 Hz, the coupling to the methyl carbon of acetaldehyde, $CH_3CH = O$, is 26.7 Hz. Acetylene has a very large $^2J_{CH}$ of 49.3 Hz.

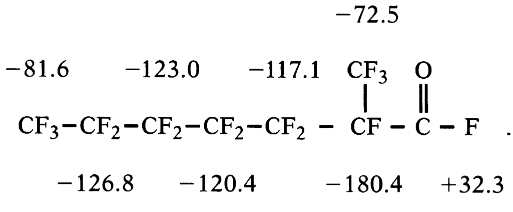
$^3J_{CH}$ couplings show orientational effects analogous to those observed in the corresponding HH couplings. Thus $^3J_{cis}$ is always less than $^3J_{trans}$ in olefins, and the same type of dihedral-angle dependence exists for saturated aliphatic groups. In aromatic rings $^3J_{CH}$ values are characteristically larger than $^2J_{CH}$ values. For benzene itself, $^3J_{CH} = 7.4$ Hz and $^2J_{CH} = 1.0$ Hz.

Note that heteronuclear couplings to magnetic nuclei other than ^{1}H (e.g., ^{19}F, ^{31}P, and ^{2}H) are observed in proton-decoupled spectra. Thus couplings to deuterium will be seen on signals from deuterated solvents.

Further information about ^{13}C chemical shifts and coupling constants can be found in several books, including Abraham *et al.* (1988), Breitmaier and Voelter (1987), Stothers (1972), and Wehrli *et al.* (1988). Large, computer-searchable ^{13}C libraries available from Chemical Concepts (SPECINFO) and BIO-RAD/Sadtler (CSEARCH) probably contain the largest available collections of ^{13}C reference data. The SPECINFO database contains ^{13}C data from over 80 000 compounds.

2.2.3 Fluorine (^{19}F) With 100% natural abundance and $I = \frac{1}{2}$, ^{19}F is ideally suited to NMR investigations. Since the earliest days of NMR spectroscopy, ^{19}F applications in organic, inorganic, and organometallic chemistry have been widespread. As in the case of the ^{13}C nucleus, broadband proton decoupling is often used to simplify spectra.

2.2.3.1 Chemical Shifts. ^{19}F NMR spectroscopy has the advantage of a very large chemical-shift range. Organofluorine compounds alone cover over 400 ppm, while the range is extended to some 700 ppm if inorganic compounds are included. $CFCl_3$ is now the generally adopted internal reference. Most organofluorine resonances are to the high-field side of the $CFCl_3$ peak. In NMR spectroscopy the accepted convention is for shifts to high field of the reference to be assigned negative values. While this sign convention is now generally observed, there are many publications where authors have used the opposite convention without explanation. Moreover, the confusion was frequently compounded by the use of alternative reference compounds. Table 3 gives some representative ^{19}F chemical shifts. The shifts are sensitive not only to directly attached substituents but also to long-range effects and thus are very good probes of changes in molecular structure. The chemical shifts in ppm given for the following compound provide an idea of the wide chemical-shift range observed for some fluorocarbons:



$$CF_3-CF_2-CF_2-CF_2-CF_2-\underset{}{\overset{CF_3}{\overset{|}{CF}}}-\overset{O}{\overset{\|}{C}}-F\ .$$

Table 3. Representative ^{19}F chemical shifts[a].

Compound	δ/ppm	Compound	δ/ppm
CH_3F	−271.9	CF_2Cl	−6.9

2.2.3.2 Spin–Spin Coupling. Large compilations of data are available for both fluorine–fluorine and fluorine–hydrogen coupling constants. The presence of several relatively large couplings can lead to complicated spectra even from relatively simple molecules if they are highly fluorinated. However, the spectra are often amenable to first-order analysis, and in general the coupling constants are very sensitive to structure and substituents.

Three-bond fluorine–hydrogen couplings show orientational effects similar to those observed in the corresponding HH couplings, e.g., the dihedral-angle dependence in saturated aliphatics and that $^3J_{cis}$ is less than $^3J_{trans}$ in olefins.

Wray (1980, 1983) has reviewed published ^{19}F data.

2.2.4 Phosphorus (^{31}P) The ^{31}P nucleus has 100% natural abundance and $I = \frac{1}{2}$. However, a relatively small magnetogyric ratio results in the sensitivity of the ^{31}P nucleus being only 0.066 that of the proton. Nevertheless, with Fourier-transform methodology, the nucleus is easy to detect even at low levels. There is much data in the literature covering applications involving inorganic compounds and complexes, organophosphorus chemistry, and biological studies.

2.2.4.1 Chemical Shifts. The accepted standard for ^{31}P NMR work is 85% H_3PO_4, which is normally used as an external reference. Phosphorus compounds are often reactive, and no suitable internal reference standard has been found for general use. Relative to H_3PO_4, ^{31}P shifts cover the range from ca. 250 ppm to −470 ppm. As in the case of ^{19}F NMR, there is a lack of uniformity in the sign convention adopted in earlier literature. Phosphorus(III) compounds cover the complete range, showing that the chemical shifts are very substituent dependent, while phosphorus(V) compounds cover a smaller range. To a first approximation the substituents directly attached to the phosphorus atom determine the chemical shift. Three variables are important: the bond angle, the electronegativity of the substituent, and the π-bonding character of the substituent. Some representative ^{31}P shifts are given in Table 4.

2.2.4.2 Spin–Spin Coupling. Coupling constants have been studied between ^{31}P and a wide variety of other magnetic nuclei. Couplings to protons, fluorine, and other phosphorus nuclei have been extensively used for structure elucidation. One-bond phosphorus–hydrogen couplings depend on the oxidation state of the phosphorus atom. Thus for P(III) compounds $^{1}J(^{31}P,^{1}H)$ values are of the order of 200 Hz, while for P(V) compounds they are usually in the range 400–1100 Hz. By contrast, one-bond phosphorus–fluorine coupling constants for both P(III) and P(V) compounds have a common range of ca. 800–1500 Hz. Phosphines are widely used as ligands in inorganic complexes, and therefore phosphorus couplings to some transition metals are important aids to structure determination.

2.2.5 Nitrogen (^{14}N and ^{15}N) There are two magnetic isotopes of nitrogen, ^{14}N and ^{15}N, with natural abundances of 99.63% and 0.37%, respectively. In a magnetic field of 9.4 T, the ^{14}N resonance frequency is 28.9 MHz, while that for ^{15}N is 40.5 MHz. There are problems associated with observing both nuclei. The ^{14}N nucleus possesses a quadrupole moment since $I = 1$. As a result, although ^{14}N signals can be detected easily, the lines can be very broad with widths often between 100 and 1000 Hz. With a 9.4-T applied magnetic field, this is equivalent to 3.5–34.6 ppm. This can cause resolution problems when a molecule contains more than one type of nitrogen atom.

Although $I = \frac{1}{2}$ for the ^{15}N nucleus, its very low natural abundance results in low receptivity. It also has a negative magnetogyric ratio, which results in a negative NOE when broadband proton decoupling is used. This reduces the intensity of peaks and can result in negative and even null resonances. It has therefore been necessary to use experimental procedures that minimize or eliminate the NOE. The two principal ones are inverse-gated proton decoupling (see Sec. 2.3.2.3) and the use of a paramagnetic relaxation reagent such as Cr(acetylacetonate)$_3$, which reduces T_1 and consequently the NOE. With modern FT equipment it is now possible to obtain ^{15}N spectra from most small and medium-sized nitrogen-containing molecules at natural abundance level. However, for work with large biological macromolecules, ^{15}N enrichment is commonly used.

2.2.5.1 Chemical Shifts. In principle, the use of two isotopes raises the possibility of a primary isotope shift, but in practice ^{14}N and ^{15}N shieldings differ by no more than a few tenths of a ppm and are interchangeable for practical purposes. For many years there was a reluctance to adopt a single reference standard for calibration purposes, and both nitromethane and ammonia were frequently used, in the former case with both sign conventions. Nitromethane is now generally used, and here the convention of negative values to high field of the reference is used. However, the chemical shift of nitromethane is somewhat solvent and concentration dependent. The total nitrogen chemical-shift range covers about 1000 ppm, and ranges for a selection of chemical classes are shown in Fig. 12.

2.2.5.2 Spin–Spin Coupling. It is unusual to observe coupling in ^{14}N spectra,

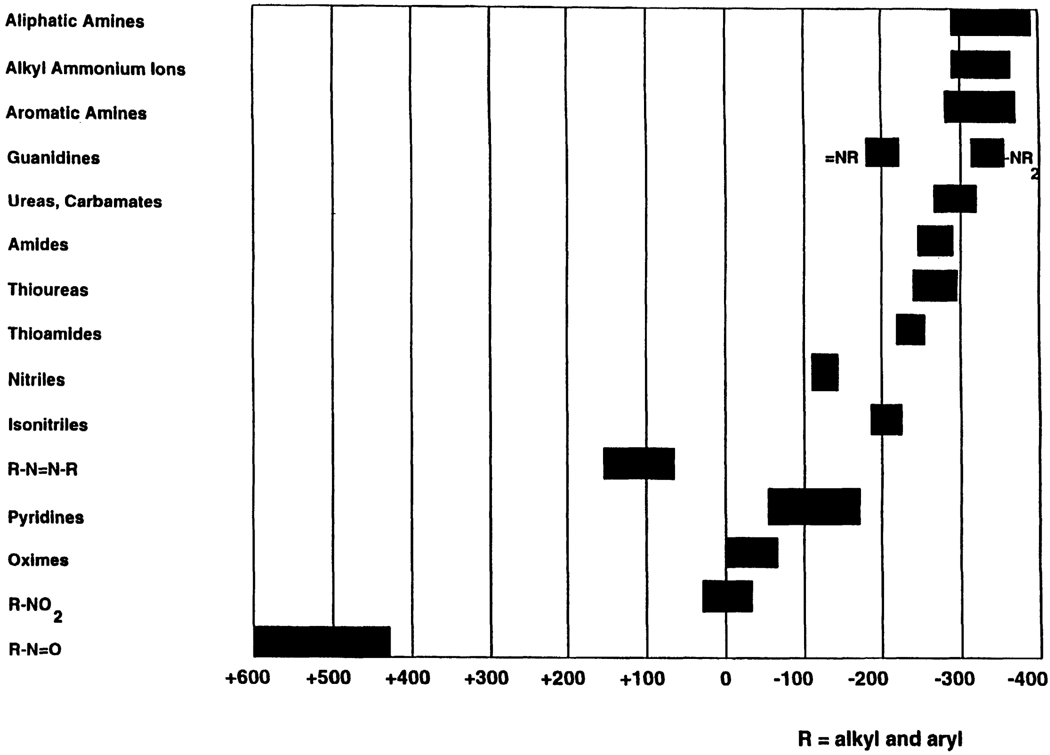

FIG. 12. $^{14}N/^{15}N$ NMR chemical-shift ranges.

where resonances are very broad as a result of quadrupolar relaxation. It is, however, often resolved for ammonium salts. The relative magnitudes of the corresponding ^{14}N and ^{15}N coupling constants are given by the ratio of their magnetogyric ratios. The discussion here will be restricted to ^{15}N coupling. The observation of coupling to low-abundance nuclei such as ^{13}C or another ^{15}N nucleus normally requires isotopic enrichment. Couplings to abundant nuclei such as ^{1}H, ^{19}F, and ^{31}P are more readily observed as in the case of ^{13}C spectroscopy.

One-bond couplings to hydrogen depend on hybridization and electronegativity. Thus the $^{1}J(^{15}N,^{1}H)$ values for $[NH_4]^+$, $O=C(NH_2)_2$, and $HC\equiv NH^+$ are 73.3, 89.0, and 134.0 Hz, respectively. One-bond couplings to ^{13}C also show a reasonable correlation with hybridization. The magnitudes of one- and two-bond couplings to ^{13}C are often comparable.

Witanowski *et al.* (1986) have reviewed ^{15}N data.

2.2.6 Oxygen (^{17}O) The only magnetic isotope of oxygen is ^{17}O. With a natural abundance of only 0.037%, a receptivity that is 0.61 that of ^{13}C, and a quadrupole moment ($I = \frac{5}{2}$), ^{17}O is relatively difficult to study. Nevertheless, because of the importance of oxygen in both inorganic and organic chemistry as well as biology, the ^{17}O nucleus has been quite widely studied both in natural abundance and in isotopically enriched samples. For small molecules, linewidths are typically in the range of several tens to several hundreds of hertz. With large molecules or viscous solutions much larger linewidths may be encountered.

2.2.6.1 Chemical Shifts. Water is the usual chemical-shift reference, being readily available in enriched form. A chemical-shift range of over 1000 ppm affords wide spectral dispersion. Figure 13 shows representative chemical-shift ranges for some organic groups. There is a clear distinction between single and double carbon–oxygen bonds. However, a single resonance is observed

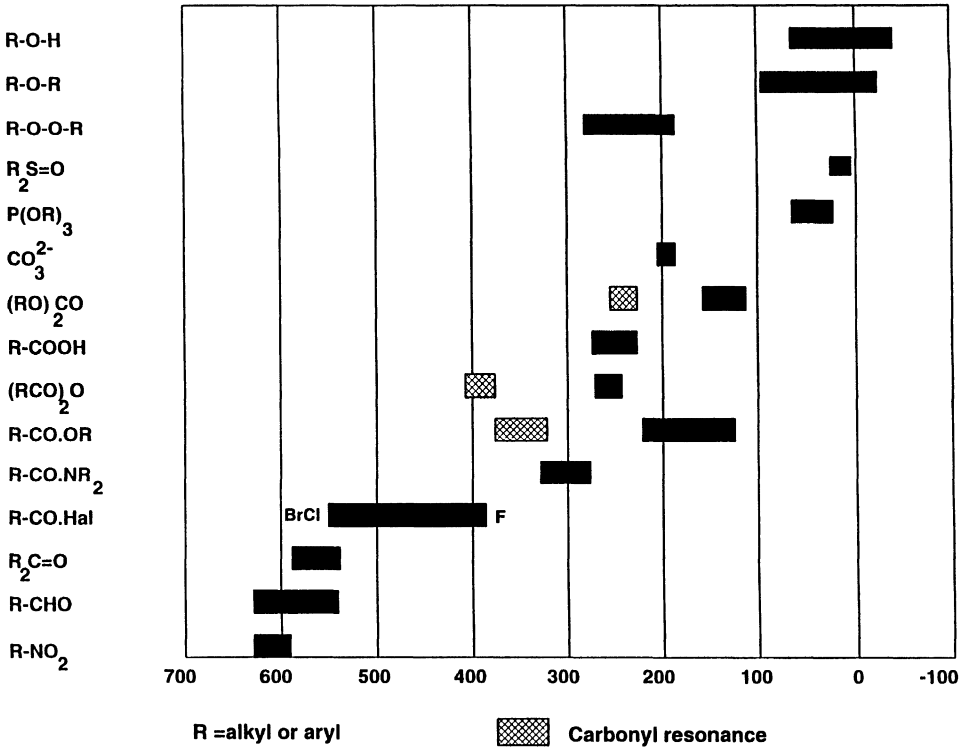

FIG. 13. ^{17}O NMR chemical-shift ranges.

from a carboxylic group at the average position expected for the carbonyl and OH groups as a result of rapid proton exchange facilitated by dimeric species. Primary alcohols and ethers resonate close to the water position, while lower field shifts are observed for secondary and tertiary species.

2.2.6.2 Spin–Spin Coupling. Since ^{17}O resonances are usually broad, the majority of reported values are for couplings between directly bonded nuclei. Values of $^1J(^{17}O,H)$ in water and alcohols are ca. 80 Hz. The $^1J(P,^{17}O)$ couplings involving P=O groups cover the range 145–210 Hz. In contrast, couplings involving P–O groups are usually smaller (90–100 Hz). Some two-bond couplings have been reported. Examples of two-bond hydrogen–oxygen couplings are 38, 7.5, and 10.5 Hz for the O–CH, O–CH_3, and HC=O interactions in methyl formate.

2.2.7 Silicon (^{29}Si) ^{29}Si, with an abundance of 4.7%, is the only naturally occurring isotope of silicon with a nonzero spin ($I = \frac{1}{2}$). While its receptivity is 2.1 times that of the ^{13}C nucleus, there are problems associated with its detection. In common with the ^{15}N nucleus, a negative magnetogyric ratio results in negative NOEs when broadband proton decoupling is employed as is usually the case. Inverse-gated decoupling and relaxation reagents are again used to circumvent the problem. Broad signals from the glass in the NMR probe head or tube can also cause problems. The glass can be replaced by alternative materials such as Teflon, or the spectrum obtained from a blank run (i.e., without sample) can be subtracted from the spectrum of the sample.

2.2.7.1 Chemical Shifts. The ^{29}Si resonance of TMS is the usual chemical-shift reference. ^{29}Si chemical shifts cover a range of ca. 400 ppm. The large dispersion arising from structural effects makes ^{29}Si NMR a valuable tool for molecular structure determination. The nature of the atoms directly bonded to silicon is of particular importance. Table 5 lists chemical shifts for a series of compounds SiX_nMe_{4-n} (Me denotes methyl). ^{29}Si NMR has proved to be an ideal tool for

Table 5. ^{29}Si chemical shifts for SiX_nMe$_{4-n}$.

structure determination of polysiloxane macromolecules.

2.2.7.2 Spin–Spin Coupling. Couplings to abundant nuclei such as the proton and fluorine can be measured either in a coupled ^{29}Si spectrum or by observing the ^{29}Si satellites in the spectrum of the abundant nucleus. The latter are relatively weak compared with peaks from the main ^{28}Si-containing species. Nevertheless, many determinations were made in this way during the 1960s using cw spectrometers. In a well-resolved ^{1}H NMR spectrum, the satellites due to a $^{2}J_{SiH}$ coupling of 6.8 Hz are readily observed at the base of the TMS reference peak. One-bond proton–silicon coupling constants in silanes are usually in the range 150–380 Hz, the magnitude of J increasing with substituent electronegativity. The literature contains data about coupling to a range of other nuclei, including ^{31}P, ^{13}C, ^{15}N, and ^{29}Si itself.

Published data have been reviewed by Williams and Cargioli (1979).

2.3 Double-Resonance Techniques

In Sec. 2.1.2, reference is made to the use of proton-noise (or broadband) decoupling to simplify ^{13}C spectra and improve the signal-to-noise ratio. This is just one example of a large number of double-resonance techniques that are available either to simplify spectra or as spectral interpretation tools to aid structure elucidation.

2.3.1 Homonuclear Spin Decoupling

The principles of homonuclear double resonance can be illustrated by considering two coupled protons, A and B, as shown in Fig. 5. In the double-resonance experiment, nucleus A is observed in the usual way in a cw or FT experiment during simultaneous selective irradiation at the nucleus-B resonance frequency. This irradiation induces transitions between the two spin states of nucleus B. If sufficient irradiating power is applied, B flips between the α and β spin states so rapidly that nucleus A can no longer distinguish between the two orientations of B and perceives an average orientation. The coupling J_{AB} disappears and the A signal doublet collapses to give a single line. In the same way, irradiation of the methyl triplet of ethylbenzene (Fig. 8) results in the methylene quartet collapsing to a singlet.

2.3.2 Heteronuclear Spin Decoupling

In the case of heteronuclear spin decoupling, the decoupled and observed nuclei are of different chemical types. The experiments are illustrated with examples in which protons are decoupled and the effect is observed on the ^{13}C spectrum. However, the methodologies are equally applicable to other heteronuclear spin systems.

2.3.2.1 Selective Spin Decoupling. Selective spin decoupling is analogous to the homonuclear decoupling experiment described above. In general, higher rf power is required than for homonuclear decoupling but lower than is generally used for broadband heteronuclear decoupling. An individual proton signal is selected and irradiated to remove all couplings to that specific proton in the ^{13}C spectrum.

2.3.2.2 Broadband Spin Decoupling. If the proton decoupler frequency is set to the center of the proton spectrum and modulated by using a noise generator with a bandwidth wide enough to cover the complete proton region, then this is equivalent to simultaneously irradiating every proton frequency. This effectively decouples all the protons in the molecule, producing the effect shown in Fig. 7. Two problems are, however, associated with this type of broadband decoupling. First, the high rf power required heats the sample, and second, the decoupling is ineffective if the bandwidth to be irradiated is large. The latter is more of a problem on higher-field spectrometers and where broadband decoupling of other nuclei such as ^{19}F or ^{31}P with their large spectral widths is required. In recent years alternative methods—e.g. WALTZ-16 (see Shaka *et al.*, 1983)—have largely overcome these problems. As has been mentioned in previous sections, broadband decoupling also produces a change in intensity, known as the nuclear Overhauser enhancement (NOE), of the observed signals. This occurs because the decoupling causes additional relaxation of the observed nucleus, resulting in increased population of the ground-state energy levels. For ^{13}C the increase in intensity can be as much as 200%, but resonances from quaternary carbon atoms that do not have attached protons are little affected.

2.3.2.3 Gated Decoupling. When decoupling is turned on or off, coupling effects appear and disappear instantaneously. The NOE effects, however, grow and decay at rates related to some relaxation process. As a result it is possible by computer control of the decoupler to separate the two effects completely.

Sometimes it is necessary to record broadband proton-decoupled spectra without any NOE. The NOE may be undesirable either because quantitative information is needed about the relative number of atoms contributing to each peak in, for example, a ^{13}C spectrum or because the nucleus being studied has a negative NOE (e.g., ^{15}N or ^{29}Si). Such spectra are also used as controls when measuring NOE values. In other instances coupled spectra with NOE are used as a means of improving sensitivity.

Figure 14 shows an FT ^{13}C experiment with three possible broadband decoupling schemes. The repetitive pulse experiment consists of three parts: a relaxation delay *t*, a ^{13}C rf pulse, and the acquisition time *AT* during which time the FID is sampled. *AT* and *t* are of the order of seconds, while the pulse duration is a few microseconds. For conventional broadband decoupling (a) the decoupler is on throughout the experiment. If the decoupler is gated off just before the rf pulse as in (b), NOE effects can be observed without any decoupling. Conversely, if the decoupler is switched on when the pulse is applied and off as soon as the acquisition is complete as shown in (c), the resultant decoupled spectrum does not exhibit an NOE. The latter experiment is referred to as inverse gated decoupling.

2.3.2.4 Off-Resonance Decoupling. While the broadband proton decoupling described above produces considerable simpli-

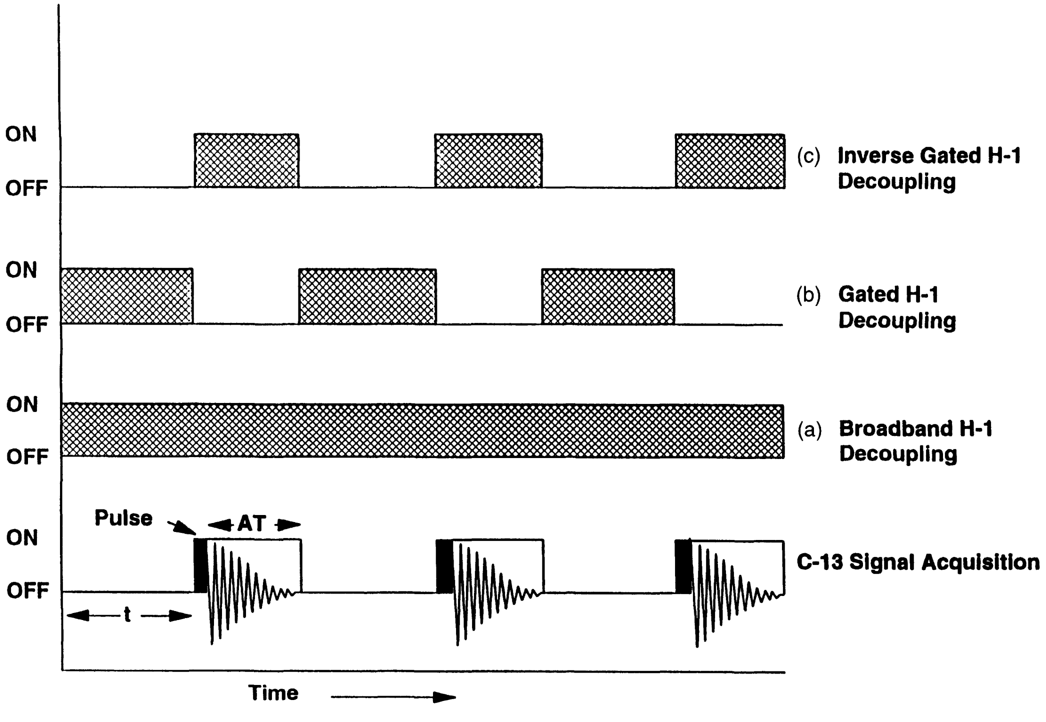

FIG. 14. ^{1}H broadband and gated decoupling schemes.

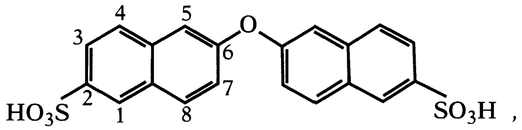
fication of ^{13}C and other spectra, it removes all the coupling information. As a result the spectra may be difficult to assign. In the early days of ^{13}C NMR, a technique known as off-resonance decoupling was used to circumvent this problem. Off-resonance decoupling is achieved by setting the central frequency of the broadband proton decoupler 1000–2000 Hz outside the proton spectrum. This results in residual couplings from protons directly bonded to ^{13}C atoms, whereas longer-range couplings are lost. The magnitude of the residual coupling, which is smaller than the true coupling J, is determined by the amount of the offset and the power of the decoupler. In such spectra it is usually possible to determine the multiplicities of all the individual carbon atoms; i.e., methyl carbons appear as quartets, methylenes as triplets, etc. Nowadays the use of gated decoupling for multiplicity determination has largely been replaced by spectral editing experiments (Sec. 2.4).

2.3.3 NOE Difference Spectroscopy

The phenomenon of NOE was introduced in Sec. 2.1.3 to explain the increase in intensity of ^{13}C peaks when broadband proton decoupling is used. In general terms the NOE is defined as the change in signal intensity of a nucleus when a second nucleus is irradiated. It is beyond the scope of this article to give a theoretical treatment of the origin of the effect, which is caused by through-space nuclear relaxation by dipolar interaction. Among other factors the magnitude of the enhancement has a $1/r^6$ dependence on the distance between the two nuclei concerned. Therefore, homonuclear NOEs between protons have been used extensively to obtain information about internuclear distances and thereby to distinguish between possible structures.

The most convenient way of observing such enhancements, which rarely exceed 20% in the most favorable cases and are sometimes <1%, is by a technique known as NOE difference spectroscopy. In such an experiment two spectra are recorded. The first is a conventional ^1H spectrum, while in the second a chosen resonance is selectively irradiated during the interpulse delay of an FT experiment. The second spectrum is then subtracted from the first to give a "difference" spectrum.

Figure 15(a) shows the ^1H NMR spectrum for the following structure, denoted as structure **1**:



From this spectrum alone it is not obvious whether the ether linkage is at C-6 or C-7. The peak at 8.2δ is clearly due to H-1, while that at ca. 8.0δ is from H-5 or H-8, depending on which isomer is present. Figure 15(b) shows the difference spectrum obtained when the resonance at 8.0δ is selectively irradiated. The irradiated resonance, which is partially or fully saturated, gives a negative signal in the difference spectrum. Positive signals are obtained from those resonances that exhibit an enhancement. Since an en-

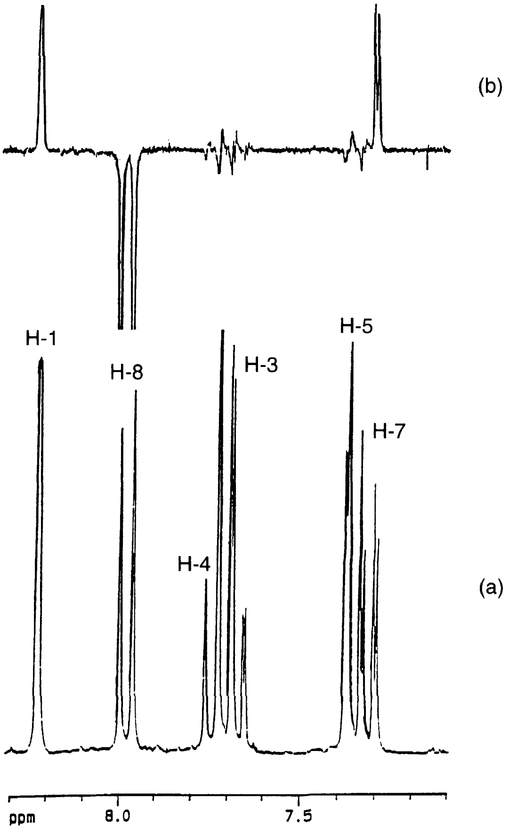


FIG. 15. (a) 250-MHz ^1H NMR spectrum of structure 1; (b) NOE difference spectrum on irradiation of H-8.

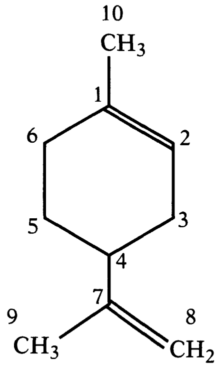
hancement is observed for H-1, this is a good indication that H-1 and H-8 are close together. Measurable effects can be observed between atoms up to about 400 pm apart. Since the above description is rather simplistic, it should be stressed that because dipolar relaxation of a particular nucleus may involve interaction with more than one other nucleus, a basic understanding of the processes involved is a prerequisite to applying the technique successfully. The reader is referred to Noggle and Shirmer (1971) and Neuhaus and Williamson (1989).

2.4 Spectral Editing Experiments

The basic FT experiment is a single-pulse experiment. This means that only one RF pulse is applied prior to recording the free-induction decay (FID) response. A large number of experiments have been developed, for a variety of purposes, in which more than one pulse is applied prior to recording the FID. The most frequently used multiple-pulse experiments are probably those for multiplicity determination in ^{13}C NMR. Both the *J*-modulated spin-echo (LeCocq and Lallemand, 1981) and the distortionless enhancement by polarization transfer (DEPT) (Doddrell *et al.*, 1982) experiments are extensively used for this purpose.

Figure 16 shows the pulse sequence used for the former experiment, which includes the three periods characteristic of all modern pulse experiments, namely preparation, evolution, and detection. The preparation period is a relaxation delay ending with a 90°_x pulse along the *x* axis of the rotating frame. The decoupler is switched off, and during the first half of the evolution period, the magnetization in the *xy* plane evolves under the influence of the proton–carbon spin–spin (*J*) couplings. At the beginning of the second period the decoupler is switched on again, and a 180°_x pulse refocusses all effects other than *J* modulation. In the detection period a proton-decoupled FID signal with NOE is observed. If $t = 1/J$, signals from quaternary and CH_2 carbons are in antiphase to those from CH and CH_3 carbons. Figure 17 shows such a *J*-modulated spin-echo ^{13}C spectrum for limonene (structure **2**),



,

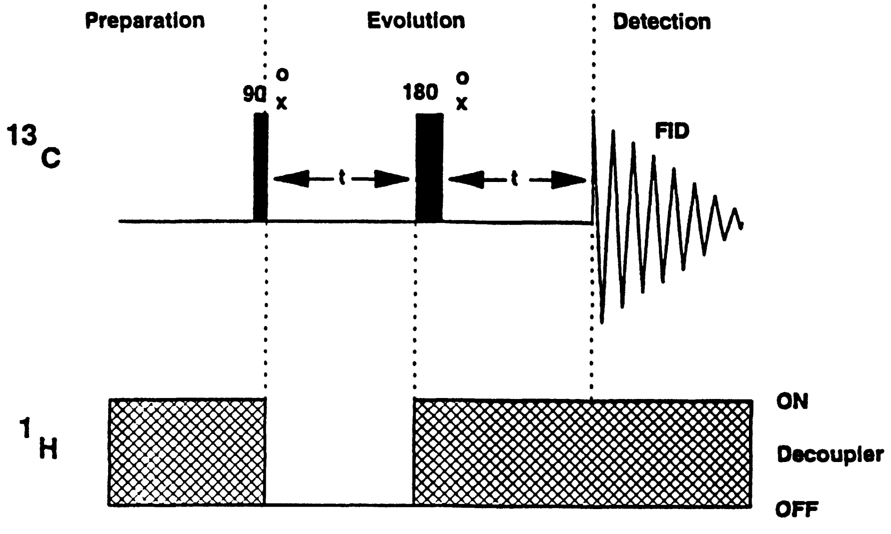


FIG. 16. *J*-modulated spin-echo pulse sequence.

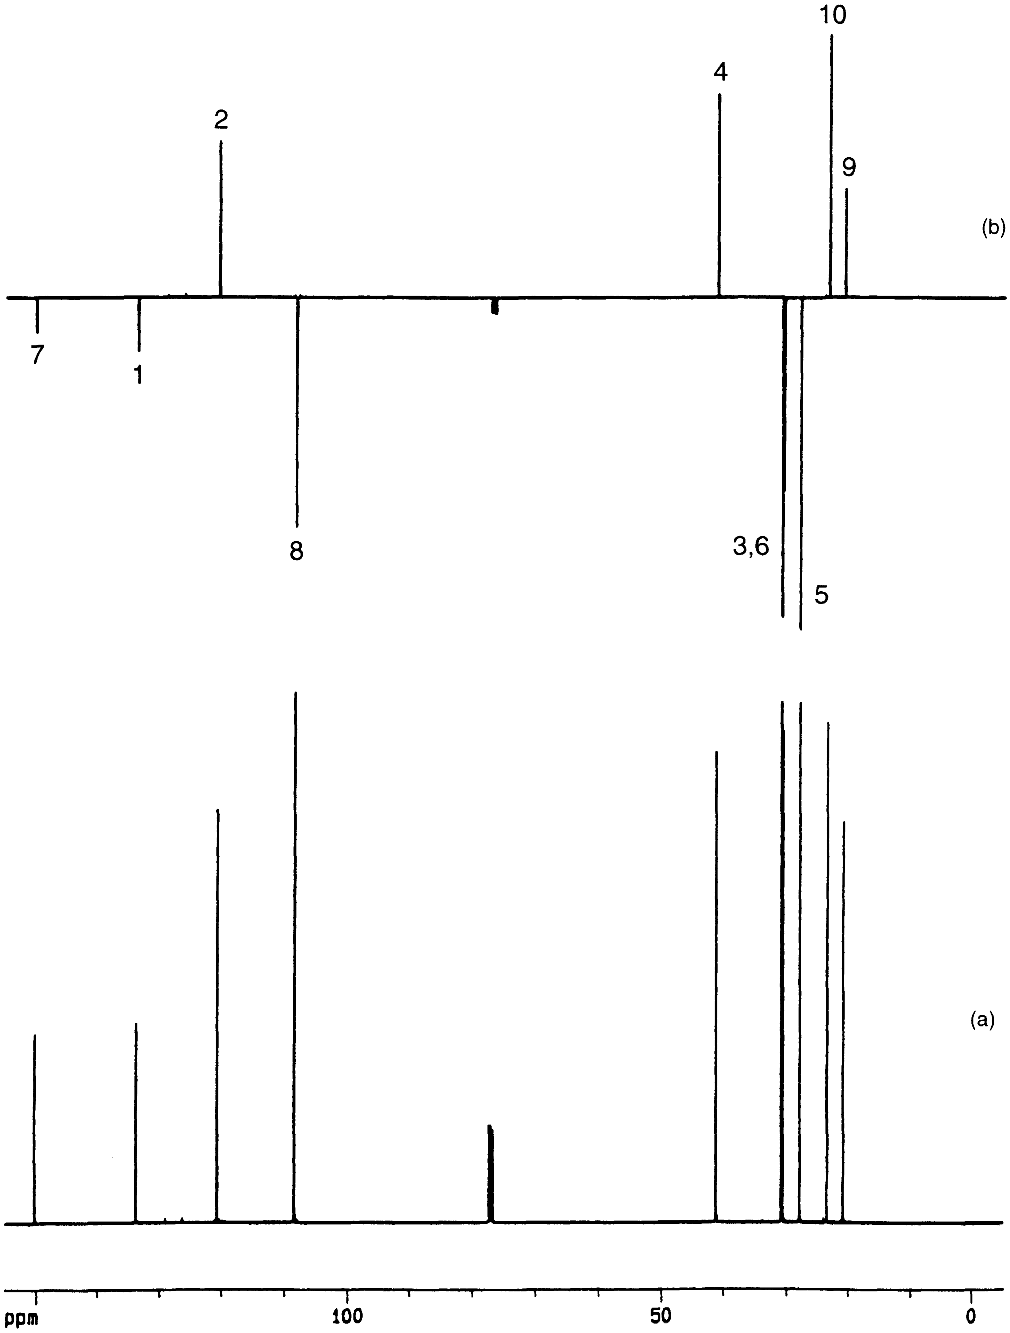

FIG. 17. 100 MHz ^{13}C NMR spectra of limonene (structure 2): (a) broadband decoupled, (b) *J*-modulated spin-echo.

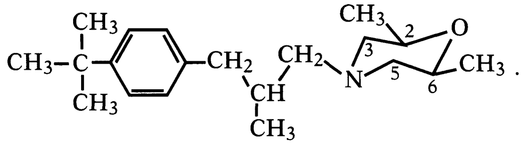
together with its conventional broadband proton decoupled spectrum. When $t = 1/2J$, only signals from quaternary carbons are observed. While widely used, this experiment has two shortcomings for multiplicity assignment. First, signals from CH and CH_3 carbons cannot be distinguished, and second, it is sensitive to variations in J values. One-bond carbon–proton couplings are typically ca. 125 and ca. 160 Hz for saturated aliphatic groups and aromatic/olefinic carbon atoms, respectively. For such compounds use of a compromise value for t works well. However, for carbon atoms with much larger couplings such as alkynyl carbons and some unsaturated heterocyclic carbons, it is less successful. In such instances the DEPT technique is more suitable. Compared with the J-modulated spin-echo experiment, it is insensitive to variations in $^1J_{CH}$. The method is based on the use of polarization transfer whereby magnetization is transferred from ^1H to ^{13}C nuclei, and as a result quaternary carbon atoms are not detected in such experiments. This experiment involves pulsing both the ^1H and ^{13}C channels. The final proton pulse is along the y axis, and by performing two experiments with angles for this pulse of 90° and 135°, full multiplicity data can be obtained. The 135° experiment gives negative CH_2 but positive CH and CH_3 carbon signals, while in the 90° experiment only CH signals are observed.

2.5 Multidimensional NMR

A wide range of two-dimensional experiments are now available as relatively routine tools, and more recently three- and four-dimensional methods have been developed. In general the experiments are used to extract information from complex spectra (e.g., about which nuclei are J coupled to each other and to measure J couplings). In this article it is only possible to give a very brief introduction to two-dimensional methodology together with a few examples of its application in ^1H and ^{13}C NMR. Further information about this most important field is available from Derome (1987), Sanders and Hunter (1987), Morris (1986), and Benn and Gunther (1983).

2.5.1 Basic Principles of 2D NMR The common feature of 1D multiple-pulse experiments is the time sequence preparation–evolution–detection, where the detected signal is only a function of the detection time t_2. The important difference in 2D NMR is that the evolution time t_1 is now a variable. In a 2D experiment, n separate experiments are performed with incremented values of t_1. For each experiment a free-induction decay $S(t_2)$ is measured. In this way a matrix $S(t_1,t_2)$ is built up. Fourier transformation of this matrix with respect to t_2 gives a series of spectra $S(t_1,f_2)$. Further transformation with respect to t_1 gives a matrix $S(f_1,f_2)$, which is a spectrum in two independent frequency dimensions. The dispersion of the signals as a function of f_1 depends on the effect of the pulse sequence used on the spin system as t_1 is varied. In general there are two distinct types of 2D experiments. These are referred to as J-resolved and correlated spectroscopy. In a J-resolved spectrum one frequency axis (f_1) contains spin–spin coupling information and the other (f_2) chemical-shift information. In correlated spectroscopy both axes contain chemical-shift information, the connection between the two being via spin–spin coupling, NOE, or exchange effects.

2.5.2 Homonuclear Chemical-Shift Correlation The most frequently applied 2D technique is proton homonuclear correlation using one of the many variants of the COSY (correlated spectroscopy) experiment. The basic COSY experiment consists of two 90°_x pulses separated by a time t_1 as shown in Fig. 18. Figure 19 shows the aliphatic part of the COSY spectrum obtained from the compound having structure **3**,



The spectrum is presented as a contour plot in which intensities above a chosen threshold level are plotted like height contours on a map. Since both frequency domains are proton chemical shifts, the matrix is square. Contours along the diagonal of the square correspond to the peaks in a one-dimensional spectrum. Homonuclear couplings give rise to the off-diagonal contours or cross peaks. The one-dimensional spectrum

FID
t1
t2

FIG. 18. Basic COSY pulse sequence.

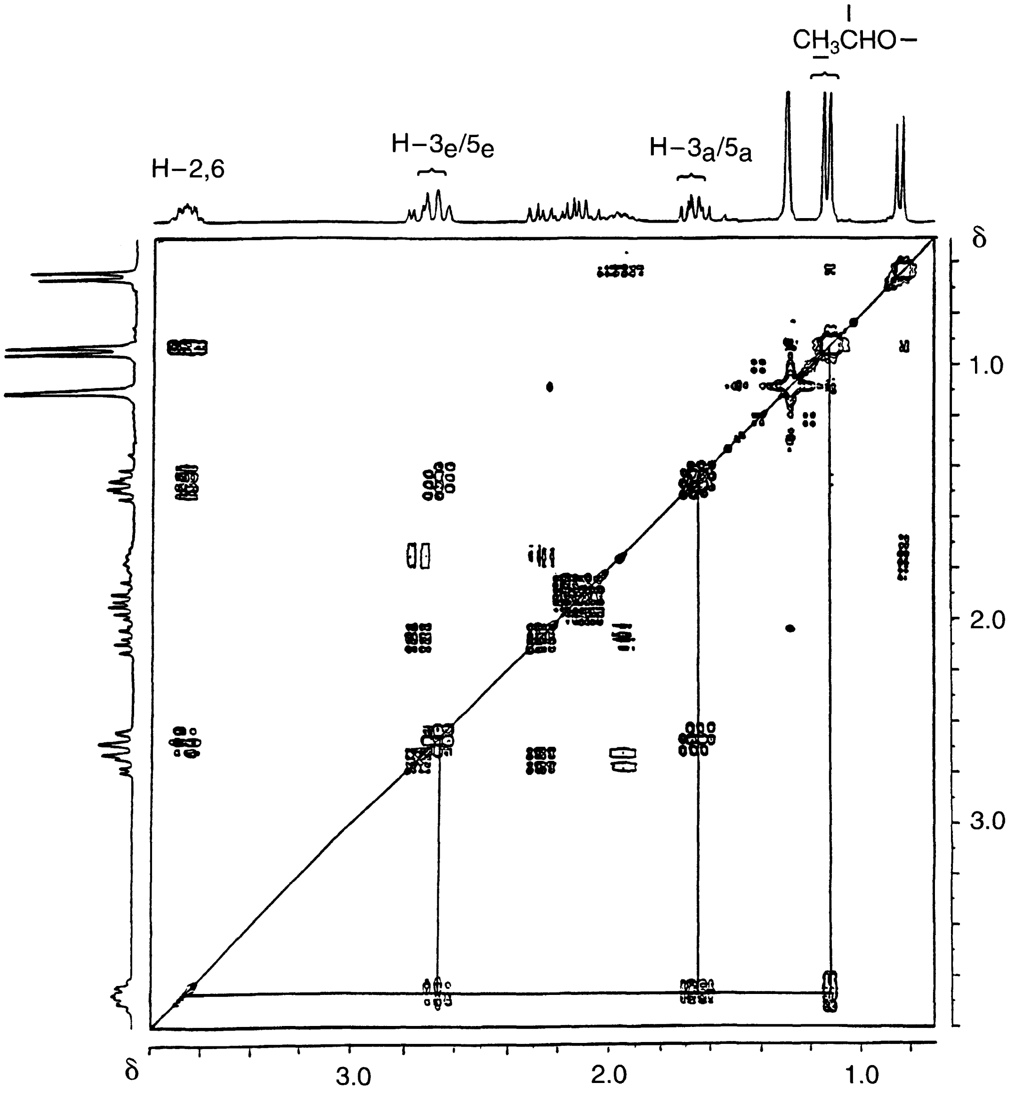

FIG. 19. 250-MHz ^{1}H COSY spectrum of structure 3.

is also plotted as a projection along both axes. The cross peaks provide the same information about proton–proton connectivities as can be obtained from a series of homonuclear decoupling experiments, but all in a single spectrum!

The connectivities for a particular proton can be extracted by drawing a horizontal line from the relevant diagonal peak that intercepts cross peaks corresponding to correlations. In Fig. 19 the multiplet at 3.68δ is due to H-2/6, and from the cross peaks it shows correlations to three other multiplets. By drawing a vertical line from each cross peak back to the diagonal, it can be determined with which peak the first diagonal peak is correlated (i.e., coupled). In this case correlations are observed at 1.11δ, 1.65δ, and 2.67δ from the attached methyl groups, H-3_a/5_a, and H-3_e/5_e, respectively. Note that the cross peaks are found symmetrically on both sides of the diagonal.

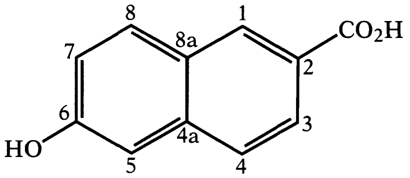
Two-dimensional methodology is inherently more time consuming than 1D principally because of the requirement to perform a large number of individual experiments. However, because of the relatively high sensitivity of the proton, COSY spectra can be readily obtained if sufficient sample is available, and a few milligrams will yield a good spectrum on a modern high-field instrument.

2.5.3 Homonuclear *J*-Resolved Spectra Overlapping absorptions in a 1D proton spectrum can sometimes be resolved by a homonuclear *J*-resolved experiment, in which chemical shifts are presented on one axis and coupling constants on the other. The pulse sequence used is

$$90^\circ_x - t_1/2 - 180^\circ_x - t_1/2 - \text{acquire}.$$

Figure 20 shows the aliphatic part of the spectrum obtained from the structure shown in Sec. 2.5.2. The spectrum was recorded to resolve the multiplet from H-3_a/5_a at 1.65δ. In the *J*-resolved spectrum the presence of two columns in this region, each from a doublet of doublets, clearly shows that H-3_a and H-5_a are magnetically inequivalent. Similarly two columns are observed for H-3_e and H-5_e from the multiplet at 2.67δ. In each of these cases the two nuclei involved are not coupled to each other and as such are ideal for this type of study. Where the overlapping resonances are from nuclei that are strongly coupled to each other, they cannot be resolved in this manner because second-order effects are observed in the 2D spectrum in the form of additional columns of peaks. Such a situation exists in Fig. 20 in the region 2.05δ to 2.15δ from the protons of the methylene group attached to the benzene ring.

2.5.4 Heteronuclear Chemical Shift Correlation (HETCOR) In the basic HETCOR experiment the peaks of a ^{13}C spectrum are correlated with those of a ^1H spectrum showing the specific protons that are attached to each ^{13}C nucleus. Figure 21 shows part of the spectrum of 2-carboxy-6-hydroxynaphthalene (structure **4**),



The relevant parts of the corresponding 1D spectra are plotted along the axes. A correlation is observed as a cross peak at the intersection of a horizontal line drawn from a proton resonance and a vertical line drawn from a carbon peak. Correlations are not observed for quaternary carbon atoms. The technique is a very important tool for chemical-shift assignment and thus structure elucidation. A number of variants of this basic experiment have been developed, some of which enable long-range proton–carbon correlations to be established. The original ^1H/^{13}C HETCOR experiments involved detection of a ^{13}C signal at the end of the pulse sequence. However, a significant enhancement in sensitivity can be achieved if nuclei with small magnetogyric ratios such as ^{13}C are detected through their effects on the more sensitive ^1H nuclei. In ^1H/^{13}C correlation experiments where optimum sensitivity is required, the proton-detected heteronuclear multiple-quantum coherence (HMQC) (see Bax and Subramanian, 1986) and heteronuclear multiple-bond connectivity (HMBC) (see Bax and Summers, 1986) are frequently used for one-bond and long-range correlations, respectively.

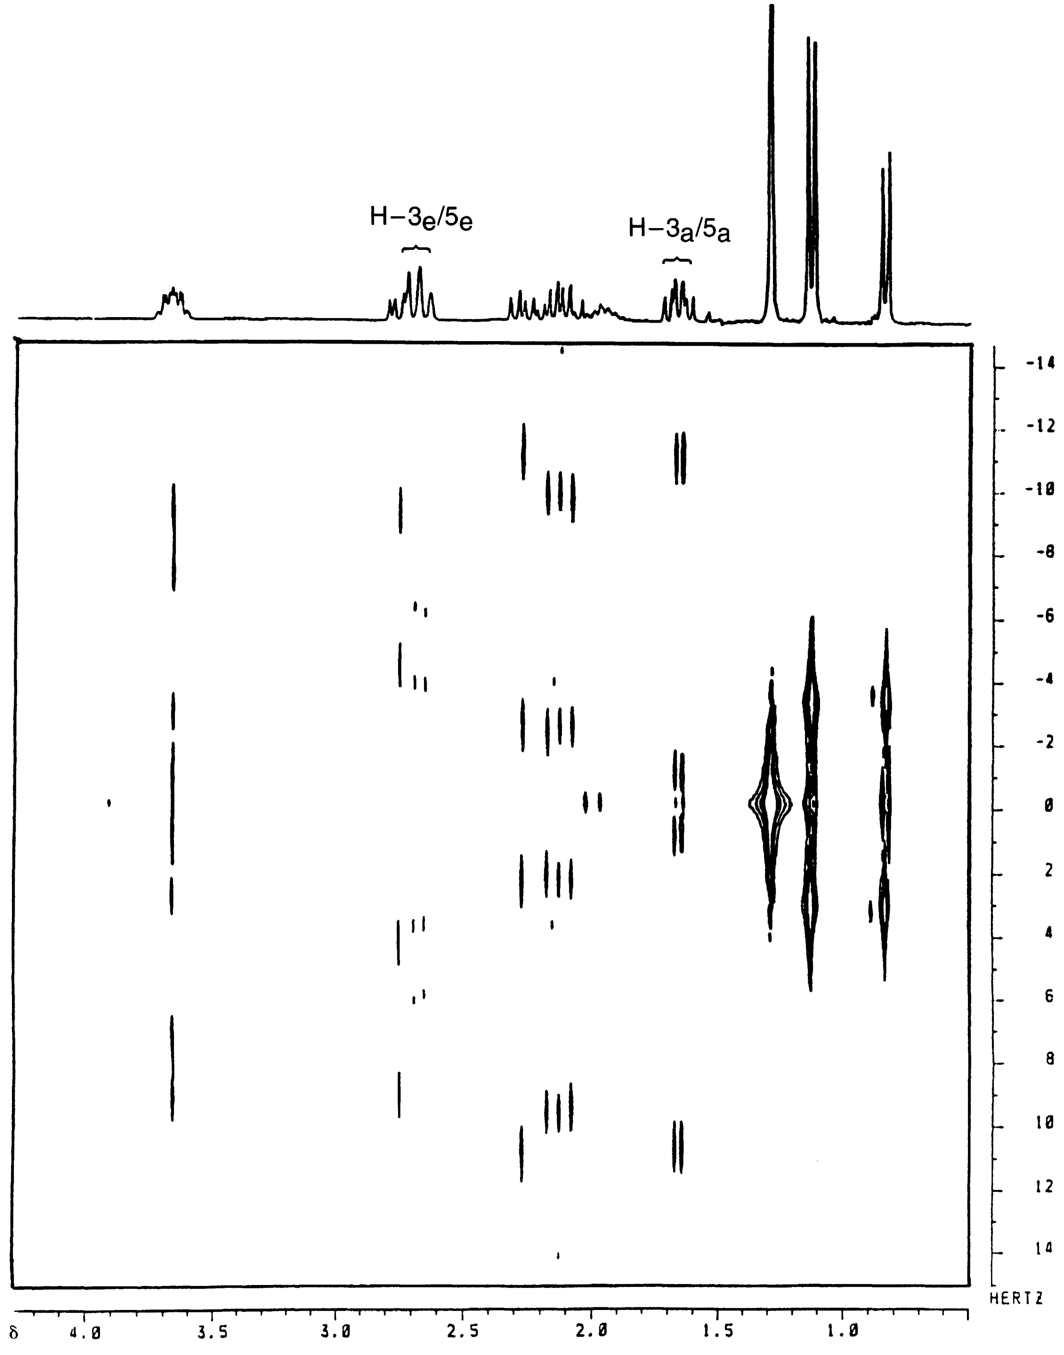


FIG. 20. 250-MHz ^{1}H 2D *J*-spectrum of structure 3.

2.5.5 Heteronuclear *J*-Resolved Spectra

In heteronuclear *J*-resolved spectra, ^{13}C chemical shifts are presented on one axis and proton–carbon *J* couplings on the other. The information content is equivalent to that in a proton-coupled ^{13}C spectrum but without the severe overlap of multiplets that is usually encountered in the latter. In common

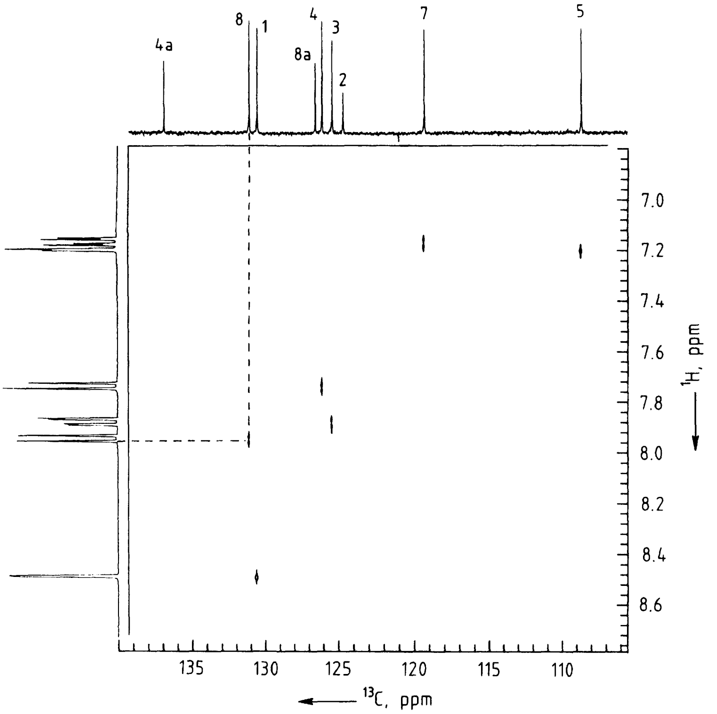

FIG. 21. Carbon–proton (400 MHz) shift-correlated spectrum of structure **4**.

with off-resonance proton decoupling, *J*-modulated spin-echo, and DEPT experiments, it facilitates multiplicity determination. In addition, it enables proton–carbon coupling constants to be measured.

2.5.6 Homonuclear NOE Correlation The 2D NOESY (nuclear Overhauser enhancement spectroscopy) technique in principle enables all the proton–proton NOE effects to be assembled in a single spectrum. Such spectra are very similar in appearance to COSY spectra, with contours on the diagonal representing the 1D spectrum and off-diagonal contours arising from through-space proton–proton interactions between protons that are nearby in space. The technique is extensively used in the determination of structures and conformations of very large molecules such as proteins. For smaller molecules with shorter correlation times where NOEs are small and slow to build up, 1D NOE difference spectroscopy is more widely used.

2.5.7 3D and 4D NMR The development of 2D spectroscopic techniques led to NMR being used as a tool for structure determination of small proteins and DNA fragments (see Wüthrich, 1986). Early investigations of proteins were limited to relatively small molecules up to a size of about 80 amino acid units since signal overlap in 2D spectra of larger proteins was too great. The impetus to study larger systems has led to a massive investment in the design of three- and four-dimensional experiments and the associated instrumental developments. It is now possible to examine systems with molecular weights up to about 35 kDa when the proteins have been uniformly labeled with ^{13}C and ^{15}N. Oschkinat *et al.* (1994) have recently reviewed the field of protein structure determination with 3D and 4D NMR. A very brief description of the type of methodology used will be given here.

Structure determination in biological macromolecules such as proteins and oligonucleotides is based mainly on the determination of *J*-coupling connectivities from homonuclear and heteronuclear chemical-shift correlation experiments, NOEs from NOESY experiments, and *J* couplings from a variety of correlation experiments. NOEs and *J* couplings correlate with distances between nuclei and dihedral angles, respectively. The following information is required from an NMR study:

1. the complete sequence assignment,
2. the complete assignment of side-chain signals,
3. the collection of a sufficient number of precisely measured NOEs, and
4. long-range homonuclear and heteronuclear *J* couplings where possible.

These data can then be used to calculate three-dimensional structures using distance geometry and molecular-dynamics computer programs.

The principles of 3D and 4D NMR spectroscopy are an extension of those used in 2D spectroscopy. While a 2D experiment has one evolution time t_1, 3D and 4D experiments have two and three evolution times, respectively. In a 3D experiment the signals resulting from the different evolution times t_1 and t_2 are ordered in a 3D matrix. The 3D spectrum is then obtained by Fourier transformation with respect to t_1, t_2, and the detection time t_3. Many 3D experiments are combinations of 2D experiments and are designed to reduce the overlapping of signals in a related 2D experiment. An example of such a 3D experiment is ^{15}N-NOESY-HMQC, which is used in the sequential assignment of α-helical regions in proteins and uses uniformly ^{15}N-labeled samples. The experiment is used to find cross peaks between NH signals from neighboring amino-acid groups. If two NH proton signals have the same chemical shift, then four cross peaks to other amino acids are expected at this frequency in a 2D NOESY experiment, and an unambiguous assignment is not possible. In the ^{15}N-NOESY-HMQC spectrum, where the f_1, f_2, and f_3 axes represent ^{1}H, ^{15}N, and ^{1}H chemical shifts, respectively, the signals are found on different ^{15}N planes if the ^{15}N nuclei have different chemical shifts.

The very large number of individual, constituent experiments in a 3D or 4D experiment make such studies very time consuming, and a lot of research work is being carried out to design more efficient experiments. One approach is to minimize the total number of multidimensional experiments required to obtain the required correlations, NOEs, etc. needed for a protein study. Another approach that is being very successfully employed in many multidimensional experiments uses pulsed magnetic-field gradients instead of phase cycling to obtain artifact-free spectra. Norwood (1994) has recently reviewed the use of magnetic gradients in multidimensional solution NMR and in other areas of NMR such as imaging and diffusion studies.

2.6 Application to Chemical Structure Determination

Solution NMR spectra usually contain a wealth of information. Previous sections have provided an overview of the parameters that can be determined from NMR spectra, and techniques that can be used for the assignment of signals in spectra. Here some of the applications of solution NMR spectroscopy to chemical structure determination are briefly summarized. The list is by no means exhaustive, and further information about applications can be found in many of the reference books as well as the specialist literature referred to in this section.

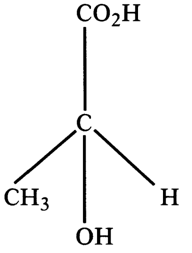
NMR spectroscopy is the most powerful tool available for the unambiguous determination of molecular structures of compounds in solution. In a modern chemical research laboratory, the principal tools for structure determination are usually mass spectrometry, to obtain molecular mass data, and NMR spectroscopy, which provides detailed information about the groups present and how they are assembled. The abundant nuclei ^{1}H, ^{19}F, and ^{31}P have been used for well over 30 years to study the structures of organic and inorganic chemicals. In the early 1970s the advent of FT methodology enabled a much wider range of nuclei to be studied and in particular resulted in an explosive growth in the use of ^{13}C NMR as a complementary technique to ^{1}H NMR in the identification of organic compounds. The most useful NMR parameters are, in general, chemical shifts, coupling constants, and integrals from which structural information can be deduced.

In addition to the study of monomeric species, NMR is a long established tool for studying the structures of synthetic polymers. In the case of copolymers the various groups present can be identified, their relative concentrations determined, and often information about sequence distributions obtained. The latter provides a measure of the random/block character of the polymer. While ^1H and ^{13}C are the most commonly studied nuclei for such work, several others such as ^{19}F and ^{29}Si have been used where appropriate. For vinyl polymers, ^{13}C and ^1H NMR spectra provide information on tacticity. Chain branching and end groups can also be identified from NMR spectra of polymers.

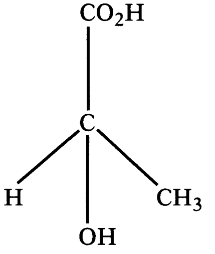
During the last decade NMR has developed as a powerful tool for biochemical structure determination. The most impressive applications are in the determination of protein structures with molecular masses up to the 25 000–35 000 range (see Bax and Grzesiek, 1993). Such work has been made possible by the development of multidimensional NMR techniques. 2D and 3D techniques are widely used for such work, and 4D experiments are being developed (see Sec. 2.5.7). Since NMR allows the study of biological macromolecules in solution, it has proved complementary to solid-state studies by x-ray crystallography. The value of the solution structure lies in the fact that it provides a starting point for the study of protein/substrate interactions, a knowledge of which may then aid drug design.

NMR has also become established as a valuable technique in the field of clinical biochemistry where ^1H NMR, in particular, is used to study complex biochemical fluids such as plasma, urine, and bile. The major problem associated with such work is the removal or reduction of the very large water signal. One method involves freeze drying the sample and redissolving it in deuterated water. NMR techniques are also available for selective suppression of the water signal. Under the conditions used only low-molecular-mass constituents are observable, the signals from proteins and other large molecules not being resolved. Applications include screening and monitoring for metabolic diseases, the study of biochemical mechanisms associated with disease processes, and the identification of drug metabolites. Nicholson and Wilson (1989) have reviewed applications.

During the past decade NMR has become an increasingly important tool for the determination of enantiomeric purity (see Parker, 1991). The four different substituents around a tetrahedral chiral center (see Sec. 2.2.1.2), often a carbon atom, can be arranged in two ways. The two arrangements, which are not superimposable, are mirror images of each other. Isomers that differ only in their arrangement at a single chiral center are known as enantiomers. Lactic acid is an example of a chiral compound that exists as two enantiomers:



,



.

Many pharmaceutical and agrochemical products are chiral with only one enantiomer having the required effect. At best the other is inactive; at worst it may have undesirable properties. This situation has led to a surge in enantioselective synthesis, the products of which require analysis. In an achiral medium, enantiomers cannot be distinguished from their NMR spectra, which are identical. Molecules that contain two chiral centers have four isomeric forms, which comprise of two pairs of enantiomers, known as diastereoisomers. Diastereoisomers have different physical properties and can be distinguished by NMR. Therefore, the determination of enantiomeric purity by NMR requires the use of a chiral auxiliary that converts a mixture of enantiomers into a mixture of diastereoisomers. Chiral lanthanide shift reagents and chiral solvating agents form diastereomeric complexes *in situ* and can be used directly for NMR analysis. In favorable cases absolute configuration can be determined from the NMR spectrum of the diastereoisomer formed.

3. NMR OF SOLIDS

Solids often give very broad NMR spectra devoid of the fine structure that provides detailed information about chemical structures. The restriction of NMR to the liquid/solution or gas phase does, however, impose considerable limitations on the applicability of the NMR technique. Solid-state spectra can be useful to

1. study insoluble materials,

2. compare solution and solid-state molecular structures and conformations, and
3. study solid-state (e.g., crystallographic) properties.

Various aspects of NMR studies of solid samples up the early 1980s are covered by Fyfe (1983).

3.1 Magnetic Interactions in the Solid State

The principal interactions are

1. interaction with the applied magnetic field,
2. magnetic shielding by the surrounding electrons,
3. spin–spin coupling to other nuclei,
4. direct dipole–dipole interactions with other nuclei, and
5. quadrupolar interactions for nuclei with spin $>\frac{1}{2}$.

The first three have been discussed in the context of solution-state NMR. In solids all the interactions are anisotropic; i.e., they depend on molecular orientation, whereas in solution fast isotropic motion results in averaging. For chemical shifts and spin–spin couplings, discrete, average, isotropic values are obtained in solution. Dipolar and quadrupolar couplings are not observed in solution since the average values are zero. In solids spin–spin coupling interaction is usually much smaller than all the other interactions, and its effects are rarely observed. A more in-depth treatment on magnetic interactions in solids and low-resolution spectra can be found in the article NUCLEAR MAGNETIC RESONANCE AND QUADRUPOLE RESONANCE.

3.1.1 Dipole–Dipole Interactions Dipolar coupling results from direct dipole–dipole interactions between nuclei. Its magnitude is independent of the applied magnetic field H_0, proportional to the magnetogyric ratios of the nuclei involved, and inversely proportional to the cube of the distance between the two nuclei. Its effects are most significant for spin-$\frac{1}{2}$ nuclei such as ^1H with large magnetic moments. The spectrum produced by a pair of identical spin-$\frac{1}{2}$ nuclei consists of two lines whose positions are given by

$$\nu = \nu_0 \pm \tfrac{3}{4}R(3\cos^2\theta - 1), \qquad (11)$$

where R is the dipolar coupling constant and θ is the angle between the internuclear vector and the applied magnetic field. Such a situation exists for isolated H_2O molecules present as water of crystallization in single crystals of gypsum, $CaSO_4 \cdot 2H_2O$. A study of the orientation dependence of the splitting as a function of the angle between H_0 and the x crystallographic axis gives information about the orientation of the water molecules in the unit cell and the internuclear distance between the water protons. For polycrystalline material, averaging over all possible orientations to the magnetic field gives a "Pake doublet" (Pake, 1948).

3.1.2 Chemical-Shift Anisotropy If dipolar interactions are absent or can be removed, the NMR spectrum of a single crystal will contain one sharp line for each magnetically unique orientation of a nucleus relative to the direction of the applied magnetic field. However, the positions of the lines will change as the orientation of the crystal is changed. Shielding is a tensor property characterized by three principal components σ_{11}, σ_{22}, and σ_{33} specified in a molecule-fixed coordinate system. The observed shielding constant is given by a linear combination of the principal components, which have a $\cos^2$ dependence on the angle between the component and the applied magnetic field. For a microcrystalline powder sample, a broad line, known as a powder pattern, will result whose shape will depend on the principal components of the shielding tensor. For examples of chemical shift powder patterns, see Fig. 4 in the article NUCLEAR MAGNETIC RESONANCE AND QUADRUPOLE RESONANCE. Shielding anisotropies can be very large. For example, those for ^{13}C nuclei can be as large as 438 ppm (see Spiess *et al.*, 1971). While the principal components can be determined from a powder pattern, a single-crystal study is required to relate them to the molecular-axis system.

3.1.3 Quadrupole Interactions For nuclei with spin $> \frac{1}{2}$, solid-state NMR spectra are usually dominated by nuclear quadrupole interactions; even the effects of anisotropic chemical shifts and dipole–dipole interactions can be neglected to a first approximation. The latter may produce some line broadening. Quadrupolar effects result from the interaction of the nuclear electric quadrupole moment with the non-spherically-symmetrical field gradient around the nucleus. The effect of the quadrupolar interaction is to perturb the energy levels resulting from the interaction of the nuclei with the applied magnetic field. For instance, a spin-1 nucleus has three energy levels corresponding to $m_I = 1$, 0, and -1. For a single spin-1 nucleus, such as ^{2}H, in the absence of quadrupolar interaction, there would be two allowed, degenerate transitions giving a single peak. The quadrupolar interaction perturbs the energy levels such that the transitions are no longer degenerate, and a doublet results with the peak separation given by

$$\Delta v = \tfrac{3}{4}\chi(3\cos^2\theta - 1), \tag{12}$$

where χ is the quadrupole coupling constant and θ is the angle between the principal component of the symmetric electric-field-gradient tensor and the magnetic field. For deuterons attached to carbon the quadrupole coupling constant is in the range 170–200 kHz, while for ^{14}N and ^{35}Cl, values of up to 5 and 80 MHz, respectively, have been determined. For a powder all values of θ are possible and, as in the case of anisotropic dipolar and chemical shift effects, a powder pattern results. See Sec. 1.1.3 in the article NUCLEAR MAGNETIC RESONANCE AND QUADRUPOLE RESONANCE.

3.2 NMR Spectra of Solids

The type of experiments that can be performed and the structural information that can be obtained from a solid depend largely on the relative magnitudes of the interactions described in the preceding section. These will depend on the characteristics of the chosen nucleus, its abundance in the system under study, and the local and long-range molecular ordering present. Nuclei can be conveniently grouped into three types: abundant spin-$\frac{1}{2}$, dilute spin-$\frac{1}{2}$, and quadrupolar.

3.2.1 Abundant Spin-$\frac{1}{2}$ Nuclei In the absence of a quadrupole moment, homonuclear dipole–dipole interactions between abundant nuclei are the dominant contribution to the spectra of spin-$\frac{1}{2}$ nuclei such as ^{1}H and ^{19}F. For all but the simplest spin systems, spectra are broad and featureless (10–100 kHz). The relatively high sensitivity of experiments with abundant nuclei enables them to be studied with cw methodology. While little structural information can be obtained from such spectra, they are sensitive to molecular motions. NMR variable-temperature and relaxation studies can therefore provide information about such processes.

3.2.2 Dilute Spin-$\frac{1}{2}$ Nuclei Homonuclear dipolar interactions are essentially eliminated if the nucleus of interest is "dilute" in the system being studied. Dilution can result either from the spin-$\frac{1}{2}$ isotope being present in low natural abundance—e.g., ^{13}C—or from a high-abundance spin-$\frac{1}{2}$ nucleus being present in low concentration, as for ^{31}P in organophosphates. Any heteronuclear—e.g., ^{1}H–^{13}C—dipolar interactions present can also be removed by the application of powerful decoupling fields. With the elimination of all dipolar interactions, chemical-shift anisotropy is the dominant line-broadening interaction.

However, while magnetic dilution is an effective way of removing homonuclear dipolar interactions, it also drastically reduces NMR sensitivity such that FT techniques are essential to observe nuclei such as ^{13}C. Even with these techniques, averaging of several thousand signals is often required. To compound the problem, many of the nuclei of interest also have very long relaxation times. A technique known as cross polarization (CP) (see Pines *et al.,* 1973) is used to largely overcome these sensitivity problems. It is based on the transfer of magnetization from abundant spins, usually ^{1}H, to dilute spins such as ^{13}C. Briefly, CP is achieved in the following manner, illustrated by a ^{1}H/^{13}C system using the rotating frame of reference. A 90° pulse is first applied to the proton channel, and the ^{1}H magnetization is spin-locked in the y direction. The ^{13}C channel is then switched on, also orienting the ^{13}C spins in the y direction. The magnitudes of the proton and carbon spin-locking fields are chosen so that the following condition is fulfilled:

$$\gamma_H B_{1H} = \gamma_C B_{1C}. \tag{13}$$

Magnetization transfer takes place during a contact period after which the ^{13}C field is switched off and the ^{13}C FID recorded. A maximum enhancement equal to the ratio of the magnetogyric ratios of the abundant and rare spins may be obtained.

The shift anisotropy is a potential source of information on structure and bonding interactions. It is best studied in single-crystal systems (see Mehring, 1976) where an assignment of the principal tensor components with respect to the molecular geometry may be made. Principal shift-tensor components obtained from single crystals of model compounds can be used to assist in the interpretation of spectra from more complex polycrystalline samples. While ^{13}C has been the most commonly studied nucleus, others include ^{31}P, ^{29}Si, ^{207}Pb, and ^{77}Se.

A very simple, elegant example of the use of chemical-shift anisotropy patterns to probe solid-state structures is the use of xenon gas intercalated into solid systems such as β-quinol clathrate, reported by Ripmeester (1982). The ^{129}Xe nucleus is very sensitive to induced-shift anisotropy. The isolated atom is spherically symmetrical and shows no chemical-shift anisotropy. Any anisotropy observed therefore results from its environment, making it a sensitive probe to the interior shape of cages in clathrates.

3.2.3 Quadrupolar Nuclei Solid-state spectra of quadrupolar nuclei are normally dominated by quadrupolar interaction. In a single crystal the spectrum obtained from nuclei with $I = 1$, such as ^{2}H and ^{14}N, consists of two lines from each nucleus in each crystalline environment. Variation of crystal orientation enables quadrupolar coupling constants and asymmetry parameters of the electric field gradient to be determined. For polycrystalline materials all possible orientations are represented, and, in the case of deuterium, a powder pattern with a doublet splitting is obtained from which the quadrupolar coupling constant can be determined. The quadrupolar interaction is too large for powder patterns to be observed for other quadrupolar nuclei with integral spins, and studies have therefore been limited mainly to deuterium. Extensive ^{2}H studies (see Mantsch *et al.*, 1977) have been performed on a wide range of deuterium-labeled systems that include membranes, polymers (see Spiess, 1983), and liquid crystals. Information about structure and dynamics can be obtained in this way. While early solid-state ^{2}H spectra were recorded on cw spectrometers, more recent studies have been facilitated by the use of FT methodology and in particular the quadrupolar spin-echo technique (Sternin *et al.*, 1983). For most quadrupolar nuclei with nonintegral spins (e.g., ^{11}B, $I = \frac{3}{2}$; and ^{17}O, ^{27}Al, $I = \frac{5}{2}$) the central $M_I = \frac{1}{2}$ to $m_I = -\frac{1}{2}$ transition is usually the only one to be observed since it is much less affected than the others by quadrupolar interaction. The shape of the spectrum obtained from a polycrystalline sample depends on the values of the quadrupolar coupling constant and asymmetry parameter. ^{11}B and ^{17}O spectra of this type obtained by cw techniques have been used to investigate the structures of borosilicate glasses (see Jellison and Bray, 1977).

3.3 High-Resolution NMR of Solids

In the last 20 years techniques have been developed to obtain solution-type spectra from solids. For spin-$\frac{1}{2}$ nuclei this requires the removal of the effects of dipolar coupling and chemical shift anisotropy. As described in Sec. 3.2.2, high-power decoupling can be used to remove heteronuclear dipolar interactions.

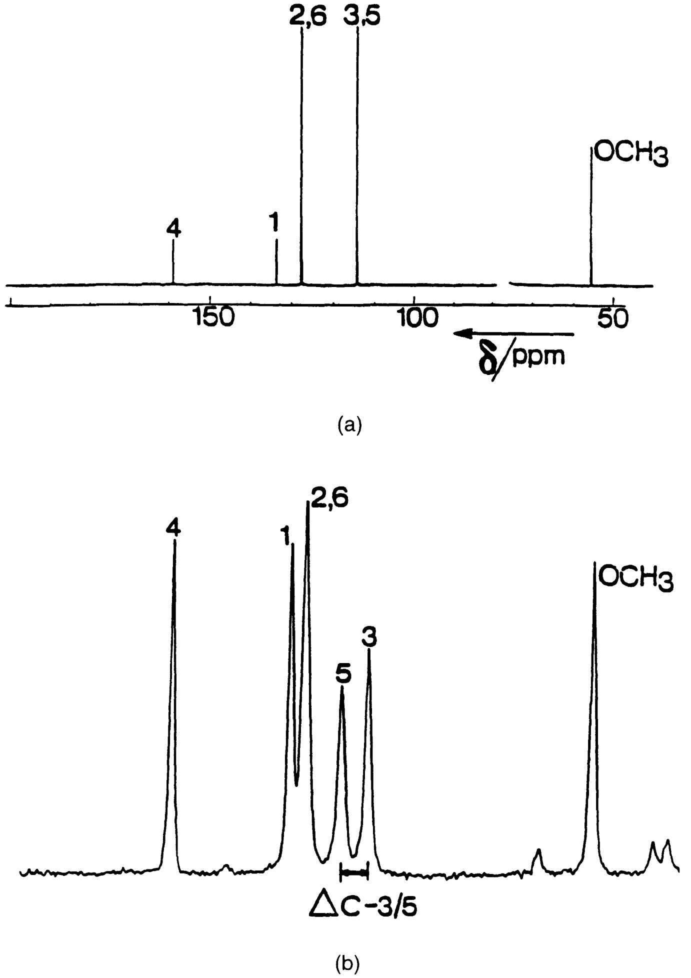
3.3.1 Resolution-Enhancement Techniques In solution molecular tumbling averages dipolar and quadrupolar interactions to zero and chemical shifts to their isotropic values. For solids a technique known as magic-angle spinning (MAS) simulates such motion and averages out angular dependences. It involves spinning the sample at an angle of 54° 44′ to the applied magnetic field. To be effective the rate of rotation must be comparable to the frequency range of the interactions involved. The effects of chemical-shift anisotropy in ^{13}C spectra can usually be removed adequately with rates in the range of 3–10 kHz. However, for dipolar and many quadrupolar interactions the speeds required are much higher and cannot be achieved. The effects of MAS and related resolution-enhancement techniques applied to quadrupolar nuclei are further discussed in Sec. 3.3.5.

For abundant spin systems, homonuclear dipolar interactions dominate the spectra. Multiple-pulse line-narrowing techniques have been developed to average out the effects of homonuclear dipolar interactions. The simplest sequence, known as WAHUHA, was developed by Waugh *et al.* (1968) and consists of a series of four pulses.

Recent developments in high-resolution techniques have been reviewed by Clayden (1992).

3.3.2 Dilute Spin-$\frac{1}{2}$ Nuclei The combined application of CP, MAS, and high-power proton decoupling can give high-resolution spectra from powders and amorphous solids that approach the quality to those obtained in solution. Nuclei studied include ^{13}C, ^{29}Si, ^{15}N, and ^{31}P. There are two principal reasons for obtaining a high-resolution NMR spectrum from a solid. Either it is insoluble or information is being sought about the solid-state structure. In the latter case cystallographic information is required either because a single-crystal x-ray structure is not available or to enable a comparison of solid- and solution-state structures/conformations to be made when spectra are available in both phases. One example of such a comparison is the ^{13}C study of a series of penicillins by Clayden *et al.* (1986).

Crystallographic effects frequently give rise to splitting of lines in spectra of solids when compared with those obtained from the sample in solution. For a particular type of atom to yield a single line in a spectrum obtained from a solid, all the atoms of that type must be related by symmetry in the crystal. Nonequivalence is not an uncommon occurrence and may be intramolecular or intermolecular in origin. Figure 22 shows the

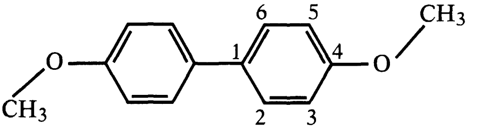


(a)

(b)

FIG. 22. ^{13}C NMR spectra of 4,4′-dimethoxybiphenyl: (a) solution, (b) solid (CP/MAS).

solution and CP/MAS solid-state ^{13}C spectra of 4,4′-dimethoxybiphenyl. In solution a single peak is observed for C-3 and C-5, whereas for the solid, two peaks separated by 6.4 ppm are present. This is attributed by Chippendale *et al.* (1986) to the fact that in the solid the compound exists in the locked conformation described by



,

whereas in solution rotation about the C-4–O bond causes an average shift to be observed.

Solid-state NMR spectroscopy, particularly of ^{13}C, has been widely used to study polymorphism since polymorphs invariably give spectra that are discernably different as for the six crystalline forms of cortisone acetate reported by Harris *et al.* (1990).
